About the Authors xix

## Abnormal Psychology: An Overview 1

### What Do We Mean by Abnormality? 3

The DSM-5 and the Definition of Mental Disorder 5

#### the WORLD around us

Extreme Generosity or Pathological Behavior? 6

Why Do We Need to Classify Mental Disorders? 7

#### THINKING CRITICALLY about DSM-5:

What Is the DSM and Why Was It Revised? 7

What Are the Disadvantages of Classification? 8

How Can We Reduce Prejudicial Attitudes Toward the Mentally Ill? 8

#### the WORLD around us

Mad, Sick, Head Nuh Good: Mental Illness and Stigma in Jamaica 9

How Does Culture Affect What Is Considered Abnormal? 10

Culture-Specific Disorders 11

### How Common Are Mental Disorders? 12

Prevalence and Incidence 12

Prevalence Estimates for Mental Disorders 12

Treatment 13

Mental Health Professionals 14

### Research Approaches in Abnormal Psychology 14

#### Sources of Information 15

Case Studies 15

Self-Report Data 15

Observational Approaches 16

### Forming and Testing Hypotheses 17

Sampling and Generalization 17

Internal and External Validity 18

Criterion and Comparison Groups 18

#### Research Designs 19

Studying the World as It Is: Correlational Research Designs 19

Measuring Correlation 19

Statistical Significance 19

Effect Size 20

Meta-Analysis 21

Correlations and Causality 21

Retrospective Versus Prospective Strategies 21

Manipulating Variables: The Experimental Method in Abnormal Psychology 22

Studying the Efficacy of Therapy 22

Single-Case Experimental Designs 23

#### developments in RESEARCH:

Do Magnets Help with Repetitive-Stress Injury? 24

Animal Research 25

#### UNRESOLVED issues

Are We All Becoming Mentally Ill? The Expanding Horizons of Mental Disorder 26

summary 27 key terms 27

## Historical and Contemporary Views of Abnormal Behavior 28

### Historical Views of Abnormal Behavior 29

Demonology, Gods, and Magic 29

Hippocrates' Early Medical Concepts 30

#### developments in THINKING:

Melancholia Through the Ages 31

Early Philosophical Conceptions of Consciousness 31

Later Greek and Roman Thought 32

Early Views of Mental Disorders in China 32

Views of Abnormality During the Middle Ages 33

### Toward Humanitarian Approaches 35

The Resurgence of Scientific Questioning in Europe 35

The Establishment of Early Asylums 35

Humanitarian Reform 36

Nineteenth-Century Views of the Causes and Treatment of Mental Disorders 40

Changing Attitudes Toward Mental Health in the Early Twentieth Century 40

#### the WORLD around us

Chaining Mental Health Patients 41

Mental Hospital Care in the Twentieth Century 41

### The Emergence of Contemporary Views of Abnormal Behavior 43

Biological Discoveries: Establishing the Link Between the Brain and Mental Disorder 43

The Development of a Classification System 44

Development of the Psychological Basis of Mental Disorder 44

#### developments in RESEARCH:

The Search for Medications to Cure Mental Disorders 45

The Evolution of the Psychological Research Tradition: Experimental Psychology 47

#### UNRESOLVED issues

Interpreting Historical Events 51

summary 52 key terms 53

## 3 Causal Factors and Viewpoints 54

### Causes and Risk Factors for Abnormal Behavior 55

- Necessary, Sufficient, and Contributory Causes 55
- Feedback and Bidirectionality in Abnormal Behavior 56
- Diathesis-Stress Models 57

### Viewpoints for Understanding the Causes of Abnormal Behavior 59

#### The Biological Viewpoint and Biological Causal Factors 60

- Imbalances of Neurotransmitters and Hormones 60
- Genetic Vulnerabilities 63

#### developments in THINKING:

- Nature, Nurture, and Psychopathology:  
A New Look at an Old Topic 66
- Temperament 67
- Brain Dysfunction and Neural Plasticity 68
- The Impact of the Biological Viewpoint 69

#### The Psychological Viewpoints 70

- The Psychodynamic Perspectives 70
- The Behavioral Perspective 75

#### developments in THINKING:

- The Humanistic and Existential Perspectives 77
- The Cognitive-Behavioral Perspective 79
- What the Adoption of a Perspective Does and Does Not Do 82

#### Psychological Causal Factors 83

- Early Deprivation or Trauma 83
- Inadequate Parenting Styles 86
- Marital Discord and Divorce 88
- Maladaptive Peer Relationships 89

#### The Sociocultural Viewpoint 91

- Uncovering Sociocultural Factors Through Cross-Cultural Studies 91

#### Sociocultural Causal Factors 93

- Low Socioeconomic Status and Unemployment 94
- Prejudice and Discrimination in Race, Gender, and Ethnicity 94

#### the WORLD around us

- Culture and Attachment Relationships 95
- Social Change and Uncertainty 96
- Urban Stressors: Violence and Homelessness 96
- The Impact of the Sociocultural Viewpoint 96

#### UNRESOLVED issues

- Theoretical Viewpoints and the Causes of Abnormal Behavior 97
- summary 98 key terms 99

## 4 Clinical Assessment and Diagnosis 100

### The Basic Elements in Assessment 101

- The Relationship Between Assessment and Diagnosis 102

- Taking a Social or Behavioral History 102
- Ensuring Culturally Sensitive Assessment Procedures 103
- The Influence of Professional Orientation 103
- Reliability, Validity, and Standardization 104
- Trust and Rapport Between the Clinician and the Client 104

### Assessment of the Physical Organism 105

- The General Physical Examination 105
- The Neurological Examination 105
- The Neuropsychological Examination 107

### Psychosocial Assessment 108

- Assessment Interviews 108
- The Clinical Observation of Behavior 109
- Psychological Tests 110

#### developments in PRACTICE:

- The Automated Practice: Use of the Computer in Psychological Testing 111

### The Case of Andrea C.: Experiencing Violence in the Workplace 117

- developments in PRACTICE:  
Computer-Based MMPI-2 Report for Andrea C. 118

### The Integration of Assessment Data 120

- Ethical Issues in Assessment 120

### Classifying Abnormal Behavior 121

- Differing Models of Classification 122
- Formal Diagnostic Classification of Mental Disorders 122
- Criteria for Persistent Depressive Disorder (Dysthymia) 123

#### THINKING CRITICALLY about DSM-5:

- Completion Does Not Assure Acceptance 125

summary 126 key terms 127

## 5 Stress and Physical and Mental Health 128

### What Is Stress? 130

- Stress and the DSM 130
- Factors Predisposing a Person to Stress 130
- Characteristics of Stressors 131
- Measuring Life Stress 132
- Resilience 132

### Stress and the Stress Response 133

- Biological Costs of Stress 134
- The Mind-Body Connection 134
- Understanding the Immune System 134
- Stress, Depression, and the Immune System 136

### STRESS AND PHYSICAL HEALTH 137

- Cardiovascular Disease 138**
- Hypertension 138
- Coronary Heart Disease 139
- Risk and Causal Factors in Cardiovascular Disease 140

<b>the WORLD around us</b>	Prevalence, Age of Onset, and Gender Differences 168
Racial Discrimination and Cardiovascular Health in African Americans 142	Psychological Causal Factors 168
<b>Treatment of Stress-Related Physical Disorders 143</b>	Biological Causal Factors 171
Biological Interventions 143	Treatments 171
Psychological Interventions 143	
<b>STRESS AND MENTAL HEALTH 145</b>	<b>Social Phobias 173</b>
Adjustment Disorder 145	Prevalence, Age of Onset, and Gender Differences 173
Adjustment Disorder Caused by Unemployment 145	Psychological Causal Factors 174
<b>Posttraumatic Stress Disorder 145</b>	Criteria for Social Anxiety Disorder (Social Phobia) 175
Criteria for Posttraumatic Stress Disorder 146	Biological Causal Factors 176
<b>THINKING CRITICALLY about DSM-5:</b>	Treatments 177
Changes to the Diagnostic Criteria for PTSD 147	Panic Disorder 178
Acute Stress Disorder 148	Criteria for Panic Disorder 178
Clinical Description 148	Agoraphobia 179
Prevalence of PTSD in the General Population 148	Criteria for Agoraphobia 179
Rates of PTSD After Traumatic Experiences 149	Prevalence, Age of Onset, and Gender Differences 180
Causal Factors in Posttraumatic Stress Disorder 152	Comorbidity with Other Disorders 181
Individual Risk Factors 153	The Timing of a First Panic Attack 181
Sociocultural Factors 154	Biological Causal Factors 181
Long-Term Effects of Posttraumatic Stress 155	Psychological Causal Factors 183
<b>Prevention and Treatment of Stress Disorders 155</b>	<b>developments in RESEARCH:</b>
Prevention 155	Nocturnal Panic Attacks 185
<b>the WORLD around us</b>	Treatments 187
Does Playing Tetris After a Traumatic Event Reduce Flashbacks? 156	
Treatment for Stress Disorders 156	<b>Generalized Anxiety Disorder 188</b>
Psychological Debriefing 157	Criteria for Generalised Anxiety Disorder 189
<b>the WORLD around us</b>	Prevalence, Age of Onset, and Gender Differences 190
Virtual Reality Exposure Treatment for PTSD in Military Personnel 158	Comorbidity with Other Disorders 190
Challenges in Studying Disaster Victims 159	Psychological Causal Factors 190
Trauma and Physical Health 159	Biological Causal Factors 192
<b>UNRESOLVED issues</b>	Treatments 193
Why Is the Study of Trauma so Contentious? 160	
summary 160 key terms 161	<b>Obsessive-Compulsive and Related Disorders 194</b>
	Obsessive-Compulsive Disorder 194
<b>Panic, Anxiety, Obsessions, and Their Disorders 162</b>	Criteria for Obsessive-Compulsive Disorder 195
<b>The Fear and Anxiety Response Patterns 164</b>	Prevalence, Age of Onset, and Gender Differences 196
Fear 164	Comorbidity with Other Disorders 197
<b>THINKING CRITICALLY about DSM-5:</b>	Psychological Causal Factors 197
Why is OCD No Longer Considered to Be an Anxiety Disorder? 164	Biological Causal Factors 199
Anxiety 165	Treatments 201
<b>Overview of the Anxiety Disorders and Their Commonalities 165</b>	Body Dysmorphic Disorder 202
<b>Specific Phobias 166</b>	Criteria for Body Dysmorphic Disorder 204
Criteria for Specific Phobia 167	Hoarding Disorder 206
	Trichotillomania 206
	<b>Cultural Perspectives 206</b>
	Cultural Differences in Sources of Worry 207
	Taijin Kyofusho 207
	<b>UNRESOLVED issues</b>
	The Choice of Treatments: Medications or Cognitive-Behavior Therapy? 208
	summary 209 key terms 210

## Mood Disorders and Suicide 211

### Mood Disorders: An Overview 212

- Types of Mood Disorders 212
- Criteria for Major Depressive Disorder 213
- Criteria for Manic Episode 214
- The Prevalence of Mood Disorders 214

### Unipolar Depressive Disorders 214

- Other Forms of Depression 215

#### **THINKING CRITICALLY about DSM-5:**

- Was It Wise to Drop the Bereavement Exclusion for Major Depression? 215

#### **developments in THINKING:**

- A New DSM-5 Diagnosis: Premenstrual Dysphoric Disorder 216
- Dysthymic Disorder (Persistent Depressive Disorder) 216
- Criteria for Persistent Depressive Disorder (Dysthymia) 217
- Major Depressive Disorder 218

### Causal Factors in Unipolar Mood Disorders 221

- Biological Causal Factors 221
- Psychological Causal Factors 226

#### **developments in RESEARCH:**

- Why Do Sex Differences in Unipolar Depression Emerge During Adolescence? 235

### Bipolar and Related Disorders 237

- Cyclothymic Disorder 238
- Criteria for Cyclothymic Disorder 238
- Bipolar Disorders (I and II) 239

### Causal Factors in Bipolar Disorders 242

- Biological Causal Factors 242
- Psychological Causal Factors 244

### Sociocultural Factors Affecting Unipolar and Bipolar Disorders 244

- Cross-Cultural Differences in Depressive Symptoms 244
- Cross-Cultural Differences in Prevalence 245
- Demographic Differences in the United States 246

### Treatments and Outcomes 246

- Pharmacotherapy 247
- Alternative Biological Treatments 249
- Psychotherapy 249

### Suicide: The Clinical Picture and the Causal Pattern 252

- Who Attempts and Who Commits Suicide? 253
- Suicide in Children 254
- Suicide in Adolescents and Young Adults 254
- Other Psychosocial Factors Associated with Suicide 254

#### **the WORLD around us**

- Warning Signs for Student Suicide 255
- Biological Causal Factors 256

#### Sociocultural Factors 256

### Suicidal Ambivalence 257

- Communication of Suicidal Intent 258
- Suicide Notes 258

## Suicide Prevention and Intervention 258

- Treatment of Mental Disorders 258
- Crisis Intervention 259
- Focus on High-Risk Groups and Other Measures 259
- UNRESOLVED issues**
- Is There a Right to Die? 259
- summary 261 key terms 262

## Somatic Symptom and Dissociative Disorders 263

### Somatic Symptom and Related Disorders 264

- Somatic Symptom Disorders 265
- Hypochondriasis 265
- Criteria for Somatic Symptom Disorder 265
- Somatization Disorder 268
- Pain Disorder 269
- Conversion Disorder (Functional Neurological Symptom Disorder) 270
- Criteria for Illness Anxiety Disorder 270
- Criteria for Conversion disorder 271
- Distinguishing Somatization, Pain, and Conversion Disorders from Malingering and Factitious Disorder 274
- Criteria for Factitious Disorder 274

#### **the WORLD around us**

- Factitious Disorder Imposed on Another (Munchausen's Syndrome by Proxy) 275

### Dissociative Disorders 276

- Depersonalization/Derealization Disorder 276
- Criteria for Depersonalization/Derealization Disorder 277
- Dissociative Amnesia and Dissociative Fugue 278
- Criteria for Dissociative Amnesia 278
- Dissociative Identity Disorder (DID) 280

#### **THINKING CRITICALLY about DSM-5:**

- Where Does Conversion Disorder Belong? 280
- Criteria for Dissociative Identity Disorder 281

#### **the WORLD around us**

- DID, Schizophrenia, and Split Personality: Clearing Up the Confusion 282

- Sociocultural Factors in Dissociative Disorders 288
- Treatment and Outcomes in Dissociative Disorders 288

#### **UNRESOLVED issues**

- DID and the Reality of "Recovered Memories" 290
- summary 291 key terms 292

## Eating Disorders and Obesity 293

### Clinical Aspects of Eating Disorders 295

- Anorexia Nervosa 295
- Criteria for Anorexia Nervosa 295
- Bulimia Nervosa 297

# 10

## Personality Disorders 327

### Clinical Features of Personality Disorders 328

### Difficulties Doing Research on Personality Disorders 330

Difficulties in Diagnosing Personality Disorders 330

### THINKING CRITICALLY about DSM-5:

Why Were No Changes Made to the Way Personality Disorders Are Diagnosed? 331

Difficulties in Studying the Causes of Personality Disorders 332

### Cluster A Personality Disorders 333

Paranoid Personality Disorder 333

Criteria for Paranoid Personality Disorder 334

Schizoid Personality Disorder 335

Criteria for Schizoid Personality Disorder 336

Schizotypal Personality Disorder 336

Criteria for Schizotypal Personality Disorder 337

### Cluster B Personality Disorders 338

Histrionic Personality Disorder 338

Narcissistic Personality Disorder 339

Criteria for Histrionic Personality Disorder 339

Criteria for Narcissistic Personality Disorder 340

Antisocial Personality Disorder 341

Borderline Personality Disorder 342

Criteria for Borderline Personality Disorder 342

### THINKING CRITICALLY about DSM-5:

Nonsuicidal Self-Injury: Distinct Disorder or Symptom of Borderline Personality Disorder? 343

### Cluster C Personality Disorders 345

Avoidant Personality Disorder 345

Criteria for Avoidant Personality Disorder 346

Dependent Personality Disorder 347

Obsessive-Compulsive Personality Disorder 348

Criteria for Dependent Personality Disorder 348

Criteria for Obsessive-Compulsive Personality Disorder 349

### General Sociocultural Causal Factors for Personality Disorders 350

### Treatments and Outcomes for Personality Disorders 350

Adapting Therapeutic Techniques to Specific Personality Disorders 351

Treating Borderline Personality Disorder 351

Treating Other Personality Disorders 352

Criteria for Antisocial Personality Disorder 353

### Antisocial Personality Disorder and Psychopathy 353

## What's New in DSM-5? A Quick Guide

Many changes occurred from *DSM-IV* to *DSM-5*. Here is a summary of some of the most important revisions. Many of these changes are highlighted in the “Thinking Critically about *DSM-5*” boxes throughout this edition.

- The chapters of the *DSM* have been re-organized to reflect a consideration of developmental and lifespan issues. Disorders that are thought to reflect developmental perturbations or that manifest early in life (e.g., neurodevelopmental disorders and disorders such as schizophrenia) are listed before disorders that occur later in life.
- The multiaxial system has been abandoned. No distinction is now made between Axis I and Axis II disorders.
- *DSM-5* allows for more gender-related differences to be taken into consideration for mental health problems.
- It is extremely important for the clinician to understand the client’s cultural background in appraising mental health problems. *DSM-5* contains a structured interview that focuses upon the patient’s cultural background and characteristic approach to problems.
- The term *intellectual disability* is now used instead of the term *mental retardation*.
- A new diagnosis of autism spectrum disorder now encompasses autism, Asperger’s disorder, and other forms of pervasive developmental disorder. The diagnosis of Asperger’s disorder has been eliminated from the *DSM*.
- Changes to the diagnostic criteria for attention deficit disorder now mean that symptoms that occur before age 12 (rather than age 7) have diagnostic significance.
- A new diagnosis, called disruptive mood regulation disorder, has been added. This will be used to diagnose children up to age 18 who show persistent irritability and frequent episodes of extreme and uncontrolled behavior.
- The subtypes of schizophrenia have been eliminated.
- The special significance afforded to bizarre delusions with regard to the diagnosis of schizophrenia has been removed.
- Bipolar and related disorders are now described in a separate chapter of the *DSM* and are no longer listed with depressive disorders.
- Premenstrual dysphoric disorder has been promoted from the appendix of *DSM-IV* and is now listed as a new diagnosis.
- A new diagnosis of persistent depressive disorder now subsumes dysthymia and chronic major depressive disorder.
- The bereavement exclusion has been removed in the diagnosis of major depressive episode.
- The diagnosis of phobia no longer requires that the person recognize that his or her anxiety is unreasonable.
- Panic disorder and agoraphobia have been unlinked and are now separate diagnoses in *DSM-5*.
- Obsessive-compulsive disorder is no longer classified as an anxiety disorder. *DSM-5* contains a new chapter that covers obsessive compulsive and related disorders.
- New disorders in the obsessive compulsive and related disorders category include hoarding disorder and excoriation (skin picking) disorder.
- Post-traumatic stress disorder is no longer considered to be an anxiety disorder. Instead, it is listed in a new chapter that covers trauma- and stressor-related disorders.
- The diagnostic criteria for post-traumatic stress disorder have been significantly revised. The definition of what counts as a traumatic event has been clarified and made more explicit. *DSM-5* now also recognizes four-symptom clusters rather than the three noted in *DSM-IV*.
- Dissociative fugue is no longer listed as a separate diagnosis. Instead, it is listed as a form of dissociative amnesia.
- The *DSM-IV* diagnoses of hypochondriasis, somatoform disorder, and pain disorder have been removed and are now subsumed into the new diagnosis of somatic symptom disorder.
- Binge eating disorder has been moved from the appendix of *DSM-IV* and is now listed as an official diagnosis.
- The frequency of binge eating and purging episodes has been reduced for the diagnosis of bulimia nervosa.
- Amenorrhea is no longer required for the diagnosis of anorexia nervosa.
- The *DSM-IV* diagnoses of dementia and amnestic disorder have been eliminated and are now subsumed into a new category called major neurocognitive disorder.
- Mild neurocognitive disorder has been added as a new diagnosis.
- No changes have been made to the diagnostic criteria for personality disorders.
- Substance-related disorders are divided into two separate groups: substance use disorders and substance-induced disorders.
- A new disorder, gambling disorder, has been included in substance-related and addictive disorders.
- Included for the first time in Section III of *DSM-5* are several new disorders regarded as being in need of further study. These include attenuated psychosis syndrome, non-suicidal self-injury disorder, Internet gaming disorder, and caffeine use disorder.

The guidelines and standards that we follow in our professional activities are not set in stone. Change is a big part of life and new research or novel new theories can impact the way mental health professionals view problems. Although many of the ideas and diagnostic concepts in the field of abnormal psychology have persisted for hundreds of years, changes in thinking do occur. And, at some point there are events that occur that force a rethinking of some issues. Most recently in abnormal psychology, the publication of the *DSM-5*, after years of development and considerable controversy, is one of those momentous changes. Reflecting this, we have revised this new edition of *Abnormal Psychology* to reflect the most up-to-date information about diagnostic categories, classifications, and criteria.

Every time we work on a revision of *Abnormal Psychology* we are reminded of how dynamic and vibrant our field is. Developments in areas such as genetics, brain imaging, behavioral observation, and classification, as well changes in social and government policy and in legal decisions, add to our knowledge base and stimulate new treatments for those whose lives are touched by mental disorders. This is exciting. But the rapid progress of our field also presents its own challenges. One of the most important is how best to provide students with an integrated perspective—one that respects new ideas and discoveries and places them into the existing body of knowledge in a way that emphasizes multiple perspectives, provokes thought, and increases awareness.

We use a biopsychosocial approach to provide a sophisticated appreciation of the total context in which abnormalities of behavior occur. For ease of understanding we also present material on each disorder in a logical and consistent way. More specifically, we focus on three significant aspects: (1) the clinical picture, where we describe the symptoms of the disorder and its associated features; (2) factors involved in the development of the disorder; and (3) treatment approaches. In each case, we examine the evidence for biological, psychosocial (i.e., psychological and interpersonal), and sociocultural (the broader social environment of culture and subculture) influences. Because we wish never to lose sight of the person, we try to integrate as much case material as we can into each chapter. An additional feature of this book is a focus on treatment. Although treatment is discussed in every chapter in the context of specific disorders, we also include a separate chapter that addresses issues in treatment more broadly. This provides students with increased understanding of a wide range of treatment approaches and permits more in-depth coverage than is possible in specific disorder-based chapters.

The Butcher–Hooley–Mineka author team is in a unique position to provide students with an integrated and comprehensive understanding of abnormal psychology. Each author is a noted researcher, an experienced teacher, and a licensed clinician.

Each brings different areas of expertise and diverse research interests to the textbook. Importantly, these different perspectives come together in a systematically integrated text that is accessible to a broad audience. The depth and breadth of the author team provides students with learning experiences that can take them to new levels of understanding. Our approach emphasizes the importance of research as well as the need to translate research findings into informed and effective clinical care for all who suffer from mental disorders.

*Abnormal Psychology* has a long and distinguished tradition as an undergraduate text. Ever since James Coleman wrote the first edition many years ago, this textbook has been considered the most comprehensive in the field. Along the way there have been many changes. However, the commitment to excellence in this now-classic textbook has remained ever constant. In this new edition, we seek to open up the fascinating world of abnormal psychology, providing students with comprehensive and up-to-date knowledge in an accessible and engaging way. We hope that this newest edition conveys some of the passion and enthusiasm for the topic that we still experience every day.

## Why Do You Need This New Edition?

If you’re wondering why you should buy this new edition of *Abnormal Psychology*, here are 7 good reasons!

1. The sixteenth edition of *Abnormal Psychology* includes the most up-to-date and in-depth information about biological influences on the entire spectrum of behavioral abnormalities, while still maintaining its comprehensive and balanced biopsychosocial approach to understanding abnormal behavior.
2. After years of planning, *DSM-5* was published in May 2013. This major revision of the diagnostic system means that the diagnostic criteria for many disorders have changed. To stay current, you need to know about the changes that have been made in *DSM-5*. Books that do not include coverage of *DSM-5* are books that are out of date.
3. Our new edition provides you with detailed tables showing the current *DSM-5* diagnostic criteria for all the disorders covered in the book.
4. New highlight boxes alert you to some of the most important changes in *DSM-5*. These include changes to the diagnostic criteria for attention-deficit hyperactivity disorder as well as new diagnoses such as binge eating disorder and premenstrual dysphoric disorder.
5. Other feature boxes provide opportunities for critical thinking by illustrating some of the controversies associated with the changes that were (or were not) made. Throughout the

- book we also provide readers with different perspectives on the likely implications that these changes will have for clinical diagnosis and research in psychopathology.
- 6. Changes have been made in many chapters to improve the flow of the writing and enhance learning. Reflecting the ever-changing field of abnormal psychology, new references have been added and new research findings highlighted.
  - 7. Finally, at the beginning of each chapter clearly defined Learning Objectives provide the reader with an overview of topics and issues that will be included in the chapter. At the end of each chapter a summary of answers to these Learning Objective questions are provided. In-Review Questions at the end of major sections within chapters also provide additional opportunities for self-assessment and increased learning.

## What's New

A major change in the 16th edition of *Abnormal Psychology* is the focus on *DSM-5*. This important revision to the diagnostic system was published in May 2013. To assist both instructors and students, we include specialized feature boxes, highlighting many of the key changes that were made in *DSM-5*. This makes new material immediately accessible. Other important changes in *DSM-5* are also mentioned throughout the text. Providing students with this material as soon as possible after the publication of *DSM-5* reflects our commitment to staying ahead of the curve and to providing students with the most up-to-date information possible.

This new edition of *Abnormal Psychology* has been redesigned to remain visually engaging to the newest generation of students. Chapters begin with learning objective questions. These orient the reader to the material that will be presented in each specific chapter. Learning objective questions are also repeated at the end of each chapter and answers to each are provided. Most chapters also begin with a case study that illustrates the mental health problems to be addressed in the chapter. This serves to capture students' interest and attention right from the outset. Numerous new photographs and illustrations have also been added. In addition, this edition also contains updated case material, new unresolved issues (e.g., why is the study of trauma so contentious?; why are recovery rates in schizophrenia not improving?), and new feature boxes designed to be of high interest to students (e.g., non-suicidal self-injury disorder). Reflecting the ever-changing field of abnormal psychology, numerous new references have been added. Outdated material has been replaced, current findings have been included, and new developments have been identified. The 16th edition also includes the most up-to-date and in-depth information about the role of biological factors in abnormal behavior, while at the same time placing this in the context of a comprehensive biopsychosocial approach. Our coverage of cultural issues and diversity has also been strengthened. We hope readers will be

pleased to know that all of this has been accomplished without adding length to the book!

## Features and Pedagogy

The extensive research base and accessible organization of this book are supported by high-interest features and helpful pedagogy to further engage students and support learning. We also hope to encourage students to think in depth about the topics they are learning about through specific highlight features that emphasize critical thinking.

### Features

#### FEATURE BOXES

Special sections, called Developments in Research, Developments in Thinking, Developments in Practice, and The World Around Us, highlight topics of particular interest, focusing on applications of research to everyday life, current events, and the latest research methodologies, technologies, and findings.

#### CRITICAL THINKING

New to this edition are special highlight boxes about *DSM-5*. Many of the revisions to *DSM-5* were highly contentious and controversial. A new feature box called "Thinking Critically About *DSM-5*" introduces students to the revised *DSM* and encourages them to think critically about the implications of these changes.

#### UNRESOLVED ISSUES

All chapters include end-of-chapter sections that demonstrate how far we have come and how far we have yet to go in our understanding of psychological disorders. The topics covered here provide insight into the future of the field and expose students to some controversial topics. New to this edition is a discussion of the problems associated with the study of trauma. In another chapter, we raise the contentious issue of whether treatment with antipsychotic medications is helpful or harmful in the very long term.

### Pedagogy

#### LEARNING OBJECTIVES

Each chapter begins with learning objective questions. These orient the reader to the material that will be presented in each specific chapter. Learning objective questions are also repeated at the end of each chapter, along with their answers. This provides students with an excellent tool for study and review. In this edition, sections of many chapters have also been reorganized and material has been streamlined whenever possible. All the changes that have been made are designed to improve the flow of the writing and enhance pedagogy.

## CASE STUDIES

Extensive case studies of individuals with various disorders are integrated in the text throughout the book. Some are brief excerpts; others are detailed analyses. These cases bring important aspects of the disorders to life. They also remind readers that the problems of abnormal psychology affect the lives of people—people from all kinds of diverse backgrounds who have much in common with all of us.

## IN REVIEW QUESTIONS

Questions appear at the end of each major section within the chapter, providing regular opportunities for self-assessment as students read and further reinforce their learning.

## DSM-5 BOXES

Throughout the book these boxes contain the most up-to-date (*DSM-5*) diagnostic criteria for all of the disorders discussed. In a convenient and visually accessible form, they provide a helpful study tool that reflects current diagnostic practice. They also help students understand disorders in a real-world context.

## RESEARCH CLOSE-UP TERMS

Appearing throughout each chapter, these terms illuminate research methodologies. They are designed to give students a clearer understanding of some of the most important research concepts in the field of abnormal psychology.

## CHAPTER SUMMARIES

Each chapter ends with a summary of the essential points of the chapter organized around the learning objectives presented at the start of the chapter. These summaries use bulleted lists rather than formal paragraphs. This makes the information more accessible for students and easier to scan.

## KEY TERMS

Key terms are identified in each chapter. Key terms are also listed at the end of every chapter with page numbers referencing where they can be found in the body of the text. Key terms are also defined in the Glossary at the end of the book.

## Supplements Package

### MyPsychLab® for Abnormal Psychology

MyPsychLab is an online homework, tutorial, and assessment program that truly engages students in learning. It helps students better prepare for class, quizzes, and exams—resulting in better performance in the course. It provides educators a dynamic set of tools for gauging individual and class performance.

To order the 16th edition with MyPsychLab, use ISBN 0205965091

## Speaking Out: Interviews with People Who Struggle with Psychological Disorders

This set of video segments allows students to see firsthand accounts of patients with various disorders. The interviews were conducted by licensed clinicians and range in length from 8 to 25 minutes. Disorders include major depressive disorder, obsessive-compulsive disorder, anorexia nervosa, PTSD, alcoholism, schizophrenia, autism, ADHD, bipolar disorder, social phobia, hypochondriasis, borderline personality disorder, and adjustment to physical illness. These video segments are available on DVD or through MyPsychLab.

Volume 1: ISBN 0131933329

Volume 2: ISBN 0136003036

Volume 3: ISBN 0132308916

## Instructor's Manual (0205971946)

A comprehensive tool for class preparation and management, each chapter includes teaching objectives; a chapter overview; a detailed lecture outline; a list of key terms; teaching resources, including lecture launchers, class activities, demonstrations, assignments, teaching tips and handouts; a list of video, media, and Web resources; and a sample syllabus. Available for download on the Instructor's Resource Center at [www.pearsonhighered.com](http://www.pearsonhighered.com).

## Test Bank (0205971938)

The Test Bank is composed of approximately 2,000 fully referenced multiple-choice, completion, short-answer, and concise essay questions. Each question is accompanied by a page reference, difficulty level, skill type (factual, conceptual or applied), topic, and a correct answer. Available for download on the Instructor's Resource Center at [www.pearsonhighered.com](http://www.pearsonhighered.com).

## MyTest (020591537X)

A powerful assessment-generation program that helps instructors easily create and print quizzes and exams. Questions and tests can be authored online, allowing instructors ultimate flexibility and the ability to efficiently manage assessments anytime, anywhere. Instructors can easily access existing questions and edit, create, and store questions using a simple drag-and-drop technique and Word-like controls. Data on each question provides information on difficulty level and the page number of corresponding text discussion. For more information, go to [www.PearsonMyTest.com](http://www.PearsonMyTest.com).

## Lecture PowerPoint Slides (0205978398)

The PowerPoint slides provide an active format for presenting concepts from each chapter and feature relevant figures and tables from the text. Available for download on the Instructor's Resource Center at [www.pearsonhighered.com](http://www.pearsonhighered.com).

### Enhanced Lecture PowerPoint Slides with Embedded Videos

on DVD (0205997422). The lecture PowerPoint slides have been embedded with select Speaking Out video pertaining to each disorder chapter, enabling instructors to show videos within the context of their lecture. No internet connection is required to play videos.

### **PowerPoint Slides for Photos, Figures, and Tables**

(0205988814) contain only the photos, figures, and line art from the textbook. Available for download on the Instructor's Resource Center at [www.pearsonhighered.com](http://www.pearsonhighered.com).

### **CourseSmart** (0205971768)

**CourseSmart** Textbooks Online is an exciting choice for students looking to save money. As an alternative to purchasing the print textbook, students can subscribe to the same content online and save up to 60 percent off the suggested list price of the print text. With a CourseSmart eTextbook, students can search the text, make notes online, print out reading assignments that incorporate lecture notes, and bookmark important passages for later review. For more information or to subscribe to the CourseSmart eTextbook, visit [www.coursesmart.com](http://www.coursesmart.com).

## Acknowledgments

It takes each member of the author team more than a year of focused work to produce a new edition of this textbook. During this time, family and friends receive much less attention than they deserve. We are aware that a few lines of acknowledgement in a preface do little to compensate those close to us for all the inconveniences and absences they have endured. Nonetheless, James Butcher would like to thank his wife, Carolyn L. Williams, and his children, Holly Butcher, Sherry Butcher, and Jay Butcher, for their patience and support during this time. Jill Hooley is ever grateful to Kip Schur for his patience, love, support, and ability to retain a sense of humor throughout the revision process. She also thanks Blake T. Haskell for providing valuable information used in Chapter 9. The efforts of graduate student Sara Masland and undergraduates Lauren Fields and Deirdre Gorman are also gratefully acknowledged. Susan Mineka wishes to thank her graduate students, friends, and family for their patience and support for the duration of this project. She also extends special thanks to J. Michael Bailey.

Singled out for special praise and endless appreciation is our wonderful development editor, LeeAnn Doherty. Her editorial expertise, insightful recommendations, and grace under pressure made her a delight to work with. A big thank you also goes to Erin Mitchell, acquisitions editor, for her advice, support, and dedication to the book. Without Erin's ability to manage every challenge that arose, this book might still be in the production stages. Another special thank you goes to Sherry Lewis for her skillful management of the production of this book as well as to Amber Mackey for her efforts to secure all the permissions necessary for the figures and photographs.

Many experts, researchers, and users of this book provided us with comments on individual chapters. We are extremely grateful for their input and feedback. Their knowledge and expertise help us keep this text current and accurate. We thank Tia Almpoura

and Mohsen Jadidi who provided valuable help. We are also especially grateful to the many reviewers who have given us invaluable feedback on this and previous editions of *Abnormal Psychology*.

# about the authors

## James N. BUTCHER

*Professor Emeritus, University of Minnesota*

James N. Butcher was born in West Virginia. He enlisted in the army when he was 17 years old and served in the airborne infantry for 3 years, including a 1-year tour in Korea during the Korean War. After military service, he attended Guilford College, graduating in 1960 with a BA in psychology. He received an MA in experimental psychology in 1962 and a PhD in clinical psychology from the University of North Carolina at Chapel Hill. He was awarded Doctor Honoris Causa from the Free University of Brussels, Belgium, in 1990 and an honorary doctorate from the University of Florence, Florence, Italy, in 2005. He is currently professor emeritus in the Department of Psychology at the University of Minnesota. He was associate director and director of the clinical psychology program at the university for 19 years. He was a member of the University of Minnesota Press's MMPI Consultative Committee, which undertook the revision of the MMPI in 1989. He was formerly the editor of *Psychological Assessment*, a journal of the American Psychological Association, and serves as consulting editor or reviewer for numerous other journals in psychology and psychiatry. Dr. Butcher was actively involved in developing and organizing disaster response programs for dealing with human problems following airline disasters during his career. He organized a model crisis intervention disaster response for the Minneapolis-St. Paul Airport and organized and supervised the psychological services offered following two major airline disasters: Northwest Flight 255 in Detroit, Michigan, and Aloha Airlines on Maui. He is a fellow of the Society for Personality Assessment. He has published 60 books and more than 250 articles in the fields of abnormal psychology, cross-cultural psychology, and personality assessment.

## Jill M. HOOLEY

*Harvard University*

Jill M. Hooley is a professor of psychology at Harvard University. She is also the head of the experimental psychopathology and clinical psychology program at Harvard. Dr. Hooley was born in England and received a B.Sc. in psychology from the University of Liverpool. This was followed by research work at Cambridge University. She then attended Magdalen College, Oxford, where she completed her D.Phil. After a move to the United States and additional training in clinical psychology at SUNY Stony Brook, Dr. Hooley took a position at Harvard, where she has been a faculty member since 1985.

Dr. Hooley has a long-standing interest in psychosocial predictors of psychiatric relapse in patients with severe psychopathology such as schizophrenia and depression. Her research has been supported by grants from the National Institute of Mental Health and by the Borderline Personality Disorder Research Foundation. She uses fMRI to study emotion regulation in people who are vulnerable to depression and in people who are suffering from borderline personality disorder. Another area of research interest is nonsuicidal self-harming behaviors such as skin cutting or burning.

In 2000, Dr. Hooley received the Aaron T. Beck Award for Excellence in Psychopathology Research. She is also a past president of the Society for Research in Psychopathology. The author of many scholarly publications, Dr. Hooley was appointed as Associate Editor for Clinical Psychological Science in 2012. She is also an associate editor for *Applied and Preventive Psychology* and serves on the editorial boards of several journals including the *Journal of Consulting and Clinical Psychology*, the *Journal of Family Psychology*, *Family Process*, and *Personality Disorders: Theory, Research and Treatment*.

At Harvard, Dr. Hooley has taught graduate and undergraduate classes in introductory psychology, abnormal psychology, schizophrenia, mood disorders, clinical psychology, psychiatric diagnosis, and psychological treatment. Reflecting her commitment to the scientist-practitioner model, she also does clinical work specializing in the treatment of people with depression, anxiety disorders, and personality disorders.

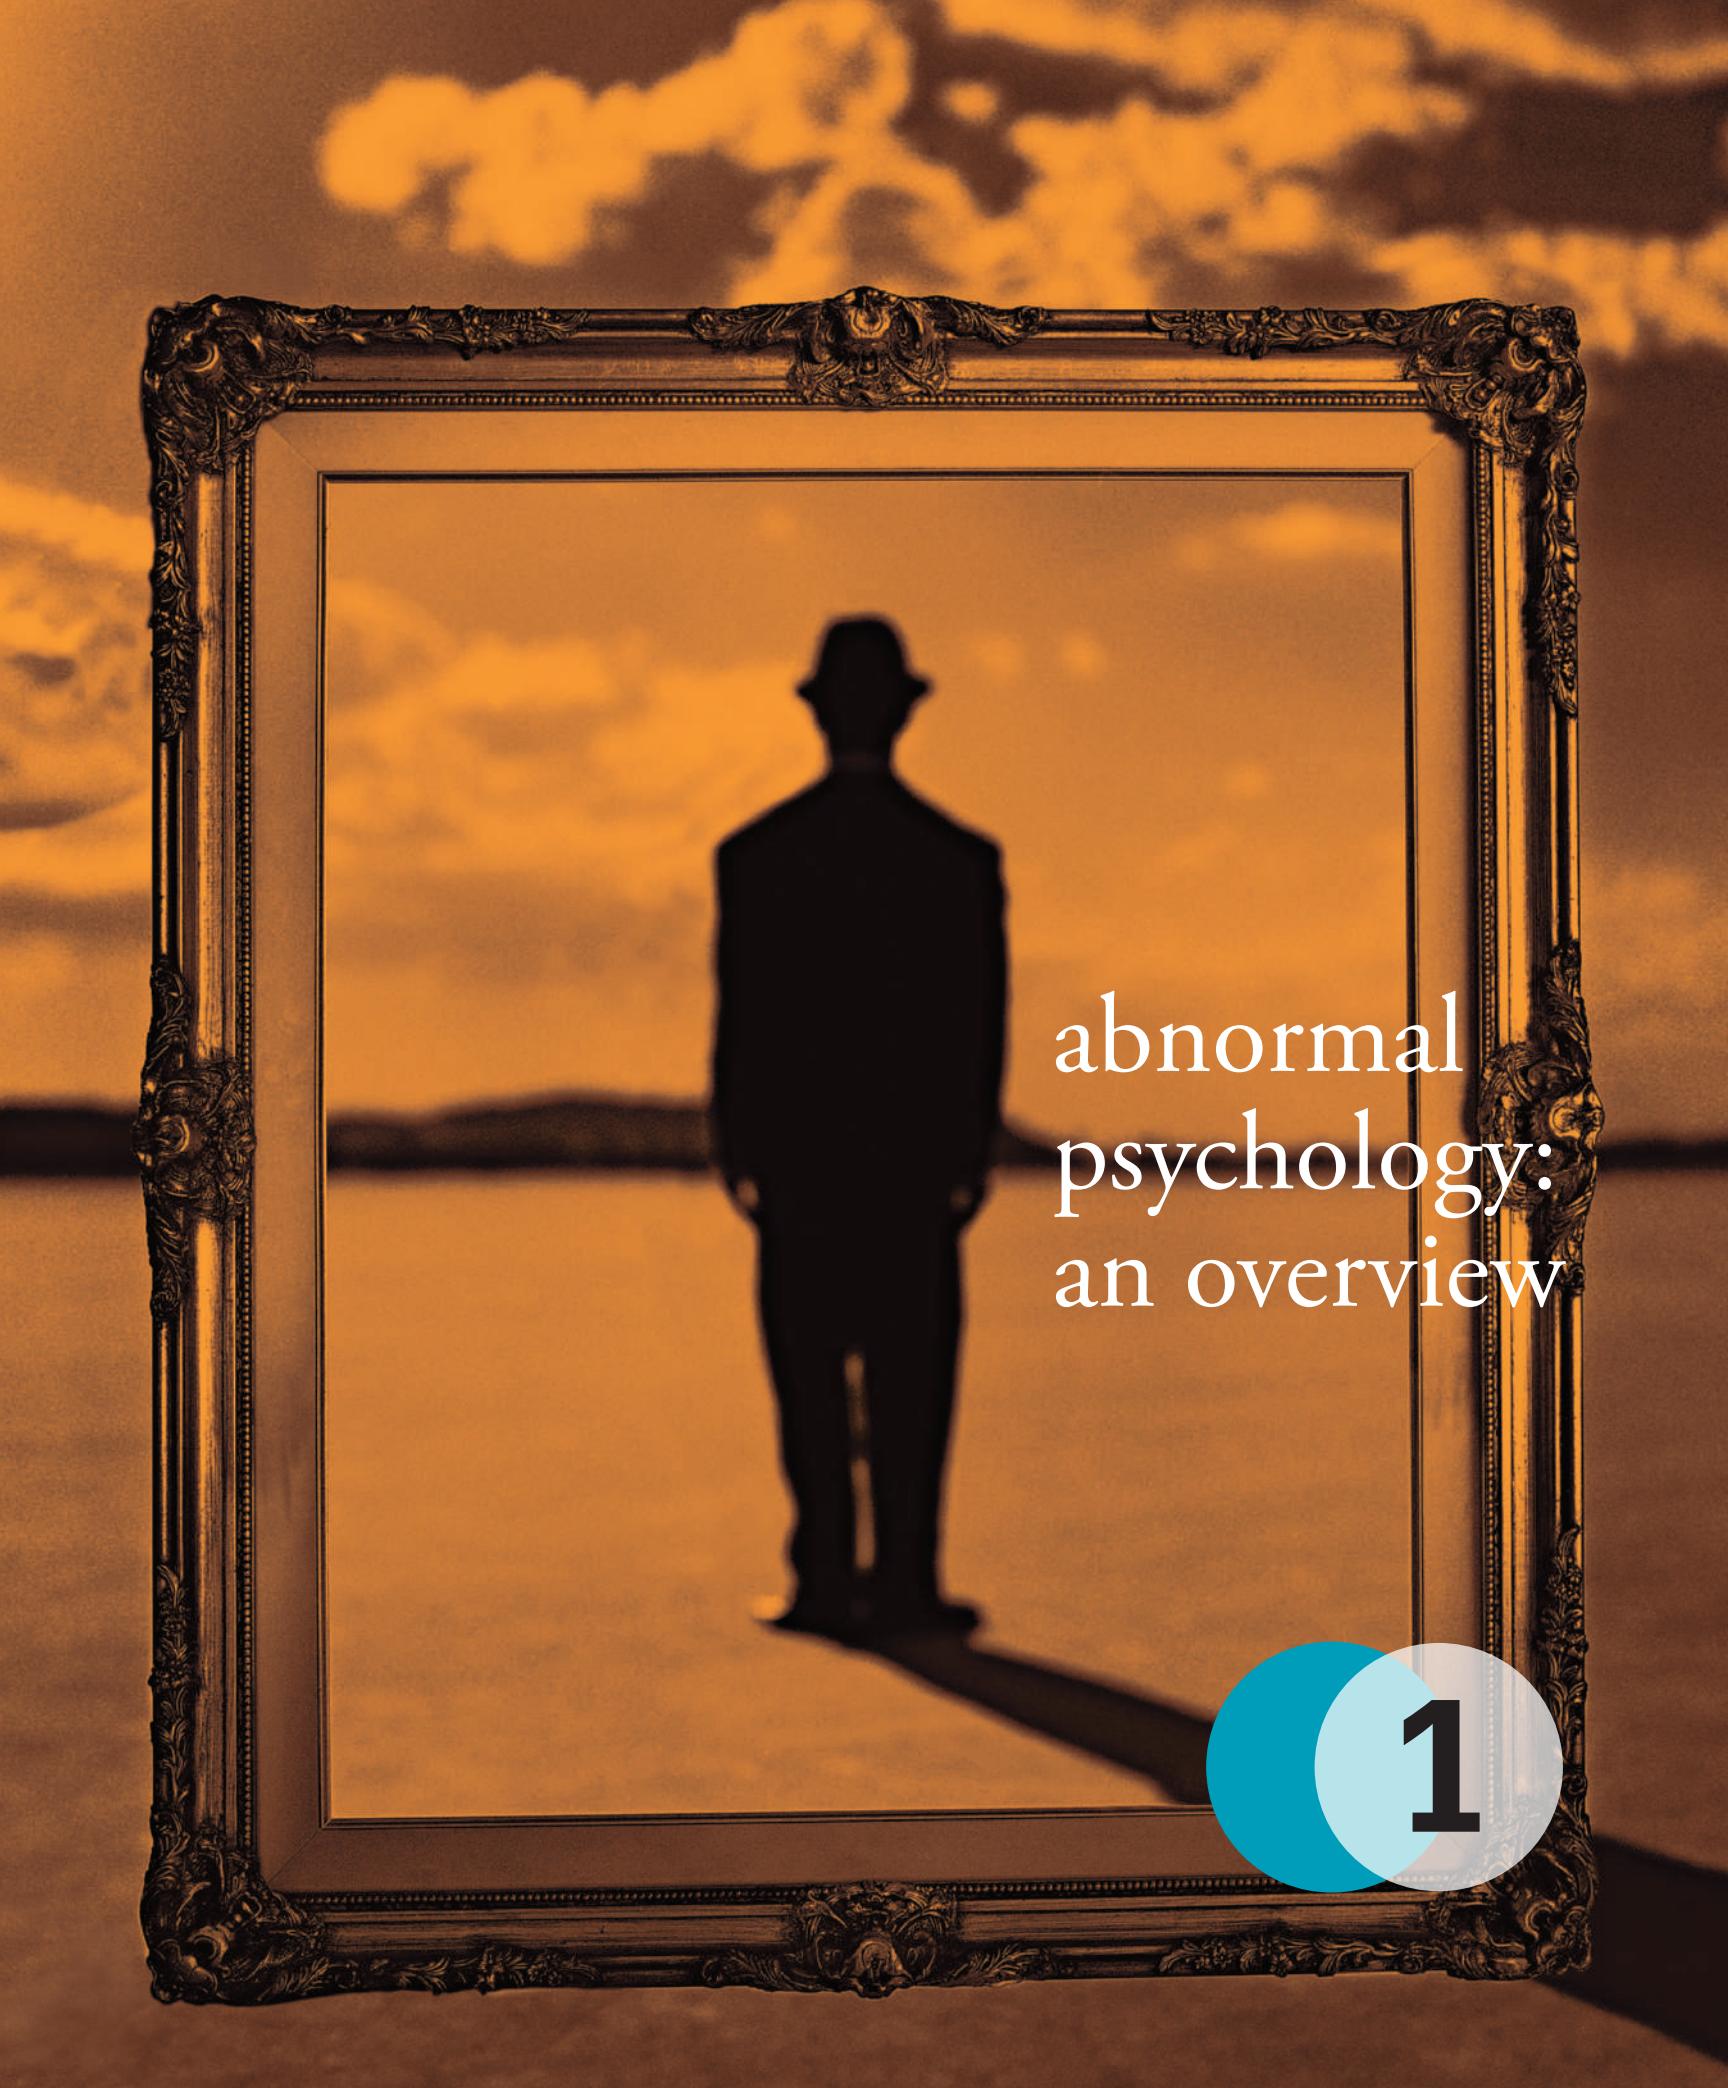

## Susan MINEKA

*Northwestern University*

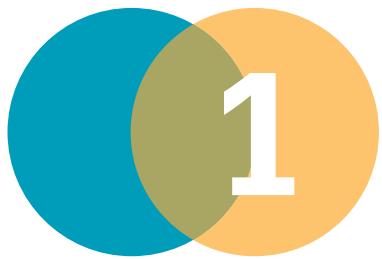

Susan Mineka, born and raised in Ithaca, New York, received her undergraduate degree magna cum laude in psychology at Cornell University. She received a PhD in experimental psychology from the University of Pennsylvania and later completed a formal clinical retraining program from 1981 to 1984. She taught at the University of Wisconsin-Madison and at the University of Texas at Austin before moving to Northwestern University in 1987. Since 1987 she has been a professor of psychology at Northwestern, and from 1998 to 2006 she served as director of clinical training there. She has taught a wide range of undergraduate and graduate courses, including introductory psychology, learning, motivation, abnormal psychology, and cognitive-behavior therapy. Her current research interests include cognitive and behavioral approaches to understanding the etiology, maintenance, and treatment of anxiety and mood disorders. She is currently a Fellow of the American Psychological Association, the American Psychological Society, and the Academy of Cognitive Therapy. She has served as editor of the *Journal of Abnormal Psychology* (1990–1994). She also served as associate editor for *Emotion* from 2002 to 2006 and is on the editorial boards of several of the leading journals in the field. She was also president of the Society for the Science of Clinical Psychology (1994–1995) and was president of the Midwestern Psychological Association (1997). She also served on the American Psychological Association's Board of Scientific Affairs (1992–1994, chair 1994), on the Executive Board of the Society for Research in Psychopathology (1992–1994, 2000–2003), and on the Board of Directors of the American Psychological Society (2001–2004). During 1997 and 1998 she was a fellow at the Center for Advanced Study in the Behavioral Sciences at Stanford.

A large, ornate gold frame surrounds a central image. Inside the frame, a silhouette of a man wearing a fedora and a suit jacket is standing with his back to the viewer, looking out over a landscape under a dramatic, cloudy sky.

## learning objectives

### 1.1

How do we define abnormality and classify mental disorders?

### 1.2

What are the advantages and disadvantages of classification?

### 1.3

How common are mental disorders? Which disorders are most prevalent?

### 1.4

Why do we need a research-based approach in abnormal psychology?

### 1.5

How do we gather information about mental disorders?

### 1.6

What kinds of research designs are used to conduct research in abnormal psychology?

may even be the disheveled street person in the aluminum foil hat who shouts, “Leave me alone!” to voices only he can hear.

The issues of abnormal psychology capture our interest, demand our attention, and trigger our concern. They also compel us to ask questions. To illustrate further, let’s consider two clinical cases.

→ **Monique** Monique is a 24-year-old law student. She is attractive, neatly dressed, and clearly very bright. If you were to meet her, you would think that she had few problems in her life; but Monique has been drinking alcohol since she was 14, and she smokes marijuana every day. Although she describes herself as “just a social drinker,” she drinks four or five glasses of wine when she goes out with friends and also drinks a couple of glasses of wine a night when she is alone in her apartment in the evening. She frequently misses early-morning classes because she feels too hung over to get out of bed. On several occasions her drinking has caused her to black out. Although she denies having any problems with alcohol, Monique admits that her friends and family have become very concerned about her and have suggested that she seek help. Monique, however, says, “I don’t think I am an alcoholic because I never drink in the mornings.” The previous week she decided to stop smoking marijuana entirely because she was concerned that she might have a drug problem. However, she found it impossible to stop and is now smoking regularly again.

→ **John** John comes from a family with no history of mental illness. He had a normal birth and seemed to develop normally when he was a child. However, when he was 21, John began to hear voices and started to believe that there was a conspiracy against him. Since that time, he has been on various different anti-psychotic medications. Although these have helped a little, he still has symptoms of psychosis. Now aged 46, John has been unable to work since he became ill. He has also been hospitalized many times. John lives in sheltered accommodation, although he maintains contact with his parents and his older brother.

Perhaps you found yourself asking questions as you read about Monique and John. For example, because Monique doesn’t drink in the mornings, you might have wondered whether she could really have a serious alcohol problem. She does. This is a question that concerns the criteria that must be met before someone receives a particular diagnosis. Or perhaps you wondered whether other people in Monique’s family likewise have drinking problems. They do. This is a question about what we call **family aggregation**—that is, whether a disorder runs in families.

You may also have been curious about what is wrong with John and why he is hearing voices. Questions about the age of onset of his symptoms as well as predisposing factors may also have occurred to you. John has schizophrenia, a disorder that often strikes in late adolescence or early adulthood. Also, as

**Abnormal psychology** is concerned with understanding the nature, causes, and treatment of mental disorders. The topics and problems within the field of abnormal psychology surround us every day. You have only to pick up a newspaper, flip through a magazine, surf the web, or sit through a movie to be exposed to some of the issues that clinicians and researchers deal with on a day-to-day basis. Almost weekly some celebrity is in the news because of a drug or alcohol problem, an eating disorder, or some other psychological difficulty. Countless books provide personal accounts of struggles with schizophrenia, depression, phobias, and panic attacks. Films and TV shows portray aspects of abnormal behavior with varying degrees of accuracy. And then there are the tragic news stories of mothers who kill their children, in which problems with depression, schizophrenia, or postpartum difficulties seem to be implicated.

Abnormal psychology can also be found much closer to home. Walk around any college campus, and you will see flyers about peer support groups for people with eating disorders, depression, and a variety of other disturbances. You may even know someone who has experienced a clinical problem. It may be a cousin with a cocaine habit, a roommate with bulimia, or a grandparent who is developing Alzheimer’s disease. It may be a coworker of your mother’s who is hospitalized for depression, a neighbor who is afraid to leave the house, or someone at your gym who works out intensely despite being worrisomely thin. It

Fergie has spoken about her past struggles with substance abuse, specifically crystal meth.

John's case illustrates, it is not unusual for someone who develops schizophrenia to develop perfectly normally before suddenly becoming ill. You can read more about John's case and treatment in Valmaggia and colleagues (2008).

These cases, which describe real people, give some indication of just how profoundly lives can be derailed because of mental disorders. It is hard to read about difficulties such as these without feeling compassion for the people who are struggling. Still, in addition to compassion, clinicians and researchers who want to help people like Monique and John must have other attributes and skills. If we are to understand mental disorders, we must learn to ask the kinds of questions that will enable us to help the patients and families who have mental disorders. These questions are at the very heart of a research-based approach that looks to use scientific inquiry and careful observation to understand abnormal psychology.

Asking questions is an important aspect of being a psychologist. Psychology is a fascinating field, and abnormal psychology is one of the most interesting areas of psychology (although we are undoubtedly biased). Psychologists are trained to ask questions and to conduct research. Though not all people who are trained in abnormal psychology (this field is sometimes called psychopathology) conduct research, they still rely heavily on their scientific skills and ability both to ask questions and to put information together in coherent and logical ways. For example, when a clinician first sees a new client or patient, he or she asks many questions to try and understand the issues or problems related to that person. The clinician will also rely on current research to

choose the most effective treatment. The best treatments of 20, 10, or even 5 years ago are not invariably the best treatments of today. Knowledge accumulates and advances are made. And research is the engine that drives all of these developments.

In this chapter, we will outline the field of abnormal psychology and the varied training and activities of the people who work within its demands. First we describe the ways in which abnormal behavior is defined and classified so that researchers and mental health professionals can communicate with each other about the people they see. Some of the issues here are probably more complex and controversial than you might expect. We also outline basic information about the extent of behavioral abnormalities in the population at large.

You will notice that a large section of this chapter is devoted to research. We make every effort to convey how abnormal behavior is studied. Research is at the heart of progress and knowledge in abnormal psychology. The more you know and understand about how research is conducted, the more educated and aware you will be about what research findings do and do not mean.

## What Do We Mean by Abnormality?

It may come as a surprise to you that there is still no universal agreement about what is meant by *abnormality* or *disorder*. This is not to say we do not have definitions; we do. However, a truly satisfactory definition will probably always remain elusive (Lilienfeld & Landfield, 2008; Stein et al., 2010) even though there is a great deal of general agreement about which conditions are disorders and which are not (Spitzer, 1999).

Why does the definition of a mental disorder present so many challenges? A major problem is that there is no one behavior that makes someone abnormal. However, there are some clear elements or indicators of abnormality (Lilienfeld & Marino, 1999; Stein et al., 2010). No single indicator is sufficient in and of itself to define or determine abnormality. Nonetheless, the more that someone has difficulties in the following areas, the more likely he or she is to have some form of mental disorder.

1. **Suffering:** If people suffer or experience psychological pain we are inclined to consider this as indicative of abnormality. Depressed people clearly suffer, as do people with anxiety disorders. But what of the patient who is manic and whose mood is one of elation? He or she may not be suffering. In fact, many such patients dislike taking medications because they do not want to lose their manic "highs." You may have a test tomorrow and be suffering with worry. But we would hardly label your suffering abnormal. Although suffering is an element of abnormality in many cases, it is neither a sufficient condition (all that is needed) nor even a necessary condition (a feature that all cases of abnormality must show) for us to consider something as abnormal.
2. **Maladaptiveness:** Maladaptive behavior is often an indicator of abnormality. The person with anorexia may restrict her intake of food to the point where she becomes so emaciated

that she needs to be hospitalized. The person with depression may withdraw from friends and family and may be unable to work for weeks or months. Maladaptive behavior interferes with our well-being and with our ability to enjoy our work and our relationships. However, not all disorders involve maladaptive behavior. Consider the con artist and the contract killer, both of whom have antisocial personality disorder. The first may be able glibly to talk people out of their life savings, the second to take someone's life in return for payment. Is this behavior maladaptive? Not for them, because it is the way in which they make their respective livings. We consider them abnormal, however, because their behavior is maladaptive for and toward society.

3. ***Statistical Deviancy:*** The word *abnormal* literally means "away from the normal." But simply considering statistically rare behavior to be abnormal does not provide us with a solution to our problem of defining abnormality. Genius is statistically rare, as is perfect pitch. However, we do not consider people with such uncommon talents to be abnormal in any way. Also, just because something is statistically common doesn't make it normal. The common cold is certainly very common, but it is regarded as an illness nonetheless.

On the other hand, intellectual disability (which is statistically rare and represents a deviation from normal) is considered to reflect abnormality. This tells us that in defining abnormality we make value judgments. If something is statistically rare and undesirable (as is severely diminished intellectual functioning), we are more likely to consider it abnormal than something that is statistically rare and highly desirable (such as genius) or something that is undesirable but statistically common (such as rudeness).

4. ***Violation of the Standards of Society:*** All cultures have rules. Some of these are formalized as laws. Others form the norms and moral standards that we are taught to follow. Although

many social rules are arbitrary to some extent, when people fail to follow the conventional social and moral rules of their cultural group we may consider their behavior abnormal. For example, driving a car or watching television would be considered highly abnormal for the Amish of Pennsylvania. However, both of these activities reflect normal everyday behavior for most other Pennsylvania residents.

Of course, much depends on the magnitude of the violation and on how commonly the rule is violated by others. As illustrated in the example above, a behavior is most likely to be viewed as abnormal when it violates the standards of society and is statistically deviant or rare. In contrast, most of us have parked illegally at some point. This failure to follow the rules is so statistically common that we tend not to think of it as abnormal. Yet when a mother drowns her children there is instant recognition that this is abnormal behavior.

5. ***Social Discomfort:*** When someone violates a social rule, those around him or her may experience a sense of discomfort or unease. Imagine that you are sitting in an almost empty movie theater. There are rows and rows of unoccupied seats. Then someone comes in and sits down right next to you. How do you feel? In a similar vein, how do you feel when someone you met only 4 minutes ago begins to chat about her suicide attempt? Unless you are a therapist working in a crisis intervention center, you would probably consider this an example of abnormal behavior.

6. ***Irrationality and Unpredictability:*** As we have already noted, we expect people to behave in certain ways. Although a little unconventionality may add some spice to life, there is a point at which we are likely to consider a given unorthodox behavior abnormal. If a person sitting next to you suddenly began to scream and yell obscenities at nothing, you would probably regard that behavior as abnormal. It would be unpredictable, and it would make no sense to you. The disordered speech and the disorganized behavior of patients with schizophrenia are often irrational. Such behaviors are also a hallmark of the manic phases of bipolar disorder. Perhaps the most important factor, however, is our evaluation of whether the person can control his or her behavior. Few of us would consider a roommate who began to recite speeches from King Lear to be abnormal if we knew that he was playing Lear in the next campus Shakespeare production—or even if he was a dramatic person given to extravagant outbursts. On the other hand, if we discovered our roommate lying on the floor, flailing wildly, and reciting Shakespeare, we might consider calling for assistance if this was entirely out of character and we knew of no reason why he should be behaving in such a manner.

7. ***Dangerousness:*** It seems quite reasonable to think that someone who is a danger to him- or herself or to another person must be psychologically abnormal. Indeed, therapists are required to hospitalize suicidal clients or contact the police (as well as the person who is the target of the threat) if they have a client who makes an explicit threat to harm another person.

As with most accomplished athletes, Venus and Serena Williams' physical ability is abnormal in a literal and statistical sense. Their behavior, however, would not be labeled as being abnormal by psychologists. Why not?

How important is dangerousness to the definition of mental illness? If we are a risk to ourselves or to others, does this mean we are mentally ill?

But, as with all of the other elements of abnormality, if we rely only on dangerousness as our sole feature of abnormality, we will run into problems. Is a soldier in combat mentally ill? What about someone who is an extremely bad driver? Both of these people may be a danger to others. Yet we would not consider them to be mentally ill. Why not? And why is someone who engages in extreme sports or who has a dangerous hobby (such as free diving, race car driving, or keeping poisonous snakes as pets) not immediately regarded as mentally ill? Just because we may be a danger to ourselves or to others does not mean we are mentally ill. Conversely, we cannot assume that someone diagnosed with a mental disorder must be dangerous. Although mentally ill people do commit serious crimes, serious crimes are also committed every day by people who have no signs of mental disorder. Indeed, research suggests that in people with mental illness, dangerousness is more the exception than it is the rule (Corrigan & Watson, 2005).

One final point bears repeating. Decisions about abnormal behavior always involve social judgments and are based on the values and expectations of society at large. This means that culture plays a role in determining what is and is not abnormal. For example, in the United States, people do not believe that it is acceptable to murder a woman who has a premarital or an extramarital relationship. However, *karo-kari* (a form of honor killing

Tattoos, which were once regarded as highly deviant, are now quite commonplace and considered fashionable by many.

where a woman is murdered by a male relative because she is considered to have brought disgrace onto her family) is considered justifiable by many people in Pakistan (Patel & Gadit, 2008).

In addition, because society is constantly shifting and becoming more or less tolerant of certain behaviors, what is considered abnormal or deviant in one decade may not be considered abnormal or deviant a decade or two later. At one time, homosexuality was classified as a mental disorder. But this is no longer the case. A generation ago, pierced noses and navels were regarded as highly deviant and prompted questions about a person's mental health. Now, however, such adornments are commonplace, considered fashionable by many, and attract little attention. What other behaviors can you think of that are now considered normal but were regarded as deviant in the past?

As you think about these issues, consider the person described in *The World Around Us* box on page 6. Is he a courageous man of profound moral commitment? Or is his behavior abnormal and indicative of a mental disorder? Do others share your view about him?

### The DSM-5 and the Definition of Mental Disorder

In the United States, the accepted standard for defining various types of mental disorders is the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders*. This manual, commonly referred to as the *DSM*, is revised and updated from time to time. The current version, called *DSM-5*, was published in 2013. Its revision has been a topic of much debate and controversy. In the box on page 7 we explain more about the *DSM* and discuss why a revision was necessary.

## Extreme Generosity or Pathological Behavior?

Zell Kravinsky was a brilliant student who grew up in a working-class neighborhood in Philadelphia. He won prizes at school, and at the age of 12, he began investing in the stock market. Despite his abilities, his Russian immigrant parents were, in the words of a family friend, "steadfast in denying him any praise." Kravinsky eventually completed two Ph.D. degrees and indulged his growing interest in real estate. By the time he was 45 years old, he was married with children. His assets amounted to almost \$45 million.

Although Kravinsky had a talent for making money, he found it difficult to spend it. He drove an old car, did not give his children pocket money, and lived with his family in a modest home. As his fortune grew, however, he began to talk to his friends about his plans to give all of his assets to charity. His philanthropy began in earnest when he and his wife gave two gifts, totaling \$6.2 million, to the Centers for Disease Control Foundation. They also donated an apartment building to a school for the disabled in Philadelphia. The following year the Kravinskys gave real estate gifts worth approximately \$30 million to Ohio State University.

Kravinsky's motivation for his donations was to help others. According to one of his friends, "He gave away the money because he had it and there were people who needed it. But it changed his way of looking at himself. He decided the purpose of his life was to give away things." After he had put some money aside in trust for his wife and his children, Kravinsky's personal assets were reduced to a house (on which he had a substantial mortgage), two minivans, and around \$80,000 in stocks and cash. He had essentially given away his entire fortune.

Kravinsky's donations did not end when his financial assets became depleted. He began to be preoccupied with the idea of nondirected organ donations, in which an altruistic person gives an organ to a total stranger. When he learned that he could live quite normally with only one kidney, Kravinsky decided that the personal costs of giving away one of his kidneys were minimal compared to the benefits received by the kidney recipient. His wife, however, did not share his view. Although she had consented to bequeathing substantial sums of money to worthwhile charities, when it came to her husband offering his kidney, she could not support him.

For Kravinsky, however, the burden of refusing to help alleviate the suffering of someone in need was almost unbearable, even if it meant sacrificing his very own organs. He called the Albert Einstein Medical Center and spoke to a transplant coordinator. He met with a surgeon and then with a psychiatrist. Kravinsky told the psychiatrist that his wife did not support his desire to donate one of his kidneys. When the psychiatrist told him that he was

Is Zell Kravinsky's behavior abnormal, or is he a man with profound moral conviction and courage?

doing something he did not have to do, Kravinsky's response was that he did need to make this sacrifice: "You're missing the whole point. It's as much a necessity as food, water, and air."

Three months later, Kravinsky left his home in the early hours of the morning, drove to the hospital, and donated his right kidney. He informed his wife after the surgery was over. In spite of the turmoil that his kidney donation created within his family, Kravinsky's mind turned back to philanthropy almost immediately. "I lay there in the hospital, and I thought about all my other good organs. When I do something good, I feel that I can do more. I burn to do more. It's a heady feeling." By the time he was discharged, he was wondering about giving away his one remaining kidney.

After the operation, Kravinsky experienced a loss of direction. He had come to view his life as a continuing donation. However, now that his financial assets and his kidney were gone, what could he provide to the less fortunate? Sometimes he imagines offering his entire body for donation. "My organs could save several people if I gave my whole body away." He acknowledges that he feels unable to hurt his family through the sacrifice of his life.

Several years after the kidney donation, Kravinsky still remains committed to giving away as much as possible. However, his actions have caused a tremendous strain in his marriage. In an effort to maintain a harmonious relationship with his wife, he is now involved in real estate and has recently bought his family a larger home. (Taken from Parker, 2004.)

Within *DSM-5*, a mental disorder is defined as a syndrome that is present in an individual and that involves clinically significant disturbance in behavior, emotion regulation, or cognitive functioning. These disturbances are thought to reflect a dysfunction in biological, psychological, or developmental processes that are necessary for mental functioning. *DSM-5* also recognizes that mental disorders are usually associated with significant distress or disability in key areas of functioning such as social, occupational or other activities. Predictable or culturally approved responses to common stressors or losses (such as death of a loved one) are excluded. It is also important that this dysfunctional pattern of behavior not stem from social deviance or conflicts that the person has with society as a whole.

This new *DSM-5* definition of mental illness was based on input from various *DSM-5* workgroups as well as other sources (Broome & Bortolotti, 2010; First & Wakefield, 2010; Stein et al., 2010). Although this definition will still not satisfy everyone, it brings us ever closer to a good working description. Keep in mind that any definition of abnormality or mental disorder must be somewhat arbitrary. Rather than thinking of the *DSM* as a finished product, it should always be regarded as a work in progress and regular updates and modifications are to be expected. Although earlier versions of the *DSM* used Roman numerals to refer to each specific edition (e.g., *DSM-IV*), Arabic numerals are now being used instead of Roman numerals (5 versus V) to facilitate updating (e.g., *DSM-5.1*, *DSM-5.2*) in the future.

## Why Do We Need to Classify Mental Disorders?

If defining abnormality is so contentious and so difficult, why do we try to do it? One simple reason is that most sciences rely on classification (e.g., the periodic table in chemistry and the classification of living organisms into kingdoms, phyla, classes, and so on in biology). At the most fundamental level, classification systems provide us with a **nomenclature** (a naming system) and enable us to *structure information* in a more helpful manner.

Organizing information within a classification system also allows us to study the different disorders that we classify and therefore to learn more about not only what causes them but also how they might best be treated. For example, thinking back to the cases you read about, Monique has alcohol and drug use disorders, and John has schizophrenia. Knowing what disorder each of them has is clearly very helpful, as John's treatment would likely not work for Monique.

A final effect of classification system usage is somewhat more mundane. As others have pointed out, the classification of mental disorders has social and political implications (see Blashfield & Livesley, 1999; Kirk & Kutchins, 1992). Simply put, defining the domain of what is considered to be pathological establishes the range of problems that the mental health profession can address. As a consequence, on a purely pragmatic level, it furthermore delineates which types of psychological difficulties warrant insurance reimbursement and the extent of such reimbursement.

## THINKING CRITICALLY about *DSM-5*

### What Is the *DSM* and Why Was It Revised?

The *Diagnostic and Statistical Manual of Mental Disorders* (*DSM*) provides all the information necessary (descriptions, lists of symptoms) to diagnose mental disorders. As such, it provides clinicians with specific diagnostic criteria for each disorder. This creates a common language so that a specific diagnosis means the same thing to one clinician as it does to another. This also helps ensure diagnostic accuracy and consistency (reliability). *DSM* is also important for research. If patients could not be diagnosed reliably it would be impossible to compare different treatments for patients with similar conditions. Although the *DSM* does not include information about treatment, clinicians need to have an accurate diagnosis in order to select the most appropriate treatment for their patients.

Since *DSM-1* was first published in 1952, the *DSM* has been revised from time to time. Revisions are important because they allow new scientific developments to be incorporated into how we think about mental disorders. The revision process for *DSM-5*

The logo for DSM-5, featuring the text "DSM-5" in white on a blue-to-yellow gradient background.

had the goals of maintaining continuity with the previous edition (*DSM-IV*) as well as being guided by new research findings. But another guiding principle was that no constraints should be placed on the level of change that could be made. If this strikes you as a little contradictory, you are correct. Striking the right balance between change and continuity presented considerable challenges. It also created a great deal of controversy. As part of the revision process, experts in specific disorders were invited to join special *DSM-5* work groups and make specific recommendations for change. In some cases, the debates were so heated that people resigned from their work groups! Now that *DSM-5* is here, not everyone is happy with some of the changes that have been made. On the other hand, many of the revisions that have been made make a lot of sense. In the chapters that follow we highlight key changes in *DSM-5*. We also try to help you think critically about the reasons behind the specific modifications that were proposed and understand why they were accepted.

## What Are the Disadvantages of Classification?

Of course, there are a number of disadvantages in the usage of a discrete classification system. Classification, by its very nature, provides information in a shorthand form. However, using any form of shorthand inevitably leads to a *loss of information*. If we know the specific history, personality traits, idiosyncrasies, and familial relations of a person with a particular type of disorder (e.g., from reading a case summary), we naturally have much more information than if we were simply told the individual's diagnosis (e.g., schizophrenia). In other words, as we simplify through classification, we inevitably lose an array of personal details about the actual person who has the disorder.

Moreover, although things are improving, there can still be some **stigma** (or disgrace) associated with having a psychiatric diagnosis. Even today, people are generally far more comfortable disclosing that they have a physical illness such as diabetes than they are in admitting to any mental disorder. This is in part due to the fear (real or imagined) that speaking candidly about having a psychological disorder will result in unwanted social or occupational consequences or frank discrimination. Be honest. Have you ever described someone as "nuts," "crazy," or "a psycho"? Now think of the hurt that people with mental disorders experience when they hear such words. In a recent study, 96 percent of patients with schizophrenia reported that stigma was a routine part of their lives (Jenkins & Carpenter-Song, 2008). In spite of the large amount of information that is now available about mental health issues, the level of knowledge about mental illness (sometimes referred to as mental health literacy) is often very poor (Thornicroft et al., 2007).

Related to stigma is the problem of **stereotyping**. Stereotypes are automatic beliefs concerning other people that are based on minimal (often trivial) information (e.g., people who wear glasses are more intelligent; New Yorkers are rude; everyone in the South has a gun). Because we may have heard about certain behaviors that can accompany mental disorders, we may automatically and incorrectly infer that these behaviors will also be present in any person we meet who has a psychiatric diagnosis. This is reflected in the comment, "People like you don't go back to work," in the case example of James McNulty.

→ **James McNulty** I have lived with bipolar disorder for more than 35 years—all of my adult life. The first 15 years were relatively conventional, at least on the surface. I graduated from an Ivy League university, started my own business, and began a career in local politics. I was married, the father of two sons. I experienced mood swings during these years, and as I got older the swings worsened. Eventually, I became so ill that I was unable to work, my marriage ended, I lost my business, and I became homeless.

At this point I had my most powerful experience with stigma. I was 38 years old. I had recently been discharged after a psychiatric hospitalization for a suicide attempt, I had no place to live, my savings were exhausted, and my only possession was

a 4-year-old car. I contacted the mental health authorities in the state where I then lived and asked for assistance in dealing with my mental illness. I was told that to qualify for assistance I would need to sell my car and spend down the proceeds. I asked how I was supposed to get to work when I recovered enough to find a job. I was told, "Don't worry about going back to work. People like you don't go back to work." (McNulty, 2004)

---

Take a moment to consider honestly your own attitudes toward people with mental disorders. What assumptions do you tend to make? Do you view people with mental illness as less competent, more irresponsible, more dangerous, and more unpredictable? Research has shown that such attitudes are not uncommon (see A. C. Watson et al., 2004). Can you recall movies, novels, or advertisements that maintain such stereotypes? What are some ways in which you can challenge the false assumptions that are so common in the media? Do you think reality TV shows such as *Hoarders*, *Obsessed*, or *My Strange Addiction* have a helpful or harmful impact on societal attitudes?

Finally, stigma can be perpetuated by the problem of **labeling**. A person's self-concept may be directly affected by being given a diagnosis of schizophrenia, depression, or some other form of mental illness. How might you react if you were told something like this? Furthermore, once a group of symptoms is given a name and identified by means of a diagnosis, this diagnostic label can be hard to shake even if the person later makes a full recovery.

It is important to keep in mind, however, that diagnostic classification systems do not classify people. Rather, *they classify the disorders that people have*. When we note that someone has an illness, we should take care not to define him or her by that illness. Respectful and appropriate language should instead be used. At one time, it was quite common for mental health professionals to describe a given patient as "a schizophrenic" or "a manic-depressive." Now, however, it is widely acknowledged that it is more accurate (not to mention more considerate) to say, "a person with schizophrenia," or "a person with manic depression." Simply put, the person is not the diagnosis.

## How Can We Reduce Prejudicial Attitudes Toward the Mentally Ill?

For a long time, it was thought that educating people that mental illnesses were "real" brain disorders might be the solution. Sadly, however, this does not seem to be the case. Although there have been impressive increases in the proportion of people who now understand that mental disorders have neurobiological causes, this increased awareness has not resulted in decreases in stigma. In a recent study, Pescosolido and colleagues (2010) asked people in the community to read a vignette (brief description) about a person who showed symptoms of mental illness. Some people read a vignette about

a person who had schizophrenia. Others read a vignette about someone with clinical depression or alcohol dependence. Importantly, no diagnostic labels were used to describe these people. The vignettes simply provided descriptive information. Nonetheless, the majority of the people who were surveyed in this study expressed an unwillingness to work with the person described in the vignette. They also did not want to have to socialize with them and did not want them to marry into their family. Moreover, the level of rejection that was shown was just as high as it was in a similar survey that was done 10 years earlier. Over that same 10-year period, however, many more people embraced a neurobiological understanding about the causes of mental illness. So what this study tells us is that just because people understand that mental illness is caused by problems in the brain doesn't mean that they are any less prejudiced toward those with mental illness. This is a disappointing conclusion for everyone who hoped that more

scientific research into the biology of mental illness would lead to the elimination of stigma.

Stigma does seem to be reduced by having more contact with people in the stigmatized group (Couture & Penn, 2003). However, there may be barriers to this. Simply imagining interacting with a person who has a mental disorder can lead to distress and also to unpleasant physical reactions. In an interesting study, Graves and colleagues (2005) asked college students enrolled in a psychology course to imagine interacting with a person whose image was shown to them on a slide. As the slide was being presented, subjects were given some scripted biographical information that described the person. In some scripts, the target person was described as having been diagnosed with schizophrenia, although it was also mentioned that he or she was "doing much better now." In other trials, the biographical description made no mention of any mental illness when the person on the slide was being described.

## the WORLD around us

### Mad, Sick, Head Nuh Good: Mental Illness and Stigma in Jamaica

Evidence suggests that negative reactions to the mentally ill may be a fairly widespread phenomenon. Using focus groups, Arthur and colleagues (2010) asked community residents in Jamaica about the concept of stigma. Some participants came from rural communities, others from more urban areas. Regardless of their gender, level of education, or where they lived, most participants described highly prejudicial attitudes toward the mentally ill. One middle-class male participant said, "We treat them as in a sense second class citizens, we stay far away from them, ostracize them, we just treat them bad" (see Arthur et al., 2010, p. 263). Fear of the mentally ill was also commonly expressed. A rural-dwelling middle-class man described a specific situation in the following way, "There is a mad lady on the road named [. . .]. Even the police are afraid of her because she throws stones at them. She is very, very terrible" (p. 261). Moreover, even when more kindly attitudes were expressed, fear was still a common response. One person put it simply, "You are fearful even though you may be sympathetic" (p. 262).

The Jamaicans in this study also made a distinction between mental illness (a term used to denote less severe conditions) and madness, which was used to describe more severe problems. Madness was invariably regarded as being a permanent condition ("once yuh mad yuh mad" or "once yuh gone yuh gone"). Moreover, homelessness was almost always taken to indicate madness. In short, the results of this study suggest that stereotyping, labeling, and stigma toward the mentally ill are not restricted to industrialized countries. Although we might wish that it were otherwise, prejudicial attitudes are common.

This highlights the need for antistigma campaigns in Jamaica, as well as everywhere else in the world.

Are attitudes toward the mentally ill in Jamaica more benign than they are in more industrialized countries?

Students who took part in the study reported more distress and had more muscle tension in their brows when they imagined interacting with a person with schizophrenia than when they imagined interacting with a person who did not have schizophrenia. Heart rate changes also suggested they were experiencing the imagined interactions with the patients as being more unpleasant than the interactions with the nonpatients. Finally, research participants who had more psychophysiological reactivity to the slides of the patients reported higher levels of stigma toward these patients. These findings suggest that people may tend to avoid those with mental illness because the psychophysiological arousal these encounters create is experienced as unpleasant.

### How Does Culture Affect What Is Considered Abnormal?

Just as we must consider changing societal values and expectations in defining abnormality, so too must we consider differences across cultures. In fact, this is explicitly acknowledged in the *DSM-5* definition of *disorder*. Within a given culture, there exist many shared beliefs and behaviors that are widely accepted and that may constitute one or more customary practices. For instance, many people in Christian countries believe that the

number 13 is unlucky. The origins of this may be linked to the Last Supper, at which 13 people were present. Many of us try to be especially cautious on Friday the 13th. Some hotels and apartment buildings avoid having a 13th floor altogether. Similarly, there is frequently no bed numbered 13 in hospital wards.

The Japanese, in contrast, are not worried about the number 13. Rather, they attempt to avoid the number 4. This is because in Japanese the sound of the word for “four” is similar to the sound of the word for “death” (see Tseng, 2001, pp. 105–6).

There is also considerable variation in the way different cultures describe psychological distress. For example, there is no word for “depressed” in the languages of certain Native Americans, Alaska Natives, and Southeast Asian cultures (Manson, 1995). Of course, this does not mean that members from such cultural groups do not experience clinically significant depression. As the accompanying case illustrates, however, the way some disorders present themselves may depend on culturally sanctioned ways of articulating distress.

**→ Depression in a Native American Elder** JGH is a 71-year-old member of a Southwestern tribe who has been brought to a local Indian Health Service hospital by one of his granddaughters and is seen in the general medical outpatient clinic for multiple complaints. Most of Mr. GH's complaints involve nonlocalized pain. When asked to point to where he hurts, Mr. GH indicates his chest, then his abdomen, his knees, and finally moves his hands “all over.” Barely whispering, he mentions a phrase in his native language that translates as “whole body sickness.” His granddaughter notes that he “has not been himself” recently. Specifically, Mr. GH, during the past 3 or 4 months, has stopped attending or participating in many events previously important to him and central to his role in a large extended family and clan. He is reluctant to discuss this change in behavior as well as his feelings. When questioned more directly, Mr. GH acknowledges that he has had difficulty falling asleep, sleeps intermittently through the night, and almost always awakens at dawn's first light. He admits that he has not felt like eating in recent months but denies weight loss, although his clothes hang loosely in many folds. Trouble concentrating and remembering are eventually disclosed as well. Asked why he has not participated in family and clan events in the last several months, Mr. GH describes himself as “too tired and full of pain” and “afraid of disappointing people.” Further pressing by the clinician is met with silence. Suddenly the patient states, “You know, my sheep haven't been doing well lately. Their coats are ragged; they're thinner. They just wander aimlessly; even the ewes don't seem to care about the little ones.” Physical examination and laboratory tests are normal. Mr. GH continues to take two tablets of acetaminophen daily for mild arthritic pain. Although he describes himself as a “recovering alcoholic,” Mr. GH reports not having consumed alcohol during the last 23 years. He denies any prior episodes of depression or other psychiatric problems. (Manson, 1995, p. 488)

There is no word for “depressed” in the languages of certain Native American tribes. Members of these communities tend to describe their symptoms of depression in physical rather than emotional terms.

Some African tribe members inflict painful and permanent scars (a process called scarification) on their faces and torsos in an effort to beautify themselves. Such a practice might be viewed as abnormal by Western European cultures, yet it is quite common among African tribes.

As is apparent in the case of JGH, culture can shape the clinical presentation of disorders like depression, which are present across cultures around the world (see Draguns & Tanaka-Matsumi, 2003). In China, for instance, individuals with depression frequently focus on physical concerns (fatigue, dizziness, headaches) rather than verbalizing their feelings of melancholy or hopelessness (Kleinman, 1986; Parker et al., 2001). This focus on physical pain rather than emotional pain is also noteworthy in Mr. GH's case.

Despite progressively increasing cultural awareness, we still know relatively little concerning cultural interpretation and expression of abnormal psychology (Arrindell, 2003). The vast majority of the psychiatric literature originates from Euro-American countries—that is, Western Europe, North America, and Australia/New Zealand (Patel & Kim, 2007; Patel & Sumathipala, 2001). To exacerbate this underrepresentation, research published in languages other than English tends to be disregarded (Draguns, 2001).

### Culture-Specific Disorders

Prejudice toward the mentally ill seems to be found worldwide (see The World Around Us box on p. 9). However, some types of psychopathology appear to be highly culture-specific: They are found only in certain areas of the world and seem to be highly linked to culturally bound concerns. A case in point is *taijin kyofusho*. This syndrome, which is an anxiety disorder, is quite prevalent in Japan. It involves a marked fear that one's body, body parts, or body functions may offend, embarrass, or otherwise make others feel uncomfortable. Often, people with this disorder are afraid of blushing or upsetting others by their gaze, facial expression, or body odor (Levine & Gaw, 1995).

Another culturally rooted expression of distress, found in Latino and Latina individuals, especially those from the Caribbean, is *ataque de nervios* (Lizardi et al., 2009; Lopez & Guarnaccia, 2005). This is a clinical syndrome that does not seem to correspond to any specific diagnosis within the *DSM*. The symptoms of an *ataque de nervios*, which is often triggered by a stressful event such as divorce or bereavement, include crying, trembling, uncontrollable screaming, and a general feeling of loss of control. Sometimes the person may become physically or verbally aggressive. Alternately, the person may faint or experience a seizure-like fit. Once the *ataque* is over, the person may promptly resume his or her normal manner, with little or no memory of the incident.

As noted earlier, abnormal behavior is behavior that deviates from the norms of the society in which the person lives. Experiences such as hearing the voice of a dead relative might be regarded as normative in one culture (e.g., in many Native American tribes) yet abnormal in another cultural milieu. Nonetheless, certain unconventional actions and behaviors are almost universally considered to be the product of mental disorder.

Many years ago, the anthropologist Jane Murphy (1976) studied abnormal behavior by the Yoruba of Africa and the Yupik-speaking Eskimos living on an island in the Bering Sea. Both societies had words that were used to denote abnormality or "craziness." In addition, the clusters of behaviors that were considered to reflect abnormality in these cultures were behaviors that most of us would also regard as abnormal. These included hearing voices, laughing at nothing, defecating in public, drinking urine, and believing things that no one else believes. Why do you think these behaviors are universally considered to be abnormal?

Some disorders are highly culture specific. For example, *taijin kyofusho* is a disorder that is prevalent in Japan. It is characterized by the fear that one may upset others by one's gaze, facial expression, or body odor.

## in review

- What is stigma? How common is it? What are the challenges in reducing stigma toward the mentally ill?
- In what ways can culture shape the clinical presentation of mental disorders?

## How Common Are Mental Disorders?

How many and what sort of people have diagnosable psychological disorders today? This is a significant question for a number of reasons. First, such information is essential when planning and establishing mental health services. Mental health planners require a precise understanding of the nature and extent of the psychological difficulties within a given area, state, or country because they are responsible for determining how resources such as funding of research projects or services provided by community mental health centers may be most effectively allocated. It would obviously be imprudent to have a treatment center filled with clinicians skilled in the treatment of anorexia nervosa (a very severe but rare clinical problem) if there were few clinicians skilled in treating anxiety or depression, which are much more prevalent disorders.

Second, estimates of the frequency of mental disorders in different groups of people may provide valuable clues as to the causes of these disorders. For example, data from the United Kingdom have shown that schizophrenia is about three times more likely to develop in ethnic minorities than in the white population (Kirkbridge et al., 2006). Rates of schizophrenia in southeast London are also high relative to other parts of the country. This is prompting researchers to explore why this might be. Possible factors may be social class and neighborhood deprivation, as well as diet or exposure to infections or environmental contaminants.

### Prevalence and Incidence

Before we can further discuss the impact of mental disorders upon society, we must clarify the way in which psychological problems are counted. **Epidemiology** is the study of the distribution of diseases, disorders, or health-related behaviors in a given population. Mental health epidemiology is the study of the distribution of mental disorders. A key component of an epidemiological survey is determining the frequencies of mental disorders. There are several ways of doing this. The term **prevalence** refers to the number of active cases in a population during any given period of time. Prevalence figures are typically expressed as percentages (i.e., the percentage of the population that has the disorder). Furthermore, there are several different types of prevalence estimates that can be made.

**Point prevalence** refers to the estimated proportion of actual, active cases of the disorder in a given population at a

given point in time. For example, if we were to conduct a study and count the number of people who have major depressive disorder (i.e., clinical depression) on January 1st of next year, this would provide us with a point prevalence estimate of active cases of depression. A person who experienced depression during the months of November and December but who managed to recover by January 1st would not be included in our point prevalence calculation. The same is true of someone whose depression did not begin until January 2nd.

If, on the other hand, we wanted to calculate a **1-year prevalence** figure, we would count everyone who experienced depression at any point in time throughout the entire year. As you might imagine, this prevalence figure would be higher than the point prevalence figure because it would cover a much longer time. It would moreover include those people who had recovered before the point prevalence assessment as well as those whose disorders did not begin until after the point prevalence estimate was made.

Finally, we may also wish to obtain an estimate of the number of people who have had a particular disorder at any time in their lives (even if they are now recovered). This would provide us with a **lifetime prevalence** estimate. Because they extend over an entire lifetime and include both currently ill and recovered individuals, lifetime prevalence estimates tend to be higher than other kinds of prevalence estimates.

An additional term with which you should be familiar is **incidence**. This refers to the number of new cases that occur over a given period of time (typically 1 year). Incidence figures tend to be lower than prevalence figures because they exclude preexisting cases. In other words, if we were assessing the 1-year incidence of schizophrenia, we would not count people whose schizophrenia began before our given starting date (even if they were still ill) because they are not “new” cases of schizophrenia. On the other hand, someone who was quite well previously but then developed schizophrenia during our 1-year window would be included in our incidence estimate.

### Prevalence Estimates for Mental Disorders

Now that you have an understanding of some basic terms, let's turn to the 1-year prevalence rates for several important disorders. Three major national mental health epidemiology studies, with direct and formal diagnostic assessment of participants, have been carried out in the United States. One, the Epidemiologic Catchment Area (ECA) study, focused on sampling citizens of five communities: Baltimore, New Haven, St. Louis, Durham (NC), and Los Angeles (Myers et al., 1984; Regier et al., 1988, 1993).

The second, the National Comorbidity Survey (NCS), was more extensive. It sampled the entire American population using a number of sophisticated methodological improvements (Kessler et al., 1994). A replication of the NCS (the NCS-R) was completed about a decade later (Kessler et al., 2004; Kessler,

**TABLE 1.1**  
**Prevalence of DSM-IV Disorders in Adults in the United States**

	1-Year (%)	Lifetime (%)
Any anxiety disorder	18.1	28.8
Any mood disorder	9.5	20.8
Any substance-abuse disorder	3.8	14.6
Any disorder	26.2	46.4

Sources: Kessler et al. (2005a, 2005c)

**TABLE 1.2**  
**Most Common Individual Mental Disorders in the United States**

Disorder	1-Year Prevalence (%)	Lifetime Prevalence (%)
Major depressive disorder	6.7	16.6
Alcohol abuse	3.1	13.2
Specific phobia	8.7	12.5
Social phobia	6.8	12.1
Conduct disorder	1.0	9.5

Sources: Kessler et al. (2005a, 2005c)

Berglund, Borges, et al., 2005a; Kessler & Merikangas, 2004). The most current 1-year and lifetime prevalence estimates of the *DSM-IV* mental disorders assessed from the NCS-R study are shown in Table 1.1.

Because *DSM-5* is so new, no lifetime prevalence data using this revised version of the *DSM* are yet available. However, the lifetime prevalence of having any *DSM-IV* disorder is 46.4 percent. This means that almost half of the Americans who were questioned had been affected by mental illness at some point in their lives (Kessler, Berglund, Demler, et al., 2005b). Although this figure may seem high, it may actually be an underestimate, as the NCS study did not assess for eating disorders, schizophrenia, or autism, for example. Neither did it include measures of most personality disorders. As you can see from Table 1.1, the most prevalent category of psychological disorders is anxiety disorders. The most common individual disorders are major depressive disorder, alcohol abuse, and specific phobias (e.g., fear of small animals, insects, flying, heights). Social phobias (e.g., fear of public speaking) are similarly very common (see Table 1.2).

Although lifetime rates of mental disorders appear to be quite high, it is important to remember that, in some cases, the duration of the disorder may be relatively brief (e.g., depression that lasts for a few weeks after the breakup of a romantic relationship). Furthermore, many people who meet criteria for a given disorder will not be seriously affected by it. For instance, in the NCS-R study, almost half (48%) of the people diagnosed with a specific phobia had disorders that were rated as mild in severity, and only 22 percent of phobias were regarded as severe (Kessler, Chiu, et al., 2005c). Meeting diagnostic criteria for a particular disorder and being seriously impaired by that disorder are not necessarily synonymous.

A final finding from the NCS-R study was the widespread occurrence of comorbidity among diagnosed disorders (Kessler, Chiu, et al., 2005c). **Comorbidity** is the term used to describe the presence of two or more disorders in the same person. Comorbidity is especially high in people who have severe forms of mental disorders. In the NCS-R study, half of the individuals with a disorder rated as serious on a scale of severity (mild, moderate, and serious) had two or more additional disorders. An

illustration of this would be a person who drinks excessively and who is simultaneously depressed and suffering from an anxiety disorder. In contrast, only 7 percent of the people who had a mild form of a disorder also had two or more other diagnosable conditions. What this indicates is that comorbidity is much more likely to occur in people who have the most serious forms of mental disorders. When the condition is mild, comorbidity is the exception rather than the rule.

## Treatment

Many treatments for psychological disorders are now available. These include medications as well as different forms of psychotherapy. Treatment is such an important topic that we discuss it

Disorders do not always occur in isolation. A person who abuses alcohol may also be depressed or pathologically anxious.

throughout the book in the various chapters on specific disorders. In addition, in Chapter 16 we discuss different approaches to treatment more broadly and describe different types of therapy in detail. However, it is important to emphasize that not all people with psychological disorders receive treatment. In some cases, people deny or minimize their suffering. Others try to cope on their own and may manage to recover without ever seeking aid from a mental health professional. Even when they recognize that they have a problem, it is typical for individuals to wait a long time before deciding to seek help. Half of individuals with depression delay seeking treatment for more than 6 to 8 years. For anxiety disorders, the delay ranges from 9 to 23 years (Wang, Berglund, et al., 2005)!

When people with mental disorders do seek help, they are often treated by their family physician rather than by a mental health specialist (Wang et al., 2005). It is also the case that the vast majority of mental health treatment is now administered on an outpatient (as opposed to an inpatient) basis (Narrow et al., 1993; O'Donnell et al., 2000). Outpatient treatment requires that a patient visit a mental health facility practitioner; however, the patient does not have to be admitted to the hospital or stay there overnight. A patient may attend a community mental health center, see a private therapist, or receive treatment through the outpatient department of a hospital.

Hospitalization and inpatient care are the preferred options for people who need more intensive treatment than can be provided on an outpatient basis. Various surveys indicate that admission to mental hospitals has decreased substantially over the past 45 years. The development of medications that control the symptoms of the most severe disorders is one reason for this change. Budget cuts have also forced many large state or county facilities to close. The limitations that insurance companies place on hospital admissions is another relevant factor here. If a hospital stay is not authorized by the insurance company, patients must seek treatment elsewhere.

Patients who need inpatient care are usually admitted to the psychiatric units of general hospitals (Narrow et al., 1993) or to private psychiatric hospitals specializing in particular mental disorders (Kiesler & Simpkins, 1993). Stays in inpatient facilities tend to be much shorter than they were in the past (see Case et al., 2007; Lay et al., 2007). Patients receive additional treatment on an outpatient basis. This trend away from the use of traditional hospitalization began several decades ago. It is referred to as deinstitutionalization and is discussed further in Chapter 2.

## Mental Health Professionals

When patients receive inpatient treatment, several different mental health professionals often work as a team to provide the necessary care. A psychiatrist may prescribe medications and monitor the patient for side effects. A clinical psychologist may provide individual therapy, meeting with the patient several times a week. A clinical social worker may help the patient resolve family problems, and a psychiatric nurse may check in

with the patient on a daily basis to provide support and help the patient cope better in the hospital environment. The intensity of treatment that is typical in a hospital setting is designed to help the patient get better as rapidly as possible.

Patients treated in outpatient settings may also work with a team of professionals. However, the number of mental health specialists involved is typically much smaller. In some cases a patient will receive all treatment from a psychiatrist, who will prescribe medication and also provide psychotherapy. Other patients will receive medications from a psychiatrist and see a psychologist or a clinical social worker for regular therapy sessions. In other cases, depending on the type and severity of the problem, a patient (*client* is the preferred term in some settings) may see a counseling psychologist, a psychoanalyst, or a counselor specialized in the treatment of drug and alcohol problems.

## Research Approaches in Abnormal Psychology

As is apparent from the NCS-R study, the lives of large numbers of people are affected by mental disorders. To learn all that we can about these conditions, we need to conduct research. In this way, we can study the characteristics or nature of disorders. Through research we can learn about the symptoms of the disorder, its prevalence, whether it tends to be either **acute** (short in duration) or **chronic** (long in duration), and the problems and deficits that often accompany it.

Research allows us to further understand the **etiology** (or causes) of disorders. Finally, we need research to provide the best care for the patients who are seeking assistance with their difficulties. All of the authors of this book are practicing clinicians. As such, we turn to the research literature to help us provide the most effective and up-to-date care for the patients whom we see.

Students new to the field of abnormal psychology often assume that all answers may be revealed through scrutinizing past case studies. However, when we study individual cases and derive inferences from them, we are as likely to develop errors in our thinking as we are to obtain knowledge. One such error is that we often attend only to data that confirm our view of how things are. For example, Dr. Smart might believe that drinking milk causes schizophrenia. When we ask Dr. Smart why he holds this view, he might say it is because every patient he has ever treated who has schizophrenia has drunk milk at some time in his or her life. Given that Dr. Smart has treated a lot of patients with schizophrenia and clearly has a great deal of experience with the disorder, we might be persuaded that he is right. Then along comes Dr. Notsofast.

Abnormal psychology research can be conducted in a variety of settings outside the research laboratory, including clinics, hospitals, schools, or prisons.

Dr. Notsofast decides to conduct a research study. He studies two groups of people: One group has schizophrenia; the other group does not have schizophrenia. Dr. Notsofast asks all of them about their milk-drinking habits. He finds that everyone has drunk milk at some point in his or her life and that there are no differences between the two groups with respect to their milk-drinking histories. As this simple example illustrates, research prevents us from being misled by natural errors in thinking. In short, research protects investigators from their own biases in perception and inference (Raulin & Lilienfeld, 2009).

Abnormal psychology research can take place in clinics, hospitals, schools, prisons, and even highly unstructured contexts such as naturalistic observations of the homeless on the street. It is not the setting that determines whether a given research project may be undertaken. As Kazdin aptly points out (1998b, p. x), "methodology is not merely a compilation of practices and procedures. Rather it is an approach toward problem solving, thinking, and acquiring knowledge." As such, research methodology (that is, the scientific processes and procedures we use to conduct research) is constantly evolving.

As new techniques become available (brain-imaging techniques and new statistical procedures, to name a few), methodology in turn evolves. In the sections that follow, we introduce some fundamental research concepts so that you may begin to think critically like a clinical scientist. For further help, in some chapters we use a Research Close-Up to draw your attention to some key terms that are central to the comprehension of psychological research.

## Sources of Information

### Case Studies

As humans, we often direct our attention to the people around us. If you were asked to describe your best friend, your father, or even the professor teaching your abnormal psychology class, you

would undoubtedly have plenty to say. As is the case in virtually all other sciences, the foundation of psychological knowledge stems from observation. Indeed, a large amount of early knowledge was distilled from case studies in which specific individuals were described in great detail.

Astute clinicians such as the German psychiatrist Emil Kraepelin (1856–1926) and the Swiss psychiatrist Eugen Bleuler (1857–1939) provided us with detailed accounts of patients whom a modern-day reader would easily recognize as having disorders such as schizophrenia and manic depression. Alois Alzheimer (1864–1915) depicted a patient with an unusual clinical picture that subsequently became known as Alzheimer's disease. Sigmund Freud (1856–1939), the founder of psychoanalysis, published multiple clinical cases describing what we now recognize as phobia (the case of "Little Hans") and obsessive-compulsive disorder ("the Rat Man"). Such portrayals make for fascinating reading, even today.

Much can be learned when skilled clinicians use the **case study** method. Still, the information presented in them is subject to **bias** because the writer of the case study selects what information to include and what information to omit. Another concern is that the material in a case study is often relevant only to the individual being described. This means that the conclusions of a case study have low **generalizability**—that is, they cannot be used to draw conclusions about other cases even when those cases involve people with a seemingly similar abnormality. When there is only one observer and one subject, and when the observations are made in a relatively uncontrolled context and are anecdotal and impressionistic in nature, the conclusions we can draw are very narrow and may be mistaken. Nonetheless, case studies are an excellent way to illustrate clinical material. They can also provide some limited support for a particular theory or provide some negative evidence that can challenge a prevailing idea or assumption. Importantly, case studies can be a valuable source of new ideas and serve as a stimulus for research, and they may provide insight into unusual clinical conditions that are too rare to be studied in a more systematic way.

### Self-Report Data

If we wish to study behavior in a more rigorous manner, how do we go about doing so? One approach is to collect **self-report data** from the people we wish to learn more about. This might involve having our research participants complete questionnaires of various types. Another way of collecting self-report data is from interviews. The researcher asks a series of questions and then records what the person says.

Asking people to report on their subjective experiences might appear to be an excellent way to collect information. However, as a research approach it has some limitations. Self-report data can sometimes be misleading. One problem is that people may not be very good reporters of their own subjective states or experiences. For example, when asked in an interview,

one child may report that he has 20 “best friends.” Yet, when we observe him, he may always be playing alone. Because people will occasionally lie, misinterpret the question, or desire to present themselves in a particularly favorable (or unfavorable) light, self-report data cannot always be regarded as highly accurate and truthful. This is something that anyone who has ever tried online dating knows only too well! And if you still need convincing, ask three people to tell you their weight. Then ask them to step on a scale. How likely is it that the weight they self-report will be the weight that appears when they step on the scale? What reasons do you think might explain the discrepancy?

## Observational Approaches

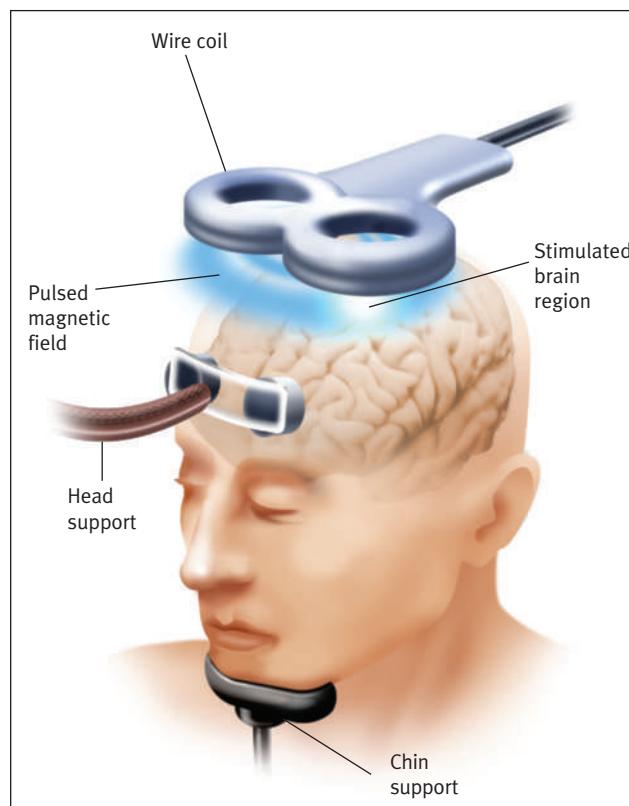

When we collect information in a way that does not involve asking people directly (self-report), we are using some form of observational approach. Exactly how we go about this depends on what it is we seek to understand. For example, if we are studying aggressive children, we may wish to have trained observers record the number of times children who are classified as being aggressive hit, bite, push, punch, or kick their playmates. This would involve **direct observation** of the children’s behavior.

We may also collect information about biological variables (such as heart rate) in our sample of aggressive children. Alternatively, we could collect information about stress hormones, such as cortisol, by asking the observed children to spit into a plastic container (because cortisol is found in saliva). We would then send the saliva samples to the lab for analysis. This, too, is a form of observational data; it tells us something that we want to know using a variable that is relevant to our interests.

Technology has advanced, and we are now developing methods to study behaviors, moods, and cognitions that have long been considered inaccessible. For example, we can now use brain-imaging techniques such as functional magnetic resonance imaging (fMRI) to study the working brain. We can study blood flow to various parts of the brain during memory tasks. We can even look at which brain areas influence imagination.

With other techniques such as transcranial magnetic stimulation (TMS; see Figure 1.1), which generates a magnetic field on the surface of the head, we can stimulate underlying brain tissue (for an overview, see Fitzgerald et al., 2002). This can be done painlessly and noninvasively while the person receiving the TMS sits in an armchair. Using TMS, we can even take a particular area of the brain “off-line” for a few seconds and measure the behavioral consequences. In short, we can now collect observational data that would have been impossible to obtain in the past.

In practice, much clinical research involves a mix of self-report and observational methods. Also, keep in mind that when we refer to observing behavior we mean much more than simply watching people. Observing behavior, in this context, refers to careful scrutiny of the conduct and manner of

**FIGURE 1.1**

Researchers use technology, such as transcranial magnetic stimulation (TMS), to study how the brain works. This TMS technique generates a magnetic field on the surface of the head through which underlying brain tissue is stimulated. Researchers can evaluate and measure behavioral consequences of this noninvasive and painless brain stimulation.

specific individuals (e.g., healthy people, people with depression, people with anxiety, people with schizophrenia). We may study social behavior in a sample of patients with depression by enlisting trained observers to record the frequency with which the patients smile or make eye contact. We may also ask the patients themselves to fill out self-report questionnaires that assess social skills. If we think that sociability in patients with depression may be related to (or correlated with) their severity of depression, we may further ask patients to complete self-report measures designed to assess that severity. We may even measure levels of certain substances in patients’ blood, urine, or cerebrospinal fluid (the clear fluid that bathes the brain and that can be obtained by performing a lumbar puncture). Finally, we could possibly study the depressed patients’ brains directly via brain-imaging approaches. These diverse sources of information would provide us with potentially valuable data, the basis of scientific inquiry.

## in review

- What are the strengths and limitations of case studies?
- Why is it desirable not to rely solely on self-report data as a source of information?

- What is the difference between self-report and observational data? What range of measures could be considered to reflect observational data?

## Forming and Testing Hypotheses

Research is all about asking questions. To make sense of behavior, researchers generate hypotheses. A **hypothesis** is an effort to explain, predict, or explore something. What distinguishes scientific hypotheses from the vague speculation that we all routinely engage in is that scientists attempt to test their hypotheses. In other words, they try to design research studies that will help them approach a fuller understanding of how and why things happen.

Anecdotal accounts such as case studies can be very valuable in helping us develop hypotheses, although case studies are not well suited for testing the hypotheses that they may have inspired. Other sources of hypotheses are unusual or unexpected research findings. One example is the higher-than-expected rate of suicide in women who have had cosmetic breast augmentation (Sarwer et al., 2007). Consider for a moment why this association might exist. Possible explanations might include higher rates of psychopathology in women who seek breast augmentation, unrealistic expectations about the positive effects that the surgery would have on their lives, postoperative complications that could lead to depressed mood, and other factors such as preoperative body image dissatisfaction.

Another observation in search of an explanation is the finding that, although men generally have lower rates of depression than women, this is not true of Jewish men. Why should Jewish men be more at risk for depression than non-Jewish men? One hypothesis is that there may be an interesting (and inverse) relationship between depression and alcohol use (Levav et al., 1997). Jewish men have lower rates of alcohol abuse and alcohol dependence than do non-Jewish men. Consistent with this idea, a study of members of Orthodox synagogues in London found no alcoholism and similar rates of depression in females and males (i.e., a 1:1 gender ratio instead of the typical 2:1 ratio; Loewenthal et al., 1995). Although much more remains to be uncovered, the hypothesis that higher rates of depression in Jewish men may be related to their lower rates of alcohol abuse appears to merit further study (see Loewenthal et al., 2003).

Hypotheses are vital because they frequently determine the therapeutic approaches used to treat a particular clinical problem. The ideas we have about what might be causing a client's difficulties will naturally shape the form of intervention we use when we provide treatment. For instance, suppose we are confronted with someone who washes his or her hands 60 to 100 times a day, causing serious injury to the skin and underlying tissues (this is an example of obsessive-compulsive disorder). If we believe that this behavior is a result of subtle problems in certain neural circuits, we may try to identify which circuits are dysfunctional in the hope of ultimately finding a means of correcting them (perhaps with medication).

Although men generally have lower rates of depression than women, the rate of depression for Jewish men and women is equal. Why would this be? A correlation between higher rates of depression and lower rates of alcohol abuse in Jewish men provides interesting ground for further study.

On the other hand, if we view the excessive hand washing as reflecting a symbolic cleansing of sinful and unacceptable thoughts, we may try to unearth and address the sources of the person's excessive guilt and concern with morality. Finally, if we regard the hand washing as merely the product of unfortunate conditioning or learning, we may devise a means to extinguish the problematic behavior. In other words, our working hypotheses regarding the causes of different disorders very much shape the approaches we use when we study and treat the disorders.

## Sampling and Generalization

We can occasionally glean instructive leads from careful scrutiny of a single case. However, this strategy rarely yields enough information to allow us to reach firm conclusions. Research in abnormal psychology is concerned with gaining enhanced understanding and, where possible, control of abnormal behavior (i.e., the ability to alter it in predictable ways). Edward, for instance, may accost women in supermarkets and try to lick their feet because his mother always gave him attention when, as a child, he tried on her shoes. In contrast, George may engage in the same behavior for an entirely different reason. We need to study a larger group of individuals with the same problem in order to discover which of our observations or hypotheses possess scientific credibility. The more people we study, the more confident we can be about our findings.

Whom should we include in our research study? In general, we want to study groups of individuals who have similar

abnormalities of behavior. If we wanted to study people with panic disorder, a first step would be to determine criteria such as those provided in the current *DSM* for identifying people affected with this clinical disorder. We would then need to find people who fit our criteria. Ideally, we would study everyone in the world who met our criteria because these people constitute our population of interest. This, of course, is impossible to do, so instead we would try to get a representative sample of people who are drawn from this underlying population. To do this, we would use a technique called **sampling**. What this means is that we would try to select people who are representative of the much larger group of individuals with panic disorder (in the same way that jury selection involves having a representative sample of eligible voters).

Ideally, we would like our smaller sample (our study group) to mirror the larger group (the underlying population) in all important ways (e.g., in severity and duration of disorder and in demographics such as age, gender, and marital status). If we could do everything perfectly, our research sample would be randomly selected from the larger population of people with panic disorder, which is tantamount to ensuring that every person in that population would have an equal chance of being included in our study. Such a procedure would automatically adjust for potential biases in sample selection. In practice, however, this does not happen, and researchers must simply do the best they can given real-world constraints (including the fact that some people don't wish to participate in a research study!).

Because finding research participants is not always easy, researchers sometimes use "samples of convenience" in their studies. This means that they study groups of people who are easily accessible to them and who are readily available. Have you noticed how much research is conducted using college students? Is this because college students are intrinsically fascinating people to study? Or are other factors in play here?

## Internal and External Validity

From a research perspective, the more representative our sample is, the better able we are to generalize (or extend the findings from our study) to the larger group. The extent to which we can generalize our findings beyond the study itself is called **external validity**. A research study that involves both males and females from all age groups, income levels, and education levels is more representative of the underlying population (and will have greater external validity) than research using only female college students, for example. In addition, when we study a group of people who all share a defining characteristic (e.g., a specific disorder), we may then be able to infer that additional commonalities that they share (such as a family history of depression or low levels of certain neurotransmitters) may be related to the disorder itself. Of course, this is based on the assumption that the characteristic in question is not widely shared by people who do not have the disorder.

Unlike external validity, which concerns the degree that research findings from a specific study can be generalized to other samples, contexts, or times, **internal validity** reflects how confident we can be in the results of a particular given study. In other words, internal validity is the extent to which a study is methodologically sound, free of confounds, or other sources of error, and able to be used to draw valid conclusions. For example, suppose that a researcher is interested in how heart rate changes when participants are told that they are about to be given an electric shock. Imagine also how much faith you might have in the results of the research if participants who have just completed the study are allowed to chat in the waiting area with people who are just about to participate. What if the latter learn that, in reality, no shocks are given at all? How might this information change how subjects respond? Failure to control the exchange of information in this way clearly jeopardizes the integrity of the study and is a threat to its internal validity. Some subjects (those who have not been given prior information) will expect to receive real shocks; others will not because, unbeknownst to the experimenter, information has been leaked to them beforehand.

## Criterion and Comparison Groups

To test their hypotheses, researchers use a **comparison group** (sometimes called a **control group**). This may be defined as a group of people who do not exhibit the disorder being studied but who are comparable in all other major respects to the **criterion group** (i.e., people with the disorder). By "comparable" we might mean that the two groups are similar in age, number of males and females in each group, education level, and similar demographic variables. Typically, the comparison group is psychologically healthy, or "normal," according to certain specified criteria. We can then compare the two groups on the variables of interest.

To further illustrate the idea of criterion and control groups, let us return to our example about schizophrenia and milk. Dr. Smart's hypothesis was that drinking milk causes schizophrenia. However, when a group of patients with

Why is so much research conducted using college students? What are the advantages and disadvantages of this?

schizophrenia (the criterion group or the group of interest) was compared with a group of patients who did not have schizophrenia (the control group), it was clear that there were no differences in milk drinking between the two groups.

Using the controlled research approaches we have just described, researchers have learned much about many different psychological disorders. We can also use extensions of this approach not only to compare one cohort of patients with healthy controls but also to compare groups of patients with different disorders.

For example, Cutting and Murphy (1990) studied how well (1) patients with schizophrenia, (2) patients with depression or mania, and (3) healthy controls performed on a questionnaire testing social knowledge. This involved a series of multiple-choice questions that presented a social problem (e.g., "How would you tell a friend politely that he had stayed too long?"). Possible answer choices included responses such as, "There's no more coffee left" and "You'd better go. I'm fed up with you staying too long." (In case you are wondering, both of these are incorrect choices; the preferred answer for this example was, "Excuse me. I've got an appointment with a friend.")

Consistent with the literature showing that social deficits are associated with schizophrenia, the patients with schizophrenia did worse on this test relative to both the healthy controls and the depressed or manic patients. The finding that the patients with schizophrenia did more poorly than the depressed or manic patients allowed the researchers to rule out the possibility that simply being a psychiatric patient is linked to poor social knowledge.

- What is a sample of convenience?
- What is the difference between internal and external validity? How can external validity be maximized?
- Why are comparison or control groups so important?

## Research Designs

### Studying the World as It Is: Correlational Research Designs

A major goal of researchers in abnormal psychology is to learn about the causes of different disorders. For ethical and practical reasons, however, we often cannot do this directly. Perhaps we want to learn about factors that result in depression. We may hypothesize that stress of losing a parent early in life may be important in this regard. Needless to say, we cannot create such situations and then see what unfolds!

Instead, the researcher uses what is known as a **correlational research** design. Unlike a true experimental research design (described later), correlational research does not involve any manipulation of variables. Rather, the researcher selects certain groups of interest (e.g., people who have recently been exposed to a great deal of stress, or people who lost a parent when they were growing up).

She would then compare the groups on a variety of different measures (including, in this example, levels of depression).

Any time we study differences between individuals who have a particular disorder and those who do not, we are utilizing this type of correlational research design. Essentially, we are capitalizing on the fact that the world works in ways that create natural groupings of people (people with specific disorders, people who have had traumatic experiences, people who win lotteries, etc.) whom we can then study. Using these types of research designs, we are able to identify factors that appear to be associated with depression, alcoholism, binge eating, or alternate psychological states of distress (for a more comprehensive description of this kind of research approach, see Kazdin, 1998b).

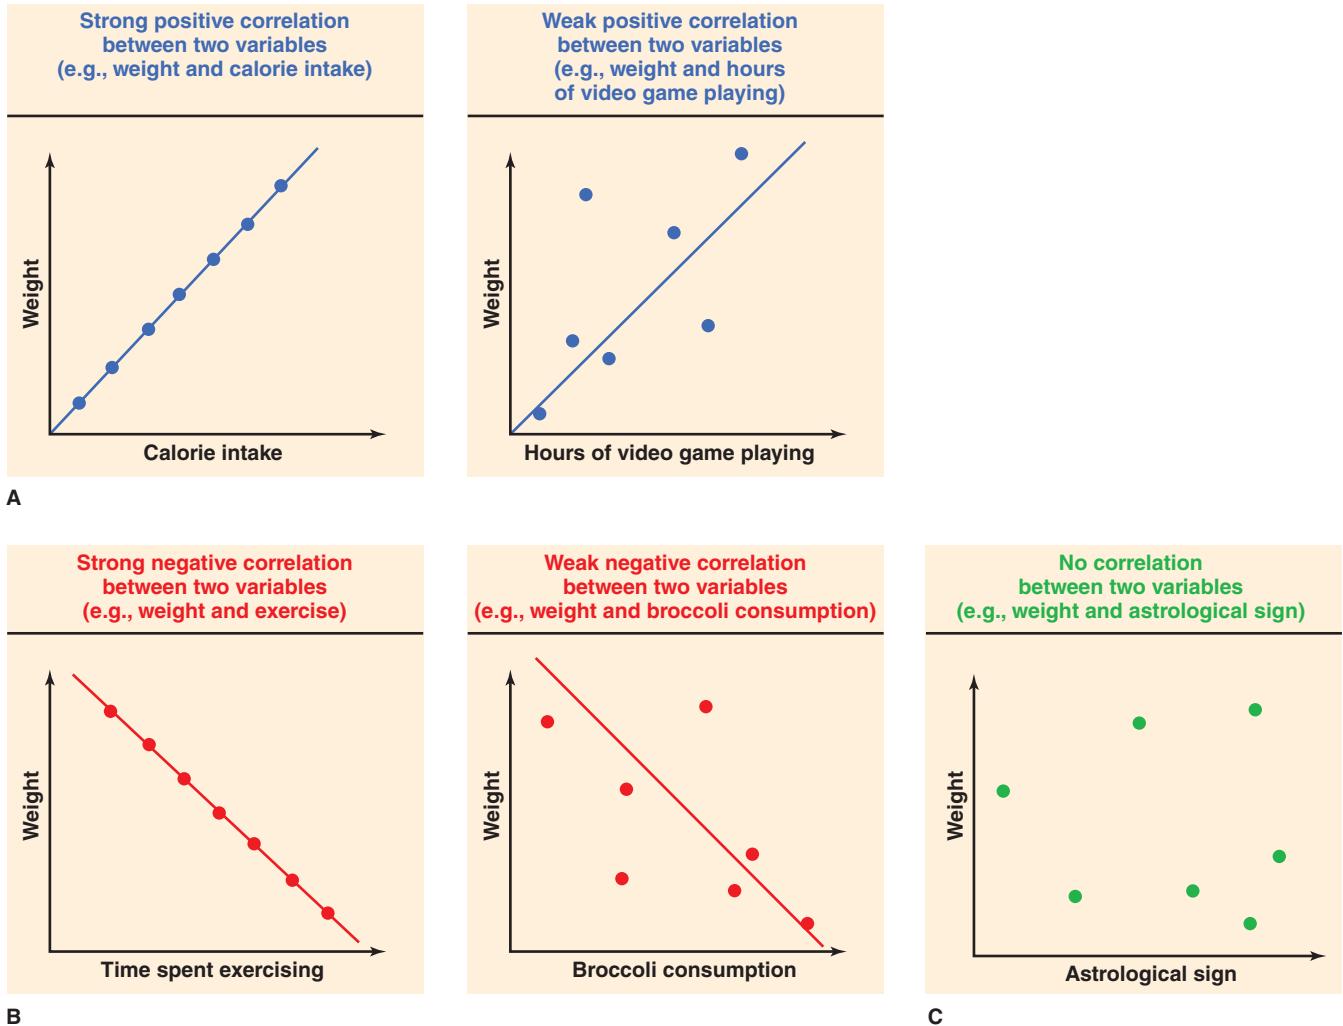

### Measuring Correlation

Correlational research takes things as they are and determines associations among observed phenomena. Do measures vary together in a direct, corresponding manner (known as a **positive correlation**—see Figure 1.2 below) such as in the example we mentioned earlier showing that breast augmentation surgery was correlated with increased risk of suicide? Or conversely, is there an inverse correlation, or **negative correlation**, between the variables of interest (such as high socioeconomic status and decreased risk of psychopathology)? Or finally, are the variables in question entirely independent of one another, or uncorrelated, such that a given state or level of one variable fails to predict reliably the degree of the other variable, as was the case with our example about milk and schizophrenia?

The strength of a **correlation** is measured by a **correlation coefficient**, which is denoted by the symbol  $r$ . A correlation runs from 0 to 1, with a number closer to 1 representing a stronger association between the two variables. The + sign or - sign indicates the direction of the association between the variables. For example, a positive correlation means that higher scores on one variable are associated with higher scores on the other variable, as might be the case for hours spent studying and grade point average. A negative correlation means that, as scores on one variable go up, scores on the other variable tend to go down. An example here might be the association between hours spent partying and grade point average.

### Statistical Significance

If you read a research article, you are likely to see correlations reported in the text. Next to the correlation you will almost certainly see a notation that reads  $p < .05$ . This is the level of **statistical significance**. But what does this mean? Simply put, it means that the probability that the correlation would occur purely by chance is less than 5 out of 100. Researchers adopt this conventional level of significance and consider correlations that have a  $p < .05$  to be statistically significant and worthy of attention. Of course, this does not mean that the result in question could not have occurred by chance; it simply means that it is not very likely.

**FIGURE 1.2**

Scatterplots of data illustrating positive, negative, and no correlation between two variables. Dots indicate a given person's score on the two variables of interest. A strong positive correlation ( $r = +1.0$ ) means that high scores on one variable are associated with high scores on the second variable, creating a forward-sloping straight line. For example, we would expect there to be a positive correlation between weight and the number of calories eaten per day. When there is a strong negative correlation ( $r = -1.0$ ), high scores on the first variable are associated with low scores on the second variable, creating a backward-sloping straight line. A relevant example here would be the association between weight and time spent exercising per day. When there is no correlation ( $r = 0$ ), scores on the independent variable tell us nothing about scores on the dependent variable. An example here might involve weight and astrological sign.

Statistical significance is influenced not only by the magnitude or size of the correlation between the two variables but also by the sample size. A correlation of .30 will not be significant if the sample size is 20 people but will be significant if the sample size is 50 people. Correlations based on very large samples (e.g., 1,000 people) can be very small and yet still reach statistical significance. Conversely, correlations drawn from small samples need to be very large to reach statistical significance.

## Effect Size

The fact that statistical significance is influenced by sample size creates a problem when we want to compare findings across studies. Suppose that Dr. Green reports a significant association

between two variables in her study. But, in a second study, Dr. Blue reports no significant correlation between these same two variables. This is not an uncommon occurrence in the scientific literature, and it often creates a lot of confusion about whose results are “correct.” But if Dr. Green has a larger sample size than Dr. Blue, the same-size correlation will be significant in Dr. Green’s study but not reach statistical significance in Dr. Blue’s study. To avoid the problems inherent in just focusing on statistical significance, and to facilitate comparison of results across different studies (which invariably have different sample sizes), researchers often report a statistic called the **effect size**. The effect size reflects the size of the association between two variables independent of the sample size. An effect size of zero means there is no association between the variables. Because it is independent of sample size, the effect size can be used as a common metric and

is very valuable when we want to compare the strength of findings across different studies. If the effect size is about the same in the studies of both Dr. Green and Dr. Blue, we can conclude that they really had similar findings, regardless of the fact that the results were significant in one study but not in the other.

## Meta-Analysis

When researchers want to summarize research findings in a specific area, they often do a literature search and write a review. In drawing their conclusions they will rely on significance levels, noting whether more studies than not found a significant association between two variables, such as smoking and health. A far better approach, however, is to conduct a **meta-analysis**. A meta-analysis is a statistical approach that calculates and then combines the effect sizes from all of the studies. Within a meta-analysis, each separate study can be thought of as being equivalent to an individual participant in a conventional research design. Because it uses effect sizes, a meta-analysis provides a better way to summarize research findings than is possible with a literature review.

## Correlations and Causality

When it comes to correlations, one thing is very important to remember: Correlation does not mean causation. Just because two variables are correlated does not tell us anything about why they are correlated. This is true regardless of the size of the correlation. Many research investigations in abnormal psychology reveal that two (or more) things regularly occur together, such as poverty and diminished intellectual development, or depression and reported prior stressors. This in no way affirms that one factor is the cause of the other.

Consider, for example, the positive correlation that exists between ice cream consumption and drowning. Does this mean that eating ice cream compromises swimming ability and so leads to drowning? Or that people who are about to drown themselves like to have one final ice cream cone before they enter the water? Both of these alternatives are clearly absurd. Much more likely is that some unknown third variable might be causing both events to happen. This is known as the **third variable problem**. What might the third variable be in this example? After a moment's reflection, you might realize that a very plausible third variable is hot summer weather. Ice cream consumption increases in the summer months. So, too, does the number of people who drown because more people swim during the summer than at any other time. The correlation between ice cream consumption and drowning is a spurious one, caused by the fact that both variables are correlated with the weather.

To use an example from abnormal psychology, it was once thought that masturbation caused insanity. This hypothesis no doubt arose from the fact that, historically, patients in mental asylums could often be seen masturbating in full view of others. Of course, we now know that masturbation and insanity were

correlated not because masturbation caused insanity but because sane people are much more likely to masturbate in private than in public. In other words, the key factor linking the insanity and masturbation (and the unmeasured third variable) was that of impaired social awareness.

Even though correlational studies may not be able to pinpoint causal relationships, they can be a powerful and rich source of inference. They often suggest causal hypotheses (increased height may cause increased weight; increased weight is unlikely to cause increased height), generate questions for further research, and occasionally provide crucial data that may confirm or refute specific hypotheses. Much of what we know about mental disorders is derived from correlational studies. The fact that we cannot manipulate many of the variables we study does not mean that we cannot learn a great deal from such approaches.

## Retrospective Versus Prospective Strategies

Correlational research designs can be used to study different groups of patients as they are at the time of the study (i.e., concurrently). For example, if we used brain imaging to look at the size of certain brain structures in patients with schizophrenia and in healthy controls, we would be using this type of approach. But if we wanted to learn what our patients were like before they developed a specific disorder, we might adopt a **retrospective research** strategy. This involves looking back in time. In other words, we would try to collect information about how the patients behaved early in their lives with the goal of identifying factors that might have been associated with what went wrong later. In some cases, our source material might be limited to a patient's recollections, the recollections of family members, material from diaries, or other records. A challenge with this technique is the potential for memories to be both faulty and selective.

There are certain difficulties in attempting to reconstruct the pasts of people already experiencing a disorder. Apart from the fact that a person who currently has a mental disorder may not be the most accurate or objective source of information, such a strategy invites investigators to discover what they already presume they will discover concerning background factors theoretically linked to a disorder. It invites biased procedure, unconscious or otherwise.

For instance, reports of a link between early sexual abuse and various forms of psychopathology began to emerge in the 1980s. After these reports came out, many therapists proceeded to suggest to their patients with such conditions that perhaps they too had been abused. For certain overzealous therapists, the fact that many patients had no memories of any abuse was taken as evidence that the painful memories had simply been "repressed." In other cases, a patient's simply having such common problems as difficulty sleeping or being easily startled was taken as evidence of past abuse. Over time, many patients became as convinced as

their therapists that they must have been abused and that this accounted for their current difficulties. But for many patients, it simply was not the case that they had been abused. This underscores the pitfalls inherent in trying to reinterpret a person's past (or past behavior) in light of his or her present problems. Adherence to fundamental scientific principles is as crucial in the clinical domain as it is in the research laboratory.

Another approach is to use a **prospective research** strategy, which involves looking ahead in time. Here the idea is to identify individuals who have a higher-than-average likelihood of becoming psychologically disordered and to focus research attention on them before any disorder manifests. We can have much more confidence in our hypotheses about the causes of a disorder if we have been tracking influences and measuring them prior to the development of the illness in question. When our hypotheses correctly predict the behavioral problems that a group of individuals will later develop, we are much closer to establishing a causal relationship. A study that follows people over time and that tries to identify factors that predate the onset of a disorder employs a **longitudinal design**. A prototypical illustration might be a study that follows, from infancy to adulthood, the children of mothers with schizophrenia. By collecting data on the children at regular intervals, researchers can compare those who later develop schizophrenia with those who do not, with the goal of identifying important differentiating factors. In another example of a longitudinal design, researchers have shown that adolescents who report suicidal thoughts at age 15 are much more likely to have psychological problems and to have attempted suicide by age 30 than people who do not have suicidal ideas in their teens (Reinherz et al., 2006).

## Manipulating Variables: The Experimental Method in Abnormal Psychology

As you have already learned, even when we find strong positive or negative associations between variables, correlational research does not allow us to draw any conclusions about directionality (i.e., does variable A cause B, or does B cause A?). This is known as the **direction of effect problem**. To draw conclusions about causality and resolve questions of directionality, an **experimental research** approach must be used. In such cases, scientists control all factors except one—the factor that could have an effect on a variable or outcome of interest. They then actively manipulate (or influence) that one factor. The factor that is manipulated is referred to as the **independent variable**. If the outcome of interest, called the **dependent variable**, is observed to change as the manipulated factor is changed, then that independent variable can be regarded as a cause of the outcome (see Figure 1.3).

In Romania, children who are abandoned by their parents are traditionally raised in orphanages rather than in foster care. To study the cognitive effects of institutional versus other forms of care, researchers randomly assigned 136 children who had been institutionalized as babies to either remain in these

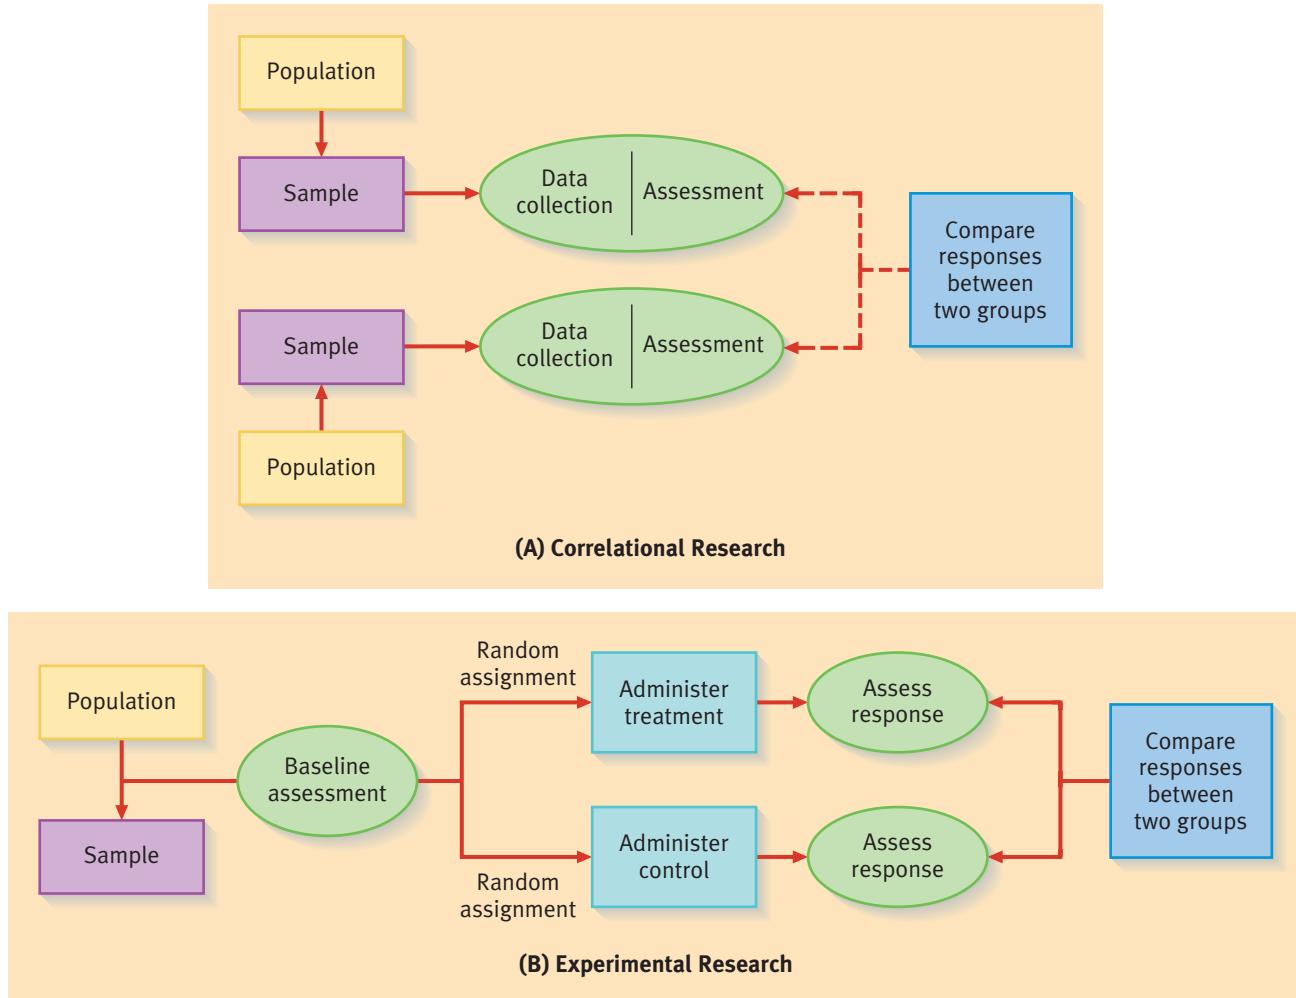

institutions or be raised by foster families (see Nelson et al., 2007). These foster parents had been recruited for the study by the researchers. Another sample of children who lived with their birth families was also studied for comparison purposes. All the children received cognitive testing when they were 30, 42, and 54 months old. In this study, the independent variable is the living situation of the child (orphanage or foster care). The dependent variable is intellectual functioning.

Did the children assigned to foster care fare better than the children who remained in institutions? The answer is yes. At both the 42-month and the 54-month assessments, the children in foster families had significantly higher scores on the measure of cognitive functioning than the children who remained institutionalized. We can therefore conclude that there was something about being raised in a foster family that was responsible for the increased intellectual development of these children. Sadly, however, the cognitive development of both groups of children was much lower than the intellectual functioning of children who were raised in typical families. The results of this unique study therefore tell us that, although foster care helps abandoned children, these children remain at a disadvantage relative to children who are raised by their biological families. However, based at least partially on the findings from this remarkable study, Romania no longer allows children without severe disabilities to be placed in institutional care.

## Studying the Efficacy of Therapy

Researchers in abnormal psychology are often interested in learning which treatments work for specific disorders. Used in the context of treatment research, the experimental method has proved to be indispensable. It is a relatively straightforward process to establish: A proposed treatment is given to a designated group of patients and withheld from a similar group of patients. Should the treated group show significantly more improvement than the untreated group, we can have confidence in the treatment's efficacy. We may not, however, know why the treatment works, although investigators are becoming increasingly sophisticated in fine-tuning their experiments to tease out the means by which therapeutic change is induced (e.g., Hollon et al., 1987; Jacobson et al., 1996; Kazdin & Nock, 2003). The Developments in Research box on page 24 provides a nice example of a treatment research study. The findings of this study also show just how powerful placebo effects can be.

In treatment research it is important that the two groups (treated and untreated) be as equivalent as possible except for the presence or absence of the proposed active treatment. To facilitate this, patients are typically randomly assigned to the treatment condition or the no-treatment condition. **Random assignment** means that every research participant has an equal chance of being placed in the treatment or the no-treatment condition. Once a treatment has been established as effective, it can then be provided for members of the original control (untreated) group, leading to improved functioning for all those involved.

**FIGURE 1.3**

**Correlational and Experimental Research Designs.** (A) In correlational research, data are collected from two different samples or groups and are then compared. (B) In experimental research, participants are assessed at baseline and then randomly assigned to different groups (e.g., a treatment and a control condition). After the experiment or treatment is completed, data collected from the two different groups are then compared. (Adapted from Petrie & Sabin, 2000. Medical Statistics at a Glance. Oxford, UK: Blackwell Science Ltd.)

Sometimes, however, this “waiting list” control group strategy is deemed inadvisable for ethical or other reasons. Withholding a treatment that has been established as beneficial just to evaluate a new form of treatment may deprive control subjects of valuable clinical help for longer than would be considered appropriate. For this reason, there need to be stringent safeguards regarding the potential costs versus benefits of conducting the particular research project.

In certain cases, an alternative research design may be called for in which two (or more) treatments are compared in differing yet comparable groups. This method is termed a *standard treatment comparison study*. Typically, the efficacy of the control condition has been previously established; thus, patients who are assigned to this condition are not disadvantaged. Instead, the question is whether patients who receive the new treatment improve to a greater extent than those receiving the control (established) treatment.

Such comparative-outcome research has much to recommend it and is being increasingly employed (Kendall et al., 2004).

### Single-Case Experimental Designs

Does experimental research always involve testing hypotheses by manipulating variables across groups? The simple answer is no. We have already noted the importance of case studies as a source of ideas and hypotheses. In addition, case studies can be used to develop and test therapy techniques within a scientific framework. Such approaches are called **single-case research designs** (Hayes, 1998; Kazdin, 1998a, 1998b). A central feature of such designs is that the same individual is studied over time. Behavior or performance at one point in time can then be compared to behavior or performance at a later time, after a specific intervention or treatment has been introduced. For example, using

### Do Magnets Help With Repetitive-Stress Injury?

Magnets are often marketed to people who have chronic hand or wrist pain. This type of problem is known as repetitive-stress injury (RSI) and can be caused by extensive computer use. But do magnets really relieve the chronic pain that is associated with RSI? Testimonials notwithstanding, the only way to answer this question is by controlled research.

Pope and McNally (2002) randomly assigned college students with RSI to one of three groups. One group was asked to wear wristbands containing magnets for a 30-minute period (magnet group). A second group was also given seemingly identical bracelets to wear. In this case, however, and unknown both to the participants and to the assistant running the study, the magnets had been removed from the wristbands (sham group). A third group of subjects did not receive any magnets (no-treatment group).

You should note here that this study is an example of what we call a **double-blind study**. In other words, neither the subjects nor the experimenter who was working with the subjects knew who got the genuine magnets. The use of the wristbands with the magnets removed is called a **placebo treatment** condition (the word *placebo* comes from the Latin meaning "I shall please"). Placebo treatment conditions enable experimenters to control for the possibility that simply believing one is getting an effective type of treatment produces a therapeutic benefit. Finally, the no-treatment control group enables the experimenters to see what happens when they do not provide any treatment (or expectation of treatment) at all.

At the start of the study, all of the student participants completed a 4-minute typing test. This provided a measure of how many words they could type in this time period. Then, 30 minutes after wearing the magnets or fake wristbands (or, for the no-treatment subjects, after waiting 30 minutes), all participants completed another 4-minute typing test. In addition,

those who had been assigned to either the genuine or the placebo magnet group were asked to rate their degree of pain relief (from no improvement to complete relief) using an 8-point scale.

What were the results? As might be expected, those people who had been assigned to the no-treatment group did not report that their level of pain changed in any appreciable way. This is hardly surprising because nothing had been done to them at all. They typed an average of about four more words on the second test (the posttest) than on the first (the pretest).

Did the people who wore the magnets do better than this? The answer is yes. Those who wore the genuine magnets reported that their pain was diminished. They also typed an average of 19 more words on the second typing test than they had on the first! In other words, with respect to both their self-report data (their pain improvement ratings) and their behavioral data (how rapidly they could type), they clearly did better than the no-treatment group.

Before you rush out to buy magnetic bracelets, however, let us look at the performance of the people who received the fake bracelets. Like the subjects who wore the genuine magnets, these participants also reported that their pain had improved. And, in fact, on the behavioral typing test, subjects in the placebo treatment group typed even more words on the second test (an average of 26 more words) than subjects who wore the real magnets did. With respect to their self-reports and their behavioral data, therefore, the group who wore the fake bracelets improved just as much as the group who wore the real magnets! On the basis of this study, then, we must conclude that magnet therapy works via the placebo effect, not because there is any genuine clinical benefit that comes from the magnets themselves. If you believe that the magnet will help your RSI, you do not actually need a magnet to bring about any clinical improvement. And this, in a nutshell, is why we need controlled research trials.

a single-case design, Wallenstein and Nock (2007) were able to show that exercise helped a 26-year-old female patient to significantly decrease the frequency of her nonsuicidal self-injuring behaviors, which included self-hitting and head-banging.

One of the most basic experimental designs in single-case research is called the **ABAB design**. The different letters refer to different phases of the intervention. The first A phase serves as a baseline condition. Here we simply collect data on or from the participant. Then, in the first B phase, we introduce our treatment. Perhaps the person's behavior changes in some way. Even if there is a change, however, we are not justified in concluding that it was

due to the introduction of our treatment. Other factors might have coincided with its introduction, so any association between the treatment and the behavior change might be spurious. To establish whether it really was the treatment that was important, we therefore withdraw the treatment and see what happens. This is the reasoning behind the second A phase (i.e., at the ABA point). Finally, to demonstrate that the behavior observed during the B phase is attainable once again, we reinstate our treatment and see if the behavioral changes we saw in the first B phase become apparent again. To further clarify the logic behind the ABAB design, let's consider the case of Kris (see Rapp et al., 2000).

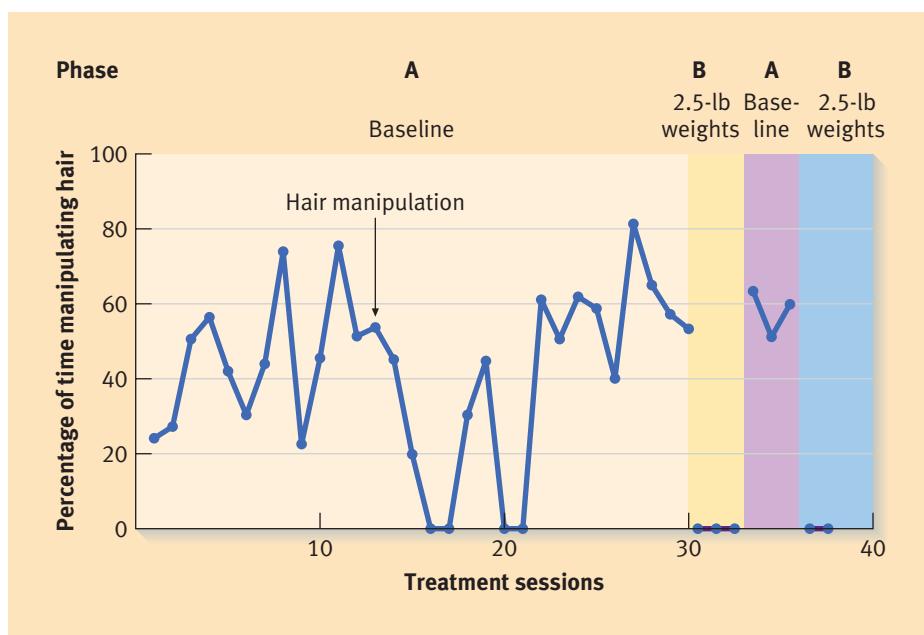

→ **Kris** Kris was a 19-year-old female with severe intellectual impairments. Since the age of 3 she had pulled her hair out. This disorder is called trichotillomania (pronounced tri-ko-til-lomania). Kris's hair pulling was so severe that she had a bald area on her scalp that was approximately 2.5 inches in diameter.

The researchers used an ABAB experimental design (see Figure 1.4) to test a treatment for reducing Kris's hair pulling. In each phase, they used a video camera to observe Kris while she was alone in her room watching television. During the baseline phase (phase A), observers measured the percentage of time that Kris spent either touching or manipulating her hair (42.5% of the time) as well as pulling hair (7.6% of the time).

In the treatment phase (B), a 2.5-lb weight was put around Kris's wrist when she settled down to watch television. When she was wearing the wrist weight, Kris's hair manipulation and

hair pulling was reduced to zero. This, of course, suggested that Kris's behavior had changed because she was wearing a weight on her wrist. To verify this, the wrist weight was withdrawn in the second A phase (i.e., ABA). Kris immediately started to touch and manipulate her hair again (55.9%). She also showed an increase in hair pulling (4% of the time).

When the wrist weight was reintroduced in the second B phase (ABAB), Kris's hair manipulation and pulling once again decreased, at least for a while. Although additional treatments were necessary (see Rapp et al., 2000), Kris's hair pulling was eventually eliminated entirely. Most important for our discussion, the ABAB design allowed the researchers to systematically explore, using experimental techniques and methods, the treatment approaches that might be beneficial for patients with trichotillomania.

**FIGURE 1.4**

#### An ABAB Experimental Design: Kris's Treatment.

**Treatment.** In the A phase, baseline data are collected. In the B phase, a treatment is introduced. This treatment is then withdrawn (second A phase) and then reinstated (second B phase). In this example, hair manipulation declines with use of wrist weights, returns to pretreatment (baseline) levels when they are withdrawn, and declines again when they are reintroduced. (Data adapted from Rapp et al., 2000. Treatment of hair pulling and hair manipulation maintained by digital-tactile stimulation. *Behavior Therapy*, 31, pp. 381–93)

## Animal Research

An additional way in which we can use the experimental method is by conducting research with animals. Although ethical considerations are still critical in animal research, we are able to perform studies using animal subjects that would not be possible to implement with humans (giving them experimental drugs, implanting electrodes to record brain activity, etc.).

Of course, one major assumption is that the findings from animal studies can be generalized to humans. Experiments of this kind are generally known as **analogue studies**, in which we study not the true item of interest but an approximation to it. Analogue studies may also involve humans (e.g., when we try to study depression by studying healthy research participants whom we have made mildly and transiently sad).

One current model of depression, called “hopelessness depression,” has its origins in early research conducted with animals (Seligman, 1975). Laboratory experiments with dogs had demonstrated that, when subjected to repeated experiences of painful, unpredictable, and inescapable electric shock, the dogs lost their ability to learn a simple escape response to avoid further shock in a different situation later on. They just sat and endured the pain. This observation led Seligman and his colleagues to argue that human depression (which he believed was analogous to the reaction of the helpless dogs) is a reaction to uncontrollable stressful events in which one's behavior has no effect on one's environment, leading to helplessness, passivity, and depression. In other words, the findings from these animal studies provided the impetus for what first

Animal research allows behavioral scientists to manipulate and study behavior under controlled conditions that would not be possible to replicate using humans as subjects. However, results of this research may not hold up when extended to humans outside the laboratory in a real-world setting.

became known as the “learned helplessness theory of depression” (Abramson et al., 1978; Seligman, 1975) and is now

termed “the hopelessness theory of depression” (Abramson et al., 1989). These theories of depression are not without their difficulties. Nevertheless, it is useful to remain aware of the broader message: Even though problems may arise when we generalize too readily from animal to human models of psychopathology, the learned helplessness analogy has generated much research and has allowed us to refine and develop our understanding of depression.

### in review

- How is experimental research different from correlational research?
- What is the difference between a positive and a negative correlation? If two variables are correlated, does this mean that one variable causes the other? If so, why? If not, why not?
- In experimental research, which variable (independent or dependent) is manipulated?
- What is a placebo?
- Explain the process of performing an ABAB design. Why are such designs helpful to clinicians and researchers?

## UNRESOLVED issues

### Are We All Becoming Mentally Ill? The Expanding Horizons of Mental Disorder

The concept of mental disorder, as we have seen, suffers from the lack of a truly objective means of determining what is disordered and what is not. Moreover, inclusion of a disorder in the *DSM* is a prerequisite for health insurers’ reimbursement of services rendered. It is therefore in the financial interests of mental health professionals to be more and more inclusive concerning the kinds of problems that might be regarded as “mentally disordered.” Not surprisingly, there is often pressure to include in the *DSM* more and more kinds of socially undesirable behavior.

The *DSM* has been growing in size for many years as new disorders are added. But it is the interests of the public at large to keep a close eye on proposed expansions of what is considered “mentally disordered.” Failure to do so could eventually lead to a situation in which much of human behavior—save for the most bland, conformist, and conventional of conduct—would be declared a manifestation of a mental disorder. For example, when *DSM-5* was being developed, some groups lobbied for “apathy syndrome” and “parental alienation syndrome” to be considered as new disorders. But is being unmotivated or having a troubled relationship with your parents really a disorder? In the end, these proposals were rejected.

Accepted into *DSM-5*, however, were several newly proposed disorders that might still cause some to raise an eyebrow. These

Internet gaming disorder will appear in *DSM-5* as a new disorder in need of further study.

include “caffeine use disorder” and “Internet gaming disorder.” These have been added to *DSM-5* in a special section that is reserved for disorders still in need of further study. Although this does not mean that they are being formally accepted as official disorders, it is certainly a first step. What do you think of this? How close do you think we are getting to the point where all of us, by virtue of drinking too much coffee or spending too much time gaming are at risk of being considered mentally ill?

# summary

## 1.1 How do we define abnormality and classify mental disorders?

- A precise definition of *abnormality* remains elusive. Elements that can be helpful in considering whether something is abnormal include suffering, maladaptiveness, statistical deviancy, dangerousness, violation of societal norms, irrationality, and unpredictability.
- The *DSM* employs a category type of classification similar to that used in medicine. Disorders are regarded as discrete clinical entities, though not all clinical disorders may be best considered in this way.
- Even though it is not without problems, the *DSM* provides us with working criteria that help clinicians and researchers identify and study specific difficulties that affect the lives of many people. It is far from a “finished product.” However, familiarity with the *DSM* is essential to significant study of the field.
- Culture shapes the presentation of clinical disorders in some cases. There are also certain disorders that appear to be highly culture specific.

## 1.2 What are the advantages and disadvantages of classification?

- Classifying disorders provides a communication shorthand and allows us to structure information in an efficient manner. This facilitates research and treatment. However, when we classify, we lose personal information about the person with the disorder. Classification also facilitates stigma, stereotyping, and labeling.
- People with mental disorders experience a great deal of stigma. Even though it is now generally known that mental illnesses have biological causes, this does not seem to have reduced the stigma associated with being mentally ill. Negative attitudes toward the mentally ill can be found in all cultures.

## 1.3 How common are mental disorders? Which disorders are most prevalent?

- Epidemiology involves the study of the distribution and frequency of disorders. Just under 50 percent of people will experience some

form of mental disorder over the course of their lifetimes. Mood disorders and anxiety disorders are particularly common.

## 1.4 Why do we need a research-based approach in abnormal psychology?

- Research in abnormal psychology allows us to learn about the duration and causes of disorders and this research can take place in a variety of settings including clinics, hospitals, schools, and prisons.
- To avoid misconception and error, we must adopt a scientific approach to the study of abnormal behavior. This requires a focus on research and research methodology, including an appreciation of the distinction between what is observable and what is hypothetical or inferred.
- To produce valid results, research must be conducted on individuals who are truly representative of the diagnostic groups to which they purportedly belong.

## 1.5 How do we gather information about mental disorders?

- Information about mental disorders is gathered by psychologists through case studies, self-report data, and observational approaches.

## 1.6 What kinds of research designs are used to conduct research in abnormal psychology?

- Research in abnormal psychology may be correlational or experimental. Correlational research examines factors as they currently are. Experimental research involves manipulating one variable (the independent variable) and observing the effect this manipulation produces with regard to another variable (the dependent variable).
- Just because two variables are correlated does not mean that there is a causal relationship between them. Always remember that correlation does not equal causation.
- Although most experiments involve the study of groups, single-case experimental designs (e.g., ABAB designs) may also be used to make causal inferences in individual instances.
- Analogue studies (e.g., animal research) are studies that provide an approximation to the human disorders of interest. Although generalizability presents an obstacle, animal research in particular has been very informative.

### 2.1

How has abnormal behavior been viewed throughout history?

### 2.2

What effect did the emergence of humanism have on abnormal psychology?

### 2.3

What developments led to the contemporary view of abnormal psychology?

→ **An Artist in Bedlam** The most famous patient committed to the historic Bethlem Hospital in England (better known as Bedlam) during its long existence was a well-known and talented young artist, Richard Dadd (1817–1886). Dadd was born in Chatham, England, in 1817. His father was a successful chemist. Dadd attended the Kings School in Rochester and also studied art at the Royal Academy School in London. He showed a strong aptitude for drawing and painting and was admitted to the prestigious Royal Academy of Arts at the early age of 20. When he was 25, he was invited to accompany Sir Thomas Phillips, the former mayor of Newport, on a grand tour through Europe, Greece, Turkey, Syria, and Egypt to serve as the draftsman and painter for the expedition. During the trip, Dadd produced a number of exceptional paintings of people and places he encountered on the journey, many of which are in museums today. The journey was reportedly difficult and stressful, and at one point, during a trip up the Nile River, Dadd underwent a remarkable personality change, becoming delusional and increasingly aggressive and violent toward people he met. He was reported to have expressed an urge to kill the Pope. He experienced delusional beliefs—for example, that he had come under the influence of the Egyptian god Osiris.

When he returned from the trip in 1843, he was diagnosed as being mentally unsound because of his hallucinations and his strange, delusional beliefs. In an effort to restore him to health, his family took him to recuperate in a countryside village in Kent, England. The records indicate that one day he came to the conclusion that his father was the Devil in disguise, and on a walk in the countryside Dadd killed his father with a knife. He attempted to escape by fleeing to France; however, his aggressive behavior continued, and he attempted to kill another tourist with a razor. He was arrested by the police and was eventually returned to England. He was committed to Bethlem Royal Hospital, where he was held in the criminal ward for dangerous inmates. He

remained in Bethlem Hospital for almost 20 years but was transferred to Broadmoor Hospital, where he died in 1886. During his stay in both the Bethlem and Broadmoor hospitals he was allowed and encouraged to paint by the staff as part of his treatment. During this time he produced a number of paintings, many of which can be seen today in art museums.

Although he appears to have experienced symptoms of a mood disorder including acute mania (see Chapter 7) it is likely that Dadd suffered from paranoid schizophrenia (see Chapter 14 for further discussion). Interestingly, two of his siblings appeared to suffer from the same symptom pattern; thus he may have been genetically predisposed to this condition (see Greysmith, 1979; MacGregor, 1989 for a discussion of his life and art work).

---

## Historical Views of Abnormal Behavior

Our historical efforts to understand abnormal psychology include both humor and tragedy. In this chapter, we will highlight some views of psychopathology, and some of the treatments administered, from ancient times to the twenty-first century. In a broad sense, we will see a progression of beliefs from what we now consider superstition to those based on scientific awareness—from a focus on supernatural explanations to knowledge of natural causes. The course of this evolution has at times been marked by periods of advancement or unique, individual contributions, followed by long years of inactivity or unproductive, backward steps.

Although human life appeared on earth some 3 million or more years ago, written records extend back only a few thousand years. Thus our knowledge of our early ancestors is limited. Two Egyptian papyri dating from the sixteenth century b.c. provide some clues to the earliest treatments of diseases and behavior disorders (Okasha & Okasha, 2000). The Edwin Smith papyrus (named after its nineteenth-century discoverer) contains detailed descriptions of the treatment of wounds and other surgical operations. In it, the brain is described—possibly for the first time in history—and the writing clearly shows that the brain was recognized as the site of mental functions. The Ebers papyrus offers another perspective on treatment. It covers internal medicine and the circulatory system but relies more on incantations and magic for explaining and curing diseases that had unknown causes. Although surgical techniques may have been used, they were probably coupled with prayers and the like, which reflected the prevailing view of the origin of mental illness.

### Demonology, Gods, and Magic

References to abnormal behavior in early writings show that the Chinese, Egyptians, Hebrews, and Greeks often attributed such behavior to a demon or god who had taken possession of a person. Whether the “possession” was assumed to involve good spirits or evil spirits usually depended on the affected individual’s

symptoms. If a person's speech or behavior appeared to have a religious or mystical significance, it was usually thought that he or she was possessed by a good spirit or god. Such people were often treated with considerable awe and respect, for people believed they had supernatural powers.

Most possessions, however, were considered to be the work of an angry god or an evil spirit, particularly when a person became excited or overactive and engaged in behavior contrary to religious teachings. Among the ancient Hebrews, for example, such possessions were thought to represent the wrath and punishment of God. Moses is quoted in the Bible as saying, "The Lord shall smite thee with madness." Apparently this punishment was thought to involve the withdrawal of God's protection and the abandonment of the person to the forces of evil. In such cases, every effort was made to rid the person of the evil spirit.

The primary type of treatment for demonic possession was exorcism, which included various techniques for casting an evil spirit out of an afflicted person. These techniques varied but typically included magic, prayer, incantation, noisemaking, and the use of horrible-tasting concoctions made from sheep's dung and wine.

## Hippocrates' Early Medical Concepts

The Greek temples of healing ushered in the Golden Age of Greece under the Athenian leader Pericles (461–429 B.C.). This period saw considerable progress in the understanding and treatment of mental disorders, in spite of the fact that Greeks of the time considered the human body sacred so little could be learned of human anatomy or physiology. During this period the Greek physician Hippocrates (460–377 B.C.), often referred to as the father of modern medicine, received his training and made substantial contributions to the field.

Hippocrates denied that deities and demons intervened in the development of illnesses and instead insisted that mental disorders, like other diseases, had natural causes and appropriate treatments. He believed that the brain was the central organ of intellectual activity and that mental disorders were due to brain pathology. He also emphasized the importance of heredity and predisposition and pointed out that injuries to the head could cause sensory and motor disorders.

Hippocrates classified all mental disorders into three general categories—mania, melancholia, and phrenitis (brain fever)—and gave detailed clinical descriptions of the specific disorders included in each category. He relied heavily on clinical observation, and his descriptions, which were based on daily clinical records of his patients, were surprisingly thorough.

Maher and Maher (1994) pointed out that the best known of the earlier paradigms for explaining personality or temperament is the doctrine of the four humors, associated with the name of Hippocrates and later with the Roman physician Galen. The four elements of the material world were thought to be earth, air, fire, and water, which had attributes of heat, cold,

Hippocrates' (460–377 B.C.) belief that mental disease was the result of natural causes and brain pathology was revolutionary for its time.

moistness, and dryness. These elements combined to form the four essential fluids of the body—blood (sanguis), phlegm, bile (choler), and black bile (melancholer). The fluids combined in different proportions within different individuals, and a person's temperament was determined by which of the humors was dominant. From this view came one of the earliest and longest-lasting typologies of human behavior: the sanguine, the phlegmatic, the choleric, and the melancholic. Each of these "types" brought with it a set of personality attributes. For example, the person of sanguine temperament was optimistic, cheerful, and unafraid.

Hippocrates considered dreams to be important in understanding a patient's personality. On this point, he was a harbinger of a basic concept of modern psychodynamic psychotherapy. The treatments advocated by Hippocrates were far in advance of the exorcistic practices then prevalent. For the treatment of melancholia (see Developments in Thinking on p. 31), for example, he prescribed a regular and tranquil life, sobriety and abstinence from all excesses, a vegetable diet, celibacy, exercise short of fatigue, and bleeding if indicated. He also recognized the importance of the environment and often removed his patients from their families.

Hippocrates' emphasis on the natural causes of diseases, on clinical observation, and on brain pathology as the root of mental disorders was truly revolutionary. Like his contemporaries, however, Hippocrates had little knowledge of physiology. He believed that hysteria (the appearance of physical illness in the absence of organic pathology) was restricted to women and was caused by the uterus wandering to various parts of the body, pinning for children. For this "disease," Hippocrates recommended marriage as the best remedy.

## Melancholia Through the Ages

**A**lthough the modern mental health sciences have made great strides in defining, describing, classifying, determining the causes of, and treating psychological disorders, we should not ignore or minimize the contributions to understanding these conditions that were made by many individuals in antiquity. Actually, some mental health problems that are receiving a great deal of research and clinical attention today have been recognized and well described for millennia. One recent study of surviving letters from patients who were hospitalized in Edinborough Asylum between 1873 and 1906 concluded that mental health problems in the nineteenth century were very similar to those in our day (Beveridge, 1997). One such disorder is depression.

### Melancholia

Perhaps no other mental disorder received so much attention from earlier scholars as depression, or (as it has been referred to in the past) melancholia. Efforts to understand melancholia have been undertaken by physicians, philosophers, writers, painters, and religious leaders in Western civilization for over 2,000 years. Moreover, conditions similar to depression are described in surviving writings from ancient Egypt (Okasha & Okasha, 2000). These disorders might have been viewed variously as medical conditions or religious states or human frailties; however, the symptom structure and behavior described were unmistakable.

Radden (2000) published an interesting compendium of important writings on melancholia that span 24 centuries, some highlights of which are provided here.

- Investigations into the nature of depression, beginning with Aristotle and Galen during the Greek and Roman eras, provide lucid descriptions of the disorder melancholia.
- Even in the Middle Ages, when scholarship and inquiry were hindered by religious persecution that included the Spanish

Inquisition, there were scholars interested in mental states such as melancholia. Hildegard (1098–1179), a nun known as the “first published woman physician,” carried the Greek views of melancholia further by noting, among other things, that melancholia took different forms in men and women. Johann Weyer (1515–1588) provided astute descriptions of melancholia and examined characteristics of persons who might be so affected, even though these observations were often couched in terms of demonic possession—perhaps as a concession to leaders of the Inquisition in order to avoid persecution.

- The premodern view of melancholia as a disorder (without the taint of demonic possession or ancient Greek humors) was introduced by Philippe Pinel (1745–1826). A French physician widely recognized for his contributions to the humane treatment of people with mental disorders, Pinel also advanced our scholarly understanding of mental disorders such as melancholia by improving a classification schema and examining the causes of the disorder.
- Two early modern contributors to our understanding of depression were Wilhelm Griesinger (1817–1868) and Emil Kraepelin (1856–1926). Griesinger’s views on the underlying biological basis for disorders such as melancholia focused the field of psychiatry on the need to seek biological determinants for disorders. Kraepelin is credited with preparing the way for the modern view of psychiatry. His classification schema is still cited today in contemporary writings as seminal in the evolution of diagnostic classification systems. He also identified manic depression as a major category of depression.

Even though much of our understanding of depression and our development of effective treatment methods has emerged over the past three decades, our debt to the ancients who struggled with describing and understanding this disorder needs to be recognized.

The earliest use of the concept “delirium” to describe symptoms of mental disorders that result from fever or physical injury or brain trauma occurred in the first century A.D. by Celsus (Adamis et al., 2007).

### Early Philosophical Conceptions of Consciousness

The Greek philosopher Plato (429–347 B.C.) studied mentally disturbed individuals who had committed criminal acts and how to deal with them. He wrote that such persons were, in some “obvious” sense, not responsible for their acts and should

not receive punishment in the same way as normal persons. He also made provision for mental cases to be cared for in the community (Plato, n.d.).

Plato viewed psychological phenomena as responses of the whole organism, reflecting its internal state and natural appetites. In *The Republic*, Plato emphasized the importance of individual differences in intellectual and other abilities and took into account sociocultural influences in shaping thinking and behavior. His ideas regarding treatment included a provision for “hospital” care for individuals who developed beliefs that ran counter to those of the broader social order. There they would be engaged periodically in conversations comparable

to psychotherapy to promote the health of their souls (Milns, 1986). Despite these modern ideas, however, Plato shared the belief that mental disorders were in part divinely caused.

The celebrated Greek philosopher Aristotle (384–322 b.c.), who was a pupil of Plato, wrote extensively on mental disorders. Among his most lasting contributions to psychology are his descriptions of consciousness. He held the view that “thinking” as directed would eliminate pain and help to attain pleasure. On the question of whether mental disorders could be caused by psychological factors such as frustration and conflict, Aristotle discussed the possibility and rejected it; his lead on this issue was widely followed. Aristotle generally subscribed to the Hippocratic theory of disturbances in the bile. For example, he thought that very hot bile generated amorous desires, verbal fluency, and suicidal impulses.

### Later Greek and Roman Thought

Hippocrates' work was continued by some of the later Greek and Roman physicians. Particularly in Alexandria, Egypt (which became a center of Greek culture after its founding in 332 b.c. by Alexander the Great), medical practices developed to a higher level, and the temples dedicated to Saturn were first-rate sanatoria. Pleasant surroundings were considered of great therapeutic value for mental patients, who were provided with constant activities including parties, dances, walks in the temple gardens, rowing along the Nile, and musical concerts. Physicians of this time also used a wide range of therapeutic measures including dieting, massage, hydrotherapy, gymnastics, and education, as well as some less desirable practices such as bleeding, purging, and mechanical restraints.

Asclepiades (c. 124–40 b.c.) was a Greek physician born at Prusa in Bithynia in Asia Minor and practiced medicine in Rome toward the end of the second century b.c. He developed a theory of disease that was based on the flow of atoms through the pores in the body and developed treatments, such as massage, special diets, bathing, exercise, listening to music, and rest and quiet, to restore to the body (Stone, 1937).

One of the most influential Greek physicians was Galen (A.D. 130–200), who practiced in Rome. Although he elaborated on the Hippocratic tradition, he did not contribute much that was new to the treatment or clinical descriptions of mental disorders. Rather, he made a number of original contributions concerning the anatomy of the nervous system. (These findings were based on dissections of animals; human autopsies were still not allowed.) Galen also took a scientific approach to the field, dividing the causes of psychological disorders into physical and mental categories. Among the causes he named were injuries to the head, excessive use of alcohol, shock, fear, adolescence, menstrual changes, economic reversals, and disappointment in love.

Roman medicine reflected the characteristic pragmatism of the Roman people. Roman physicians wanted to make their patients comfortable and thus used pleasant physical therapies

Galen (A.D. 130–200) believed that psychological disorders could have either physical causes, such as injuries to the head, or mental causes, such as disappointment in love.

such as warm baths and massage. They also followed the principle of contrariis contrarius (“*opposite by opposite*”—for example, having their patients drink chilled wine while they were in a warm tub.

### Early Views of Mental Disorders in China

China was one of the earliest developed civilizations in which medicine and attention to mental disorders were introduced (Soong, 2006). The following passage is taken from an ancient Chinese medical text supposedly written by Huang Ti (c. 2674 b.c.), the third legendary emperor.

*The person suffering from excited insanity initially feels sad, eating and sleeping less; he then becomes grandiose, feeling that he is very smart and noble, talking and scolding day and night, singing, behaving strangely, seeing strange things, hearing strange voices, believing that he can see the devil or gods.*  
(Tseng, 1973, p. 570)

Even at this early date, Chinese medicine was based on a belief in natural rather than supernatural causes for illnesses. For example, in the concept of yin and yang, the human body, like the cosmos, is divided into positive and negative forces that both complement and contradict each other. If the two forces are balanced, the result is physical and mental health; if they are not, illness results. Thus treatments focused on restoring balance (Tseng, 1973, p. 570).

Ancient Persian physician Avicenna (c. 980–1037) approached the treatment of mental disorders with humane practices unknown to Western medical practitioners of the time.

Chinese medicine reached a relatively sophisticated level during the second century, and Chung Ching, who has been called the Hippocrates of China, wrote two well-known medical works around A.D. 200. Like Hippocrates, he based his views of physical and mental disorders on clinical observations, and he implicated organ pathologies as primary causes. However, he also believed that stressful psychological conditions could cause organ pathologies, and his treatments, like those of Hippocrates, utilized both drugs and the regaining of emotional balance through appropriate activities.

As in the West, Chinese views of mental disorders regressed to a belief in supernatural forces as causal agents. From the later part of the second century through the early part of the ninth century, ghosts and devils were implicated in “ghost-evil” insanity, which presumably resulted from possession by evil spirits. The “Dark Ages” in China, however, were neither so severe (in terms of the treatment of mental patients) nor as long-lasting as in the West. A return to biological, somatic (bodily) views and an emphasis on psychosocial factors occurred in the centuries that followed. Over the past 50 years, China has been experiencing a broadening of ideas in mental health services and has been incorporating many ideas from Western psychiatry (Zhang & Lu, 2006).

### Views of Abnormality During the Middle Ages

During the Middle Ages (about A.D. 500 to A.D. 1500), the more scientific aspects of Greek medicine survived in the Islamic countries of the Middle East. The first mental hospital was established in Baghdad in A.D. 792; it was soon followed by others in Damascus and Aleppo (Polvan, 1969). In these hospitals, mentally disturbed individuals received humane treatment. One outstanding figure in ancient medicine was Avicenna from Persia (c. 980–1037), called the “prince of physicians” (Campbell, 1926), and the author of *The Canon of Medicine*, perhaps the

most widely studied medical work ever written. In his writings, Avicenna frequently referred to hysteria, epilepsy, manic reactions, and melancholia. The following case study illustrates Avicenna’s unique approach to the treatment of a young prince suffering from mental disorder.

→ **An Early Treatment Case** A certain prince was afflicted with melancholia and suffered from the delusion that he was a cow. . . . He would low like a cow, causing annoyance to everyone, . . . crying, “Kill me so that a good stew may be made of my flesh.” Finally . . . he would eat nothing. . . . Avicenna was persuaded to take the case. . . . First of all he sent a message to the patient bidding him be of good cheer because the butcher was coming to slaughter him, whereat . . . the sick man rejoiced. Some time afterward Avicenna, holding a knife in his hand, entered the sickroom saying, “Where is this cow that I may kill it?” The patient lowed like a cow to indicate where he was. By Avicenna’s orders he was laid on the ground bound hand and foot. Avicenna then felt him all over and said, “He is too lean, and not ready to be killed; he must be fattened.” Then they offered him suitable food of which he now partook eagerly, and gradually he gained strength, got rid of his delusion, and was completely cured. (Browne, 1921, pp. 88–89)

During the Middle Ages in Europe, scientific inquiry into abnormal behavior was limited, and the treatment of psychologically disturbed individuals was characterized more often by ritual or superstition than by attempts to understand an individual’s condition. In contrast to Avicenna’s era in the Islamic countries of the Middle East or to the period of enlightenment during the seventeenth and eighteenth centuries, the Middle Ages in Europe were largely devoid of scientific thinking and humane treatment for the mentally disturbed.

Mental disorders were quite prevalent throughout the Middle Ages in Europe, especially toward the end of the period, when medieval institutions, social structures, and beliefs began to change drastically. During this time, supernatural explanations of the causes of mental illness grew in popularity. Within this environment, it obviously was difficult to make great strides in the understanding and treatment of abnormal behavior. Although the influence of theology was growing rapidly, “sin” was not always cited as a causal factor in mental illness.

For example, Kroll and Bachrach (1984) examined 57 episodes of mental illness ranging from madness and possession to alcohol abuse and epilepsy. They found sin implicated in only nine cases (16%). To understand better this elusive period of history, let us look at two events of the times—mass madness and exorcism—to see how they are related to views of abnormal behavior.

**MASS MADNESS** During the last half of the Middle Ages in Europe, a peculiar trend emerged in efforts to understand abnormal behavior. It involved **mass madness**—the widespread

occurrence of group behavior disorders that were apparently cases of hysteria. Whole groups of people were affected simultaneously. Dancing manias (epidemics of raving, jumping, dancing, and convulsions) were reported as early as the tenth century. One such episode that occurred in Italy early in the thirteenth century was known as **tarantism**—a disorder that included an uncontrollable impulse to dance that was often attributed to the bite of the southern European tarantula or wolf spider. This dancing mania later spread to Germany and the rest of Europe, where it was known as **Saint Vitus's dance**.

Isolated rural areas were also afflicted with outbreaks of **lycanthropy**—a condition in which people believed themselves to be possessed by wolves and imitated their behavior. In 1541 a case was reported in which a person suffering from lycanthropy told his captors, in confidence, that he was really a wolf but that his skin was smooth on the surface because all the hairs were on the inside (Stone, 1937). To cure him of his delusions, his extremities were amputated, following which he died, still uncured.

Mass madness occurred periodically all the way into the seventeenth century but had reached its peak during the fourteenth and fifteenth centuries—a period noted for social oppression, famine, and epidemic diseases. During this time, Europe was ravaged by a plague known as the Black Death, which killed millions (according to some estimates, 50% of the population of Europe died) and severely disrupted social organization. Undoubtedly, many of the peculiar cases of mass madness were related to the depression, fear, and wild mysticism engendered by the terrible events of this period. People simply could not believe that frightening catastrophes such as the Black Death could have natural causes and thus could be within their power to control, prevent, or even create.

Today, so-called mass hysteria occurs occasionally; the affliction usually mimics some type of physical disorder such as fainting spells or convulsive movements. A case of apparent mass hysteria occurred among hundreds of West Bank Palestinian girls in April 1983. This episode threatened to have serious political repercussions because some Arab leaders initially thought that the girls had been poisoned by Israelis. Health officials later concluded that psychological factors had played a key role in most of the cases (Hefez, 1985).

Ilechukwu (1992) describes an epidemic of mass hysteria that occurred in Nigeria in 1990 in which many men feared that their genitals had simply vanished. This fear of genital retraction accompanied by a fear of death is referred to as *koro* and has been widely documented in Southeast Asia. The afflicted persons believe this genital disappearance was caused by a supernatural occurrence in which they were robbed of their genitalia in order to benefit other people magically. Ilechukwu attributes some of this panic to male resentment of women's success during a period of social strain and the symbolic equation between masculine sexuality and economic, social, and creative prowess.

**EXORCISM AND WITCHCRAFT** In the Middle Ages in Europe, management of the mentally disturbed was left largely to the clergy. Monasteries served as refuges and places of confinement. During the early part of the medieval period, the mentally disturbed were, for the most part, treated with considerable kindness. “Treatment” consisted of prayer, holy water, sanctified ointments, the breath or spittle of the priests, the touching of relics, visits to holy places, and mild forms of exorcism. In some monasteries and shrines, **exorcisms** were performed by the gentle “laying on of hands.” Such methods were often joined with vaguely understood medical treatments derived mainly from Galen, which gave rise to prescriptions such as the following: “For a fiend-sick man: When a devil possesses a man, or controls him from within with disease, a spewdrink of lupin, bishopswort, henbane, garlic. Pound these together, add ale and holy water” (Cockayne, 1864–1866).

Interestingly, there has been a recent resurgence of superstition. For example, one can find those who believe that supernatural forces cause psychological problems and that “cures” should involve exorcism to rid people of unwanted characteristics or “spells.” Fries (2001) reported on a woman tragically drowning her 4-year-old daughter in an exorcism ritual attempting to rid her of demons that the mother believed possessed her daughter. In a more recent example, CBS News reported an incident in which an autistic boy was killed in an exorcism at a church in Milwaukee (CBS News, 2003).

It had long been thought that during the Middle Ages many mentally disturbed people were accused of being witches and thus were punished and often killed (e.g., Zilboorg & Henry, 1941). But several more recent interpretations have questioned the extent to which this was so (Maher & Maher, 1985; Phillips, 2002; Schoeneman, 1984). For example, in a review of the literature, Schoeneman (1984) notes that “the typical accused witch was not a mentally ill person but an impoverished woman with a sharp tongue and a bad temper” (p. 301). He goes on to say that “witchcraft was, in fact, never considered a variety of possession either by witch hunters, the general populace, or modern historians” (p. 306). To say “never” may be overstating the case; clearly, some mentally ill people were punished as witches. Otherwise, as we will see in the next section, why did some physicians and thinkers go to great lengths to expose the fallacies of the connection? In the case of witchcraft and mental illness, the confusion may be due, in part, to confusion about demonic possession. Even Robert Burton (1576–1640), an enlightened scholar, in his classic work *The Anatomy of Melancholia* (1621), considered demonic possession a potential cause of mental disorder. There were two types of demonically possessed people: Those physically possessed were considered mad, whereas those spiritually possessed were likely to be considered witches. Over time, the distinctions between these two categories may have blurred in the eyes of historians, resulting in the perception that witchcraft and mental illness were connected more frequently in the medieval mind than was the case.

The changing view of the relationship between witchcraft and mental illness points to an even broader issue—the difficulties of interpreting historical events accurately. We will discuss this concept in more depth in the Unresolved Issues section at the end of this chapter.

### in review

- What aspects of Hippocrates' alternative approach to mental disorders were truly revolutionary?
- What were the historical views of the disorder of melancholia (known as depression today)?
- What was the role of supernatural beliefs in efforts to understand mental disorders during the Middle Ages?
- What is mass madness? Give some examples of this phenomenon.

## Toward Humanitarian Approaches

During the latter part of the Middle Ages and the early Renaissance, scientific questioning reemerged and a movement emphasizing the importance of specifically human interests and concerns began—a movement (still with us today) that can be loosely referred to as humanism. Consequently, the superstitious beliefs that had hindered the understanding and therapeutic treatment of mental disorders began to be challenged.

### The Resurgence of Scientific Questioning in Europe

Paracelsus (1490–1541), a Swiss physician, was an early critic of superstitious beliefs about possession. He insisted that the dancing mania was not a possession but a form of disease, and that it should be treated as such. He also postulated a conflict between the instinctual and spiritual natures of human beings, formulated the idea of psychic causes for mental illness, and advocated treatment by “bodily magnetism,” later called hypnosis (Mora, 1967). Although Paracelsus rejected demonology, his view of abnormal behavior was colored by his belief in astral influences (*lunatic* is derived from the Latin word *luna*, or “moon”). He was convinced that the moon exerted a supernatural influence over the brain—an idea, incidentally, that persists among some people today.

Johann Weyer (1515–1588), a German physician and writer who wrote under the Latin name of Joannus Wierus, was so deeply disturbed by the imprisonment, torture, and burning of people accused of witchcraft that he made a careful study of the entire problem. About 1583 he published a book, *On the Deceits of the Demons*, that contains a step-by-step rebuttal of the *Malleus Maleficarum*, a witch-hunting handbook published in 1486 for use in recognizing and dealing with those suspected of being witches. In his book, Weyer argued that a considerable number, if not all, of those

Johann Weyer, a sixteenth-century German physician, became so concerned over the torture and imprisonment of people accused of being witches that he wrote a book rebutting the church's witch-hunting handbook, the *Malleus Maleficarum*.

imprisoned, tortured, and burned for witchcraft were really sick in mind or body and that, consequently, great wrongs were being committed against innocent people. Weyer's work enjoyed the approval of a few outstanding physicians and theologians of his time. Mostly, however, it met with vehement protest and condemnation.

Weyer was one of the first physicians to specialize in mental disorders, and his wide experience and progressive views justify his reputation as the founder of modern psychopathology. Unfortunately, however, he was too far ahead of his time. He was scorned by his peers, many of whom called him “Weirus Hereticus” and “Weirus Insanus.” His works were banned by the Church and remained so until the twentieth century.

The clergy, however, were beginning to question the practices of the time. For example, St. Vincent de Paul (1576–1660), at the risk of his life, declared, “Mental disease is no different than bodily disease and Christianity demands of the humane and powerful to protect, and the skillful to relieve the one as well as the other” (Castiglioni, 1924).

In the face of such persistent advocates of science, who continued their testimonies throughout the next two centuries, demonology and superstition gave ground. These advocates gradually paved the way for the return of observation and reason, which culminated in the development of modern experimental and clinical approaches.

### The Establishment of Early Asylums

From the sixteenth century on, special institutions called **asylums**—sanctuaries or places of refuge meant solely for the care of the mentally ill—grew in number. The early asylums were begun as a way of removing from society troublesome individuals

who could not care for themselves. Although scientific inquiry into abnormal behavior was on the increase, most early asylums, often referred to as “madhouses,” were not pleasant places or “hospitals” but primarily residences or storage places for the insane. The unfortunate residents lived and died amid conditions of incredible filth and cruelty.

The first asylum established in Europe was probably in Spain in 1409 (Villasante, 2003), although this point has been the subject of considerable discussion (Polo, 1997; Trope, 1997). Little is known about the treatment of patients in this asylum. In 1547 the monastery of St. Mary of Bethlehem in London (initially founded as a monastery in 1247; see O'Donoghue, 1914) was officially made into an asylum by Henry VIII. Its name soon was contracted to “Bedlam,” and it became widely known for its deplorable conditions and practices. The more violent patients were exhibited to the public for one penny a look, and the more harmless inmates were forced to seek charity on the streets of London. Tuke (1882) describes Ned Ward's account, in *History of the Insane in the British Isles*, of a visit to Bedlam:

*Accordingly we were admitted in thro' an iron gate, within which sat a brawny Cerberus, of an Idico-colour, leaning upon a money-box; we turned in through another Iron-Barricado, where we heard such a rattling of chains, drumming of doors, ranting, hollowing, singing, and running, that I could think of nothing but Don Quevedo's Vision where the lost souls broke loose and put Hell in an uproar. The first whimsey-headed wretch of this lunatic family that we observed, was a merry fellow in a straw cap, who was talking to himself, “that he had an army of Eagles at his command,” then clapping his hand upon his head, swore by his crown of moonshine, he would battle all the Stars in the Skies, but he would have some claret. . . . We then moved on till we found another remarkable figure worth our observing, who was peeping through his wicket, eating of bread and cheese, talking all the while like a carrier at his supper, chewing his words with his victuals, all that he spoke being in praise of bread and cheese: “bread was good with cheese, and cheese was good with bread, and bread and cheese was good together”; and abundance of such stuff; to which my friend and I, with others stood listening; at last he counterfeits a sneeze, and shot such a mouthful of bread and cheese amongst us, that every spectator had some share of his kindness, which made us retreat. (pp. 76–77)*

Such asylums for the mentally ill were gradually established in other countries, including Mexico (1566) and France (1641). An asylum was established in Moscow in 1764, and the notorious Lunatics' Tower in Vienna was constructed in 1784. This structure was a showplace in Old Vienna, an ornately decorated round tower within which were square rooms. The doctors and “keepers” lived in the square rooms, while the patients were

confined in the spaces between the walls of the rooms and the outside of the tower, where they were put on exhibit to the public for a small fee. These early asylums were primarily modifications of penal institutions, and the inmates were treated more like beasts than like human beings.

In the United States, the Pennsylvania Hospital in Philadelphia, completed under the guidance of Benjamin Franklin in 1756, provided some cells or wards for mental patients. The Public Hospital in Williamsburg, Virginia, constructed in 1773, was the first hospital in the United States devoted exclusively to mental patients. The treatment of mental patients in the United States was no better than that offered by European institutions, however. Zwelling's 1985 review of the Public Hospital's treatment methods shows that, initially, the philosophy of treatment involved the belief that the patients needed to choose rationality over **insanity**. Thus the treatment techniques were aggressive, aimed at restoring a “physical balance in the body and brain.” These techniques, though based on the scientific views of the day, were designed to intimidate patients. They included powerful drugs, water treatments, bleeding and blistering, electric shocks, and physical restraints. For example, a violent patient might be plunged into ice water or a listless patient into hot water; frenzied patients might be administered drugs to exhaust them; or patients might be bled in order to drain their system of “harmful” fluids.

## Humanitarian Reform

Clearly, by the late eighteenth century, most mental hospitals in Europe and America were in great need of reform. The humanitarian treatment of patients received great impetus from the work of Philippe Pinel (1745–1826) in France.

**PINEL'S EXPERIMENT** In 1792, shortly after the first phase of the French Revolution, Pinel was placed in charge of La Bicêtre, a hospital in Paris. In this capacity, he received the grudging permission of the Revolutionary Commune to remove the chains from some of the inmates as an experiment to test his views that mental patients should be treated with kindness and consideration—as sick people, not as vicious beasts or criminals. Had his experiment proved a failure, Pinel might have lost his head, but fortunately it was a great success. Chains were removed; sunny rooms were provided; patients were permitted to exercise on the hospital grounds; and kindness was extended to these poor beings, some of whom had been chained in dungeons for 30 or more years. The effect was almost miraculous. The previous noise, filth, and abuse were replaced by order and peace. Interestingly, a historical document, subsequently found in the French Archives, raises some question about the date at which humanitarian reforms were begun in France. The document, provided by Jean-Baptiste Pussin (Pinel's predecessor at La Bicêtre),

This painting depicts Philippe Pinel supervising the unchaining of inmates at La Bicêtre hospital. Pinel's experiment represented both a great reform and a major step in devising humanitarian methods of treating mental disorders.

indicated that he had been the head of the hospital beginning in 1784 and had removed some of the chains from patients and employed slightly more humane straitjackets instead. He also pointed out in the document that he had issued orders forbidding the staff from beating patients (Weiner, 1979).

**TUKE'S WORK IN ENGLAND** At about the same time that Pinel was reforming La Bicêtre, an English Quaker named William Tuke (1732–1822) established the York Retreat, a pleasant country house where mental patients lived, worked, and rested

in a kindly, religious atmosphere (Narby, 1982). This retreat represented the culmination of a noble battle against the brutality, ignorance, and indifference of Tuke's time.

The Quakers believed in treating all people, even the insane, with kindness and acceptance. Their view that kind acceptance would help mentally ill people recover sparked the growth of more humane psychiatric treatment during a period when mental patients were ignored and mistreated (Glover, 1984).

The Quaker retreat at York has continued to provide humane mental health treatment for over 200 years (Borthwick et al., 2001), even though the mental hospital movement spawned by its example evolved into large mental hospitals that became crowded and often offered less-than-humane treatment in the late nineteenth and early twentieth centuries. (See the picture of the York Retreat today below.)

As word of Pinel's amazing results spread to England, Tuke's small force of Quakers gradually gained the support of English medical practitioners such as Thomas Wakley and Samuel Hitch. In 1841 Hitch introduced trained nurses into the wards at the Gloucester Asylum and put trained supervisors at the head of the nursing staffs. These innovations, quite revolutionary at the time, not only improved the care of mental patients but also changed public attitudes toward the mentally disturbed. In 1842, following Wakley's lobbying for change, the Lunacy Inquiry Act was passed, which included the requirement of effective inspection of asylums and houses every four months (Roberts, 1981) to ensure proper diet and the elimination of the use of restraints.

In 1845, the Country Asylums Act was passed in England, which required every county to provide asylum to "paupers and lunatics" (Scull, 1996). Britain's policy of providing more humane treatment of the mentally ill was substantially expanded to the colonies (Australia, Canada, India, West Indies, South

This picture shows a male ward of Bethlem hospital under the new, more humane treatment approach. Walford (1878) pointed out that by 1815, there was no more "show for a penny" at Bethlem Hospital, and patients were afforded more humane living facilities and activities.

The historic mental health facility, the York Retreat, continues to provide services in York, England, over 200 years since it was founded by William Tuke in 1796. This mental health facility is sponsored by the Quakers and provides a broad range of services in both inpatient and outpatient care.

Africa, etc.) after a widely publicized incident of maltreatment of patients that occurred in Kingston, Jamaica prompted an audit of colonial facilities and practices. In Kingston, an article written by a former patient disclosed that the staff used “tanking” to control and punish mental patients. During tanking, “lunatics” were routinely held under water in a bathing tank by nurses and sometimes other patients until they were near death (Swartz, 2010).

**RUSH AND MORAL MANAGEMENT IN AMERICA** The success of Pinel’s and Tuke’s humanitarian experiments revolutionized the treatment of mental patients throughout the Western world. In the United States, this revolution was reflected in the work of Benjamin Rush (1745–1813), the founder of American psychiatry and also one of the signers of the Declaration of Independence. While he was associated with the Pennsylvania Hospital in 1783, Rush encouraged more humane treatment of the mentally ill; wrote the first systematic treatise on psychiatry in America, *Medical Inquiries and Observations upon Diseases of the Mind* (1812); and was the first American to organize a course in psychiatry (see Gentile & Miller, 2009). But even he did not escape entirely from the established beliefs of his time. His medical theory was tainted with astrology, and his principal remedies were bloodletting and purgatives. In addition, he invented and used a device called “the tranquilizing chair,” which was probably more torturous than tranquil for patients. The chair was thought to lessen the force of the blood on the head while the muscles were relaxed. Despite these limitations, we can consider Rush an important transitional figure between the old era and the new.

During the early part of this period of humanitarian reform, the use of **moral management**—a wide-ranging method of treatment that focused on a patient’s social, individual, and occupational needs—became relatively widespread. This approach, which stemmed largely from the work of Pinel and Tuke, began in Europe during the late eighteenth century and in America during the early nineteenth century.

Moral management in asylums emphasized the patients’ moral and spiritual development and the rehabilitation of their “character” rather than their physical or mental disorders, in part because very little effective treatment was available for these conditions at the time. The treatment or rehabilitation of the physical or mental disorders was usually through manual labor and spiritual discussion, along with humane treatment.

Moral management achieved a high degree of effectiveness—which is all the more amazing because it was done without the benefit of the antipsychotic drugs used today and because many of the patients were probably suffering from syphilis, a then-incurable disease of the central nervous system. In the 20-year period between 1833 and 1853, Worcester State Hospital’s discharge rate for patients who had been ill less than a year before admission was 71 percent. Even for patients with a longer

preadmission disorder, the discharge rate was 59 percent (Bockhoven, 1972). In London, Walford (1878) reported that during a 100-year period ending in 1876, the “cure” rate was 45.7 percent for the famed Bedlam Hospital.

Despite its reported effectiveness in many cases, moral management was nearly abandoned by the latter part of the nineteenth century. The reasons were many and varied. Among the more obvious ones were ethnic prejudice against the rising immigrant population in hospitals, leading to tension between staff and patients; the failure of the movement’s leaders to train their own replacements; and the overextension of hospital facilities, which reflected the misguided belief that bigger hospitals would differ from smaller ones only in size.

Two other reasons for the demise of moral management are, in retrospect, truly ironic. One was the rise of the **mental hygiene movement**, which advocated a method of treatment that focused almost exclusively on the physical well-being of hospitalized mental patients. Although the patients’ comfort levels improved under the mental hygienists, the patients received no help for their mental problems and thus were subtly condemned to helplessness and dependency.

Advances in biomedical science also contributed to the demise of moral management and the rise of the mental hygiene movement. These advances fostered the notion that all mental disorders would eventually yield to biological explanations and biologically based treatments (Luchins, 1989). Thus the psychological and social environment of a patient was considered largely irrelevant; the best one could do was keep the patient comfortable until a biological cure was discovered. Needless to say, the anticipated biological cure-all did not arrive, and by the late 1940s and early 1950s, discharge rates were down to about 30 percent. Its negative effects on the use of moral management notwithstanding, the mental hygiene movement has accounted for many humanitarian accomplishments.

**BENJAMIN FRANKLIN’S EARLY DISCOVERY OF THE POTENTIAL CURATIVE EFFECTS OF ELECTRIC SHOCK** In school, most people learn about Benjamin Franklin’s early experimentation with electricity in the early eighteenth century. His kite-flying during electric storms and its influence on the physical sciences is common knowledge. However, most people (even mental health professionals) are not aware that his work with electricity was among the earliest efforts to explore electric shock to treat mental illness, an insight he gained accidentally. His proposals for using electricity to treat melancholia (depression) grew out of his observations that a severe shock he had experienced altered his memories (see the informative discussion by Finger & Zaromb, 2006). Franklin published articles describing his experience and suggested that physicians further study this method for treating melancholia. Shortly afterward, one of his friends, a physician named Ingenhousz, reported a similar incident in which he observed alterations in his

thinking following a shock he had received. He too called for clinical trials to study this phenomenon as a possible treatment for psychiatric patients.

Although these early efforts pointed attention to a potentially valuable treatment approach, medical research on the procedure was slow to develop. Finger and Zaromb (2006) point out that it was not until the middle of the eighteenth century that electric shock was associated with amnesia. Moreover, it was not until the twentieth century that Cerletti and Bini (1938), at the University of Rome, initiated electric shock as a treatment for depression.

**DIX AND THE MENTAL HYGIENE MOVEMENT** Dorothea Dix (1802–1887) was an energetic New Englander who became a champion of poor and “forgotten” people in prisons and mental institutions for decades during the nineteenth century. Dix, herself a child of very difficult and impoverished circumstances (Viney, 1996), later became an important driving force in humane treatment for psychiatric patients. She worked as a schoolteacher as a young adult but was later forced into early retirement because of recurring attacks of tuberculosis. In 1841, she began to teach in a women’s prison. Through this contact she became acquainted with the deplorable conditions in jails, almshouses, and asylums. In a “Memorial” submitted to the U.S. Congress in 1848, she stated that she had seen

*more than 9000 idiots, epileptics and insane in the United States, destitute of appropriate care and protection . . . bound with galling chains, bowed beneath fetters and heavy iron bails attached to drag-chains, lacerated with ropes, scourged with rods and terrified beneath storms of execration and cruel blows; now subject to jibes and scorn and torturing tricks; now abandoned to the most outrageous violations. (Zilboorg & Henry, 1941, pp. 583–584)*

As a result of what she had seen, Dix carried on a zealous campaign between 1841 and 1881 that aroused people and legislatures to do something about the inhuman treatment accorded the mentally ill. Through her efforts, the mental hygiene movement grew in America: Millions of dollars were raised to build suitable hospitals, and 20 states responded directly to her appeals. Not only was she instrumental in improving conditions in American hospitals but she also directed the opening of two large institutions in Canada and completely reformed the asylum system in Scotland and several other countries. She is credited with establishing 32 mental hospitals, an astonishing record given the ignorance and superstition that still prevailed in the field of mental health. Dix rounded out her career by organizing the nursing forces of the Northern armies during the Civil War. A resolution presented by the U.S. Congress in 1901 characterized her as “among the noblest examples of humanity in all history” (Karnesh, with Zucker, 1945, p. 18).

Dorothea Dix (1802–1887) was a tireless reformer who made great strides in changing public attitudes toward the mentally ill.

Later critics have claimed that establishing hospitals for the mentally ill and increasing the number of people in them spawned overcrowded facilities and custodial care (Bockhoven, 1972; Dain, 1964). These critics have further claimed that housing patients in institutions away from society interfered with the treatment of the day (moral therapy) and deferred the search for more appropriate and effective treatments for mental disorders (Bockhoven, 1972). These criticisms, however, do not consider the context in which Dix’s contributions were made (see the Unresolved Issues at the end of this chapter). Her advocacy of the humane treatment of the mentally ill stood in stark contrast to the cruel treatment common at the time (Viney & Bartsch, 1984).

**THE MILITARY AND THE MENTALLY ILL** Mental health treatment was also advanced by military medicine. The first mental health facility for treating mentally disordered war casualties was opened by the Confederate Army in the American Civil War (Deutsch, 1944; Gabriel, 1987). An even more extensive and influential program of military psychiatry evolved in Germany during the late 1800s. Lengweiler (2003) reviews the evolution of military psychiatry in Germany between the Franco-Prussian War in 1870 and World War I in 1914. During this period, psychiatrists, a number of whom made great contributions to the field of abnormal psychology (e.g., Emil Kraepelin and Richard von Krafft-Ebing), worked with the military administration, conducting research and training

doctors to detect mental health problems that could interfere with performance of duty. One early research program illustrates the interplay between medicine and military administration. Kraepelin, who viewed alcohol as a key cause of psychological problems among soldiers, conducted a research project evaluating the extent to which alcohol consumption adversely affected the soldiers' ability to fire their rifles effectively.

### Nineteenth-Century Views of the Causes and Treatment of Mental Disorders

In the early part of the nineteenth century, mental hospitals were controlled essentially by laypersons because of the prominence of moral management in the treatment of "lunatics." Medical professionals—or "alienists," as psychiatrists were called at this time in reference to their treating the "alienated," or insane—had a relatively inconsequential role in the care of the insane and the management of the asylums of the day. Moreover, effective treatments for mental disorders were unavailable, the only measures being such procedures as drugging, bleeding, and purging, which produced few objective results. However, during the latter part of the century, alienists gained control of the insane asylums and incorporated the traditional moral management therapy into their other rudimentary physical medical procedures.

Over time, the alienists acquired more status and influence in society and became influential as purveyors of morality, touting the benefits of Victorian morality as important to good mental health. Mental disorders were only vaguely understood, and conditions such as melancholia (depression) were considered to be the result of nervous exhaustion. That is, psychiatrists of the time thought that emotional problems were caused by the expenditure of energy or by the depletion of bodily energies as a result of excesses in living. The mental deterioration or "shattered nerves" that supposedly resulted from a person's using up precious nerve force came to be referred to as "neurasthenia," a condition that involved pervasive feelings of low mood, lack of energy, and physical symptoms that were thought to be related to "lifestyle" problems brought on by the demands of civilization. These vague symptoms, viewed by the alienists/psychiatrists as a definable medical condition, were then considered treatable by medical men of the times.

### Changing Attitudes Toward Mental Health in the Early Twentieth Century

It is difficult to partition modern views of abnormal behavior into discrete, uniform attitudes or to trace their historical precedents without appearing arbitrary and overly simplistic. However, a brief, selective overview here will bring us into the contemporary era and set the scene for our discussion of the major viewpoints and causal considerations discussed in Chapter 3. By the end of the nineteenth century, the mental

In the first half of the twentieth century, hospital care for the mentally ill afforded very little in the way of effective treatment. In many cases, the care was considered to be harsh, punitive, and inhumane.

hospital or asylum—"the big house on the hill"—with its fortress-like appearance, had become a familiar landmark in America (see Payne & Sacks, 2009). In it, mental patients lived under relatively harsh conditions despite the inroads made by moral management. To the general public, however, the asylum was an eerie place and its occupants a strange and frightening lot. Little was done by the resident psychiatrists to educate the public or reduce the general fear and horror of insanity. A principal reason for this silence, of course, was that early psychiatrists had little actual information to impart and in some cases employed procedures that were damaging to patients.

Gradually, however, important strides were made toward changing the general public's attitude toward mental patients. In America, the pioneering work of Dix was followed by that of Clifford Beers (1876–1943), whose book *A Mind That Found Itself* was first published in 1908. Beers, a Yale graduate, described his own mental collapse and told of the bad treatment he received in three typical institutions of the day. Although chains and other torture devices had long since been given up, the straitjacket was still widely used as a means of "quieting" excited patients. Beers experienced this treatment and supplied a vivid description of what such painful immobilization of the arms means to an overwrought mental patient in a widely read description of his experiences.

After Beers recovered in the home of a kind attendant, he launched a campaign to make people realize that such treatment was no way to handle the sick. He soon won the interest and support of many public-spirited individuals, including the eminent psychologist William James and the "dean of American psychiatry," Adolf Meyer.

## Chaining Mental Health Patients

Because of limited mental health treatment resources in some countries, it is not uncommon for mentally ill people to be chained. Westermeyer and Kroll (1978) conducted an epidemiologic study on the use of restraints for mentally ill people in 27 villages in Laos. They reported that mentally ill people who were aggressive toward others or who were considered to be a danger to themselves were sometimes restrained by being chained to posts. The woman from Laos in the photograph shown here suffered from a psychotic disorder and reportedly felt compelled to sweep her platform for 6 or 7 hours a day. She was restrained at a Buddhist temple in order to keep her from wandering into the jungle (Westermeyer, 2001).

Chained patient from Laos

Treatment of patients at the Mohammad Ali Shah Shrine in eastern Afghanistan involves being fed only a small piece of bread, a raw chili, and water each day for 21 days. Their family is charged 20 pounds a month. Many patients are chained as a means of controlling their behavior.

Many temples in some countries provide homes for psychologically disturbed individuals, although the care is typically inadequate. For example, Erwady, India, near Madras, has 15 privately run homes, many of which are without electricity, tap water, toilet facilities, and beds. In 2000, six people died from waterborne disease at one of the Erwady asylums, prompting the government to direct an inquiry into the conditions of the mental health asylums. Later, fire swept through a palm-thatched shed that housed mentally ill people at one Erwady asylum, killing 25 patients and injuring 5 others, many of whom were chained to heavy stones or pillars (Associated Press, 2001). At the time of the fire, the asylum housed 46 residents; only 16 of the patients escaped uninjured.

## Mental Hospital Care in the Twentieth Century

The twentieth century began with a continued period of growth in asylums for the mentally ill; however, the fate of mental patients during that century was neither uniform nor entirely positive (see The World Around Us box). At the beginning of the twentieth century, with the influence of enlightened people such as Clifford Beers, mental hospitals grew substantially in number—predominantly to house persons with severe mental disorders such as schizophrenia, depression, organic mental disorders, tertiary syphilis and paresis (syphilis of the brain), and severe alcoholism. By 1940 the public mental hospitals housed over 400,000 patients, roughly 90 percent of whom resided in large state-funded hospitals; the remainder resided in private hospitals (Grob, 1994). During this period, hospital stays were typically quite lengthy, and many mentally ill individuals were destined to be hospitalized for many years. For the first half of the twentieth century, hospital care was accompanied by little

in the way of effective treatment, and the care was often harsh, punitive, and inhumane. The year 1946, however, marked the beginning of an important period of change. In that year, Mary Jane Ward published a very influential book, *The Snake Pit*, which was popularized in a movie of the same name. This work called attention to the plight of mental patients and helped to create concern over the need to provide more humane mental health care in the community in place of the overcrowded mental hospitals. Also in 1946, the National Institutes of Mental Health was organized and provided active support for research and training through psychiatric residencies and (later) clinical psychology training programs. Moreover, the Hill-Burton Act, a program that funded community mental health hospitals, was passed during this period. This legislation, along with the Community Health Services Act of 1963, helped to create a far-reaching set of programs to develop outpatient psychiatric clinics, inpatient facilities in general hospitals, and community consultation and rehabilitation programs.

The need for reform in psychiatric hospitals was a prominent concern of many professionals and laypersons alike during the 1950s and 1960s. A great deal of professional attention was given to the need to improve conditions in mental hospitals following the publication of another influential book, *Asylums*, by the sociologist Erving Goffman (1961). This book further exposed the inhumane treatment of mental patients and provided a detailed account of neglect and maltreatment in mental hospitals. The movement to change the mental hospital environment was also enhanced significantly by scientific advances in the last half of the twentieth century, particularly the development of effective medications for many disorders—for example, the use of lithium in the treatment of manic depressive disorders (Cade, 1949) and the introduction of phenothiazines for the treatment of schizophrenia. (See Developments in Research on p. 45 and Chapter 17 for further discussion.)

During the latter decades of the twentieth century, our society had seemingly reversed its position with respect to the means of providing humane care for the mentally ill in the hospital environment. Vigorous efforts were made to close down mental hospitals and return psychiatrically disturbed people to the community, ostensibly as a means of providing more integrated and humane treatment than was available in the “isolated” environment of the psychiatric hospital and because of the success of medications (chlorpromazines) that emerged in the 1950s to alleviate psychotic symptoms (Alanen et al., 2009). Large numbers of psychiatric hospitals were closed, and there was a significant reduction in state and county mental hospital populations, from over half a million in 1950 (Lerman, 1981) to about 100,000 by the early 1990s (Narrow et al., 1993). These reductions are all the more impressive given that the U.S. population increased substantially over those years. This movement, referred to as **deinstitutionalization**, although motivated by benevolent goals, has also created great difficulties for many psychologically disturbed persons and for many communities as well.

As a phenomenon, deinstitutionalization is an international movement. For example, there has been a shift in the locus of care of patients with chronic psychiatric illnesses from psychiatric hospitals to community-based residential services in Hong Kong (Chan, 2001), in the Netherlands (Pijl et al., 2001), and in Finland (Korkeila et al., 1998). Some countries have experienced extensive deinstitutionalization over the past 20 years. For example, in England and Wales during the last decades of the twentieth century, only 14 of 130 psychiatric institutions remained open; and Australia showed a 90 percent reduction in hospital beds over the same period (Goldney, 2003). In a follow-up study of patients from 22 hospitals in Italy, D’Avanzo and colleagues (2003) report that all were closed and 39 percent of the patients in these hospitals had been discharged to nursing homes, 29 percent to residential facilities, and 29 percent to other psychiatric hospitals; only 2 percent were returned to their families.

The original impetus behind the deinstitutionalization policy was that it was considered more humane (and cost effective)

Freed from the confines of institutionalized care, or abandoned by society? Many homeless people suffer from one or more mental disorders. Deinstitutionalization, though motivated by benevolent goals, has created great difficulties for many psychologically disturbed individuals who have been released to a cruel and harsh existence.

to treat disturbed people outside of large mental hospitals because doing so would prevent people from acquiring negative adaptations to hospital confinement. Many professionals were concerned that the mental hospitals were becoming permanent refuges for disturbed people who were “escaping” from the demands of everyday living and were settling into a chronic sick role with a permanent excuse for letting other people take care of them. There was great hope that new medications would promote a healthy readjustment and enable former patients to live more productive lives outside the hospital. Many former patients have not fared well in community living, however, and authorities now frequently speak of the “abandonment” of chronic patients to a cruel and harsh existence. Evidence of this failure to treat psychiatric patients successfully in the community can be readily seen in our cities: Many of the people living on the streets in large cities today are homeless and mentally ill. The problems caused by deinstitutionalization appear to be due, in no small part, to the failure of society to develop ways to fill the gaps in mental health services in the community (Grob, 1994).

The mental institution, once thought to be the most humane way to manage the problems of the severely mentally ill, came to be seen as obsolete or as an evil alternative, more of a problem than a solution to mental health problems. By the end of the twentieth century, inpatient mental hospitals had been substantially replaced by community-based care, day treatment hospitals, and outreach.

The twentieth century closed on a note of uncertainty with respect to the best ways to manage the needs of severely disturbed psychiatric patients. It is clear that closing mental hospitals and providing treatment for severely disturbed people in the community has not proved to be the panacea it was touted to be only a few years ago (Whitaker, 2009). As we will discuss further in Chapter 17, deinstitutionalization has created problems for both patients and society as a whole. The role of the psychiatric hospital in helping those with severe psychiatric problems

is likely to undergo further evolution as society again finds itself unable to deal effectively with the problems that severe mental illness can create if ignored or left unattended (see Grob, 1994).

### in review

- Describe the changing views toward mental illness that evolved as scientific thinking came to have greater influence in Europe in the sixteenth and seventeenth centuries.
- Discuss the development of the psychiatric hospital.
- Describe the historical development of humanitarian reform, and give some of the reasons why it occurred.
- Describe the changes in social attitudes that brought about major changes in the way persons with mental disorders have been treated.

## The Emergence of Contemporary Views of Abnormal Behavior

While the mental hygiene movement was gaining ground in the United States during the latter years of the nineteenth century, great technological discoveries occurred both at home and abroad. These advances helped usher in what we know today as the scientific, or experimentally oriented, view of abnormal behavior and the application of scientific knowledge to the treatment of disturbed individuals. We will describe four major themes in abnormal psychology that spanned the nineteenth and twentieth centuries and generated powerful influences on our contemporary perspectives in abnormal behavior: (1) biological discoveries, (2) the development of a classification system for mental disorders, (3) the emergence of psychological causation views, and (4) experimental psychological research developments.

### Biological Discoveries: Establishing the Link Between the Brain and Mental Disorder

Advances in the study of biological and anatomical factors as underlying both physical and mental disorders developed in this period. A major biomedical breakthrough, for example, came with the discovery of the organic factors underlying general paresis—syphilis of the brain. One of the most serious mental illnesses of the day, general paresis produced paralysis and insanity and typically caused death within 2 to 5 years as a result of brain deterioration. This scientific discovery, however, did not occur overnight; it required the combined efforts of many scientists and researchers for nearly a century.

**GENERAL PARESIS AND SYPHILIS** The discovery of a cure for general paresis began in 1825, when the French physician A. L. J. Bayle differentiated general paresis as a specific type of mental disorder. Bayle gave a complete and accurate description of the symptom pattern of paresis and convincingly presented his reasons for believing paresis to be a distinct disorder. Many years later, in 1897, the Viennese psychiatrist Richard von Krafft-Ebbing conducted experiments involving the inoculation

of paretic patients with matter from syphilitic sores. None of the patients developed secondary symptoms of syphilis, which led to the conclusion that they must previously have been infected. This crucial experiment established the relationship between general paresis and syphilis. It was almost a decade later, in 1906, when August von Wassermann devised a blood test for syphilis. This development made it possible to check for the presence of the deadly bacteria in the bloodstream of an individual before the more serious consequences of infection appeared.

Finally, in 1917, Julius von Wagner-Jauregg, chief of the psychiatric clinic of the University of Vienna, introduced the malarial fever treatment of syphilis and paresis because he knew that the high fever associated with malaria killed off the bacteria. He infected nine paretic patients with the blood of a malaria-infected soldier and found marked improvement in paretic symptoms in three patients and apparent recovery in three others. By 1925 several hospitals in the United States were incorporating the new malarial treatment for paresis into their hospital treatments. One of the earliest controlled studies of malarial treatment for paresis was conducted by Bahr and Brutsch in Indiana in 1928. They found that out of the 100 patients studied, 37 percent of paresis patients showed significant recovery, 25 percent had been discharged, and 21 percent of those had returned to their previous or similar occupations. Today, of course, we have penicillin as an effective, simpler treatment of syphilis, but the early malarial treatment represented the first clear-cut conquest of a mental disorder by medical science. The field of abnormal psychology had come a long way—from superstitious beliefs to scientific proof of how brain pathology can cause a specific disorder. This breakthrough raised great hopes in the medical community that organic bases would be found for many other mental disorders—perhaps for all of them.

**BRAIN PATHOLOGY AS A CAUSAL FACTOR** With the emergence of modern experimental science in the early part of the eighteenth century, knowledge of anatomy, physiology, neurology, chemistry, and general medicine increased rapidly. Scientists began to focus on diseased body organs as the cause of physical ailments. It was the next logical step for these researchers to assume that mental disorder was an illness based on the pathology of an organ—in this case, the brain. In 1757 Albrecht von Haller (1708–1777), in his *Elementa physiologae corporis humani*, emphasized the importance of the brain in psychic functions and advocated postmortem dissection to study the brains of the insane. The first systematic presentation of this viewpoint, however, was made by the German psychiatrist Wilhelm Griesinger (1817–1868). In his textbook *The Pathology and Therapy of Psychic Disorders*, published in 1845, Griesinger insisted that all mental disorders could be explained in terms of brain pathology. Following the discovery that brain deterioration resulted in general paresis, other successes followed. Alois Alzheimer and other investigators established the brain

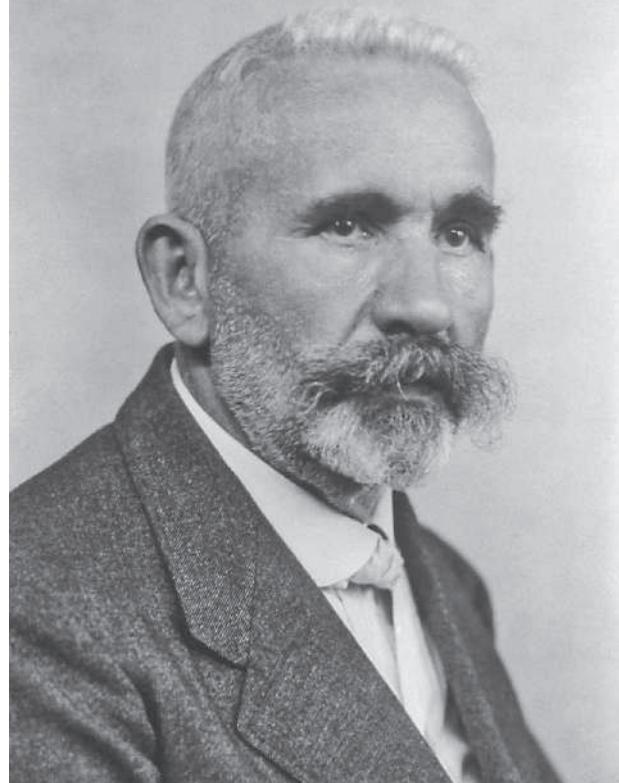

pathology in cerebral arteriosclerosis and in the senile mental disorders. Eventually, in the twentieth century, the organic pathologies underlying the toxic mental disorders (disorders caused by toxic substances such as lead), certain types of mental retardation, and other mental illnesses were discovered.

Along with the advancements in mental health treatment in the twentieth century came some unfortunate missteps. During the early years of the twentieth century, Henry Cotton, a psychiatrist at a New Jersey hospital, developed a theory that mental health problems such as schizophrenia could be cured by removing the infections that he believed caused the condition. He used surgical procedures to remove all of a person's teeth or body parts such as tonsils, parts of the colon, testicles, or ovaries in order to reduce the infection (Scull, 2005). In the 1920s through the 1940s, an American psychiatrist, Walter Freeman, followed the strategies developed by Italian psychiatrist Egas Moniz to treat severe mental disorders using surgical procedures called *lobotomies*. Freeman modified the surgery used by Moniz, using an ice pick to sever the neural connections in the brain after entering through the patient's eye sockets (see discussion on lobotomy by El-Hai, 2005). These surgical efforts to treat mental disorder were considered to be ineffective and inappropriate by many in the profession at the time and were eventually discredited, although lobotomy is still used in some rare cases.

It is important to note here that although the discovery of the organic bases of mental disorders addressed the "how" behind causation, it did not, in most cases, address the "why." This is sometimes true even today. For example, although we know what causes certain "presenile" mental disorders—brain pathology—we do not yet know why some individuals are afflicted and others are not. Nonetheless, we can predict quite accurately the courses of these disorders. This ability is due not only to a greater understanding of the organic factors involved but also, in large part, to the work of a follower of Griesinger, Emil Kraepelin.

## The Development of a Classification System

Emil Kraepelin (1856–1926), another German psychiatrist, played a dominant role in the early development of the biological viewpoint. His textbook *Compendium der Psychiatrie*, published in 1883, not only emphasized the importance of brain pathology in mental disorders but also made several related contributions that helped establish this viewpoint. The most important of these contributions was his system of classification of mental disorders, which became the forerunner of today's *DSM* classification (see Chapter 1). Kraepelin noted that certain symptom patterns occurred together regularly enough to be regarded as specific types of mental disease. He then proceeded to describe and clarify these types of mental disorders, working out a scheme of classification that is the basis of our present system. Integrating all of the clinical material underlying this classification was a Herculean task and represented a major contribution to the field of psychopathology.

Emil Kraepelin (1856–1926) was a German psychiatrist who developed an early synthesis and classification system of the hundreds of mental disorders by grouping diseases together based on common patterns of symptoms. Kraepelin also demonstrated that mental disorders showed specific patterns in the genetics, course, and outcome of disorders.

Kraepelin saw each type of mental disorder as distinct from the others and thought that the course of each was as predetermined and predictable as the course of measles. Thus the outcome of a given type of disorder could presumably be predicted even if it could not yet be controlled. Such claims led to widespread interest in the accurate description and classification of mental disorders.

## Development of the Psychological Basis of Mental Disorder

Despite the emphasis on biological research, understanding of the psychological factors in mental disorders was progressing as well. The first major steps were taken by Sigmund Freud (1856–1939), the most frequently cited psychological theorist of the twentieth century (Street, 1994). During five decades of observation, treatment, and writing, Freud developed a comprehensive theory of psychopathology that emphasized the inner dynamics of unconscious motives (often referred to as *psycho-dynamics*) that are at the heart of the **psychoanalytic perspective**. The methods he used to study and treat patients came to be called **psychoanalysis**. We can trace the ancestral roots of psychoanalysis to a somewhat unexpected place—the study of hypnosis, especially in its relation to hysteria (for a contemporary discussion of hysteria see Brown, 2006). Hypnosis, an induced state of relaxation in which a person is highly open to suggestion, first came into widespread use in late-eighteenth- and early-nineteenth-century France.

### The Search for Medications to Cure Mental Disorders

For centuries physicians have sought a medicinal cure for mental disorder. One of the earliest known treatises on the use of drugs to treat mental disorders is the work of the Roman physician Galen (A.D. 130–200). His writing details both the concoction of various medications and the clinical use of drug therapy with patients experiencing mental disorders. Most of his medications were laxatives and emetics (purgatives) that were used to cleanse the body of nonhuman materials believed to be causing the person's ills. During the Middle Ages, another notable but highly controversial physician-chemist named Paracelsus (1490–1541) experimented with various chemicals as medications to treat human disorders. He even used a substance referred to as "mummy powder" (ground up particles of mummies) and various other, seemingly more potent substances such as mercury.

A more recent phase in the development of psychotropic medicine began in the 1950s. The root *Rauwolfia serpentina* had been used for centuries as an herbal folk medicine in India, where it had been prescribed for a wide array of afflictions, including insanity. In the early 1950s the active ingredient in *Rauwolfia*, reserpine, was isolated by a Swiss drug company, and in 1953 psychiatrist R. A. Hakim wrote a prize-winning paper on using *Rauwolfia* to treat psychosis (as cited in Gupta et al., 1943). Today reserpine has been surpassed as a treatment for psychoses because of the development of other drugs and because of its side effects, and it is mostly used in the treatment of hypertension.

The second psychoactive drug to emerge in the 1950s as a treatment for severe mental disorder was chlorpromazine. A German chemist named Bernthsen, searching for compounds that would operate as dyes, first developed the drug in the latter part of the nineteenth century. He synthesized a compound that is referred to as phenothiazine. Paul Erlich, a medical researcher and father of the field of chemotherapy, thought that this compound might be effective in treating human diseases by killing nonhuman cells while preserving human tissue. The drug was first tried as a means of treating malaria, and by the 1930s it was being employed as an anesthetic. In 1951, the

French surgeon Henri Labroit employed the drug as an "artificial hibernator" to prevent shock among surgical patients. It was not until 1952 that two French psychiatrists, Jean Delay and Pierre Deniker, finding that the drug reduced psychotic symptoms, began to use chlorpromazine to treat psychiatric patients.

The almost magical impact of antipsychotic medication was immediately felt in the psychiatric community in the United States. By 1956, the first year of widespread use of reserpine and chlorpromazine, the impact on psychiatric hospitalization had begun to show a remarkable effect. The previously increasing admission rate to psychiatric hospitals leveled off at 560,000 psychiatric inpatients in the United States. This number dropped to 490,000 by 1964 and to 300,000 by 1971. Currier (2000) reported that the number of inpatient psychiatric beds decreased sharply over the past generation, both in absolute numbers and as a percentage of total hospital beds in seven countries including the United States. The drop in available hospital beds between 1960 and 1994 was from 4 per thousand to less than 1.3 per thousand of the population. In the United States, the available bed reductions were fostered by the movement for deinstitutionalization and the development of managed care. In Europe and other regions, the number of beds decreased largely as a result of intense government pressure to curtail health care budgets. Interestingly, the need for psychiatric inpatient care has remained despite the closing of public mental health hospitals. Hutchins and colleagues (2011) point out that the number of private mental hospitals doubled between 1976 and 1992 and that two-thirds of all psychiatric hospitals and half of all inpatient beds were in private facilities.

The effectiveness of drugs in reducing psychotic symptoms has also led researchers to develop more specific causal hypotheses for mental disorders such as schizophrenia. Researchers have noted that antipsychotic drugs such as the phenothiazines modify the levels of dopamine, a neurotransmitter associated with schizophrenia. These observations have led theoreticians to the "dopamine hypothesis"—that the metabolism of dopamine is associated with the cause of schizophrenia.

**MESMERISM** Our efforts to understand psychological causation of mental disorder start with Franz Anton Mesmer (1734–1815), an Austrian physician who further developed the ideas of Paracelsus (the influential sixteenth-century physician and scholar; see Developments in Research above) about the influence of the planets on the human body. Mesmer believed that the planets affected a universal magnetic fluid in the body, the distribution of which determined health or disease. In attempting to find cures

for mental disorders, Mesmer concluded that all people possessed magnetic forces that could be used to influence the distribution of the magnetic fluid in other people, thus effecting cures.

Mesmer attempted to put his views into practice in Vienna and various other cities, but it was in Paris in 1778 that he gained a broad following. There, he opened a clinic in which he treated all kinds of diseases by using "animal magnetism." In a dark room, patients were seated around a tub containing various

Mesmer believed that the distribution of magnetic fluid in the body was responsible for determining health or disease. He further thought that all people possessed magnetic forces that could be used to influence the distribution of fluid in others, thus effecting cures. In this painting of his therapy, Mesmer stands on the far right, holding a wand. He was eventually branded a fraud by his colleagues. His theories did, however, demonstrate most of the phenomena later connected with the use of hypnosis.

chemicals, and iron rods protruding from the tub were applied to the affected areas of the patients' bodies. Accompanied by music, Mesmer appeared in a lilac robe, passing from one patient to another and touching each one with his hands or his wand. By this means, Mesmer was reportedly able to remove hysterical anesthesias and paryses. He also demonstrated most of the phenomena later connected with the use of hypnosis.

Mesmer was eventually branded a charlatan by his medical colleagues and an appointed body of noted scholars that included the American scientist Benjamin Franklin (Van Doren, 1938). The committee conducted what have been referred to as the first psychological experiments (Dingfelder, 2010), or tests such as tricking a woman into believing that she had been influenced by magnetism. The committee concluded that the real source of Mesmer's power was in the patients and not in "magnetism." Mesmer was forced to leave Paris and quickly faded into obscurity. His methods and results, however, were at the center of scientific controversy for many years—in fact, **mesmerism**, as his technique came to be known, was as much a source of heated discussion in the early nineteenth century as psychoanalysis became in the early twentieth century. This discussion led to renewed interest in hypnosis itself as an explanation of the "cures" that took place.

Even after mesmerism was discredited in France, this method of inducing trance and its perceived potential for treating illness had a long life in the United States. The magical powers of mesmerism were introduced in 1836 and intrigued a number of Americans, ranging from the poet Emerson to the physician Benjamin Rush, with speculations about its higher mental powers and its potential application as an anesthetic for surgical procedures (Schmit, 2005). A number of lecturers traveled the United States illustrating its medical use and giving demonstrations, including to the U.S. Congress. The early mesmerists, though considered to be "quacks" by many physicians, had an influence on medical practice until the introduction of

ether as a surgical anesthetic (Schmit, 2005). In spite of its limitations, mesmerism clearly had an influence on psychology and hypnosis for many years and came to be influential in spiritual movements such as Christian Science in the nineteenth century.

**THE NANCY SCHOOL** Ambrose August Liébeault (1823–1904), a French physician who practiced in the town of Nancy, used hypnosis successfully in his practice. Also in Nancy at the time was a professor of medicine, Hippolyte Bernheim (1840–1919), who became interested in the relationship between hysteria and hypnosis. His interest was piqued by Liébeault's success in using hypnosis to cure a patient whom Bernheim had been treating unsuccessfully by more conventional methods for 4 years (Selling, 1943). Bernheim and Liébeault worked together to develop the hypothesis that hypnotism and hysteria were related and that both were due to suggestion (Brown & Menninger, 1940). Their hypothesis was based on two lines of evidence: (1) The phenomena observed in hysteria—such as paralysis of an arm, inability to hear, and anesthetic areas in which an individual could be stuck with a pin without feeling pain (all of which occurred when there was apparently nothing organically wrong)—could be produced in normal subjects by means of hypnosis. (2) The same symptoms also could be removed by means of hypnosis. Thus it seemed likely that hysteria was a sort of self-hypnosis. The physicians who accepted this view ultimately came to be known as the **Nancy School**.

Meanwhile, Jean Charcot (1825–1893), who was head of the Salpêtrière Hospital in Paris and the leading neurologist of his time, had been experimenting with some of the phenomena described by the mesmerists. As a result of his research, Charcot disagreed with the findings of the Nancy School and insisted that degenerative brain changes led to hysteria. In this, Charcot was eventually proved wrong, but work on the problem by so outstanding a scientist did a great deal to awaken medical and scientific interest in hysteria.

The dispute between Charcot and the Nancy School was one of the major debates of medical history, and many harsh words were spoken on both sides. The adherents to the Nancy School finally triumphed. This first recognition of a psychologically caused mental disorder spurred more research on the behavior underlying hysteria and other disorders. Soon it was suggested that psychological factors were also involved in anxiety states, phobias, and other psychopathologies. Eventually, Charcot himself was won over to the new point of view and did much to promote the study of psychological factors in various mental disorders.

The debate over whether mental disorders are caused by biological or psychological factors continues to this day. The Nancy School–Charcot debate represented a major step forward for psychology, however. Toward the end of the nineteenth century, it became clear that mental disorders could have psychological bases, biological bases, or both. But a major question remained to be answered: How do the psychologically based mental disorders actually develop?

**THE BEGINNINGS OF PSYCHOANALYSIS** The first systematic attempt to answer this question was made by Sigmund Freud (1856–1939). Freud was a brilliant, young Viennese neurologist who received an appointment as lecturer on nervous diseases at the University of Vienna. In 1885 he went to study under Charcot and later became acquainted with the work of Liébeault and Bernheim at Nancy. He was impressed by their use of hypnosis with hysterical patients and came away convinced that powerful mental processes could remain hidden from consciousness.

On his return to Vienna, Freud worked in collaboration with another Viennese physician, Josef Breuer (1842–1925), who had incorporated an interesting innovation into the use of hypnosis with his patients. Unlike hypnotists before them, Freud and Breuer directed patients to talk freely about their problems while under hypnosis. The patients usually displayed considerable emotion and, on awakening from their hypnotic states, felt a significant emotional release, which was called a **catharsis**. This simple innovation in the use of hypnosis proved to be of great significance: It not only helped patients discharge their emotional tensions by discussing their problems but also revealed to the therapist the nature of the difficulties that had brought about certain symptoms. The patients, on awakening, saw no relationship between their problems and their hysterical symptoms.

It was this approach that thus led to the discovery of the **unconscious**—the portion of the mind that contains experiences of which a person is unaware—and with it the belief that processes outside of a person's awareness can play an important role in determining behavior. In 1893, Freud and Breuer published their joint paper *On the Psychical Mechanisms of Hysterical Phenomena*, which was one of the great milestones in the study of the dynamics of the conscious and unconscious. Freud soon discovered, moreover, that he could dispense with hypnosis entirely. By encouraging patients to say whatever came into their minds without regard to logic or propriety, Freud found that patients would eventually overcome inner obstacles to remembering and would discuss their problems freely.

Two related methods enabled him to understand patients' conscious and unconscious thought processes. One method, **free association**, involved having patients talk freely about themselves, thereby providing information about their feelings, motives, and so forth. A second method, **dream analysis**, involved having patients record and describe their dreams. These techniques helped analysts and patients gain insights and achieve a better understanding of the patients' emotional problems. Freud devoted the rest of his long and energetic life to the development and elaboration of psychoanalytic principles. His views were formally introduced to American scientists in 1909, when he was invited to deliver a series of lectures at Clark University by the eminent psychologist G. Stanley Hall (1844–1924), who was then president of the university. These lectures created a great deal of controversy and helped popularize psychoanalytic concepts with scientists as well as with the general public.

Psychoanalysis was introduced to North America at a famous meeting at Clark University in Worcester, Massachusetts, in 1909. Among those present were (back row) A. A. Brill, Ernest Jones, and Sandor Ferenczi; (front row) Sigmund Freud, G. Stanley Hall, and Carl Jung.

We will discuss the psychoanalytic viewpoint further in Chapter 3. Freud's lively and seminal views attracted a substantial following over his long career, and interest in his ideas persists today, more than 100 years after he began writing. Numerous other clinician-theorists—such as Carl Jung, Alfred Adler, and Harry Stack Sullivan—launched “spin-off” theories that have elaborated on the psychoanalytic viewpoint. More will also be said of these views in Chapter 3. Here we will examine the early development of psychological research and explore the evolution of the behavioral perspective on abnormal behavior.

### The Evolution of the Psychological Research Tradition: Experimental Psychology

The origins of much of the scientific thinking in contemporary psychology lie in early rigorous efforts to study psychological processes objectively, as demonstrated by Wilhelm Wundt (1832–1920) and William James (1842–1910). Although the early work of these experimental psychologists did not bear directly on clinical practice or on our understanding of abnormal behavior, this tradition was clearly influential a few decades later in molding the thinking of the psychologists who brought these rigorous attitudes into the clinic. (For a discussion of the history of clinical psychology, see L. T. Benjamin, 2005.)

**THE EARLY PSYCHOLOGY LABORATORIES** In 1879 Wilhelm Wundt established the first experimental psychology laboratory at the University of Leipzig. While studying the psychological factors involved in memory and sensation, Wundt and his colleagues devised many basic experimental methods

and strategies. Wundt directly influenced early contributors to the empirical study of abnormal behavior; they followed his experimental methodology and also applied some of his research strategies to study clinical problems. For example, a student of Wundt's, J. McKeen Cattell (1860–1944), brought Wundt's experimental methods to the United States and used them to assess individual differences in mental processing. He and other students of Wundt's work established research laboratories throughout the United States.

It was not until 1896, however, that another of Wundt's students, Lightner Witmer (1867–1956), combined research with application and established the first American psychological clinic at the University of Pennsylvania. Witmer's clinic focused on the problems of mentally deficient children in terms of both research and therapy. Witmer, considered to be the founder of clinical psychology (McReynolds, 1996, 1997), was influential in encouraging others to become involved in this new profession. Other clinics were soon established. One clinic of great importance was the Chicago Juvenile Psychopathic Institute (later called the Institute of Juvenile Research), established in 1909 by William Healy (1869–1963). Healy was the first to view juvenile delinquency as a symptom of urbanization, not as a result of inner psychological problems. In so doing, he was among the first to recognize a new area of causation—environmental, or sociocultural, factors.

By the first decade of the twentieth century, psychological laboratories and clinics were burgeoning, and a great deal of research was being generated (Goodwin, 2011). The rapid and objective communication of scientific findings was perhaps as important in the development of modern psychology as the collection and interpretation of research findings. This period saw the origin of many scientific journals for the propagation of research and theoretical discoveries, and as the years have passed, the number of journals has grown. The American Psychological Association now publishes 54 scientific journals, many of which focus on research into abnormal behavior and personality functioning.

**THE BEHAVIORAL PERSPECTIVE** Although psychoanalysis dominated thought about abnormal behavior at the end of the nineteenth century and in the early twentieth century, another school—behaviorism—emerged out of experimental psychology to challenge its supremacy. Behavioral psychologists believed that the study of subjective experience—through the techniques of free association and dream analysis—did not provide acceptable scientific data because such observations were not open to verification by other investigators. In their view, only the study of directly observable behavior—and the stimuli and reinforcing conditions that “control” it—could serve as a basis for formulating scientific principles of human behavior.

The **behavioral perspective** is organized around a central theme: the role of learning in human behavior. Although this perspective was initially developed through research in the

laboratory rather than through clinical practice with disturbed individuals, its implications for explaining and treating maladaptive behavior soon became evident.

**Classical Conditioning** The origins of the behavioral view of abnormal behavior and its treatment are tied to experimental work on the type of learning known as **classical conditioning**—a form of learning in which a neutral stimulus is paired repeatedly with an unconditioned stimulus that naturally elicits an unconditioned behavior. After repeated pairings, the neutral stimulus becomes a conditioned stimulus that elicits a conditioned response. This work began with the discovery of the conditioned reflex by Russian physiologist Ivan Pavlov (1849–1936). Around the turn of the twentieth century, Pavlov demonstrated that dogs would gradually begin to salivate in response to a nonfood stimulus such as a bell after the stimulus had been regularly accompanied by food.

Pavlov's discoveries in classical conditioning excited a young American psychologist, John B. Watson (1878–1958), who was searching for objective ways to study human behavior. Watson reasoned that if psychology was to become a true science, it would have to abandon the subjectivity of inner sensations and other “mental” events and limit itself to what could be objectively observed. What better way to do this than to observe systematic changes in behavior brought about simply by rearranging stimulus conditions? Watson thus changed the focus of psychology to the study of overt behavior rather than the study of theoretical mentalistic constructs, an approach he called **behaviorism**.

Watson, a man of impressive energy and demeanor, saw great possibilities in behaviorism, and he was quick to point them out to his fellow scientists and a curious public. He boasted that through conditioning he could train any healthy child to become whatever sort of adult one wished. He also challenged the psychoanalysts and the more biologically oriented psychologists of his day by suggesting that abnormal behavior was the product of unfortunate, inadvertent earlier conditioning and could be modified through reconditioning.

Ivan Pavlov (1849–1936), a pioneer in demonstrating the part conditioning plays in behavior, is shown here with the staff and some of the apparatus used to condition reflexes in dogs.

By the 1930s Watson had had an enormous impact on American psychology. Watson's approach placed heavy emphasis on the role of the social environment in conditioning personality development and behavior, both normal and abnormal. Today's behaviorally oriented psychologists still accept many of the basic tenets of Watson's doctrine, although they are more cautious in their claims.

**Operant Conditioning** While Pavlov and Watson were studying stimulus-response conditioning, E. L. Thorndike (1874–1949) and subsequently B. F. Skinner (1904–1990) were exploring a different kind of conditioning, one in which the consequences of behavior influence behavior. Behavior that operates on the environment may be instrumental in producing certain outcomes, and those outcomes, in turn, determine the likelihood that the behavior will be repeated on similar occasions. For

B. F. Skinner (1904–1990) formulated the concept of operant conditioning, in which reinforcers can be used to make a response more or less probable and frequent.

example, Thorndike studied how cats could learn a particular response, such as pulling a chain, if that response was followed by food reinforcement. This type of learning came to be called instrumental conditioning and was later renamed **operant conditioning** by Skinner. Both terms are still used today. In Skinner's view, behavior is "shaped" when something reinforces a particular activity of an organism—which makes it possible "to shape an animal's behavior almost as a sculptor shapes a lump of clay" (Skinner, 1951, pp. 26–27).

In this chapter we have touched on several important trends in the evolution of the field of abnormal psychology and have recounted the contributions of numerous individuals from history who have shaped our current views. The vast amount of information available can cause confusion and controversy when efforts are made to obtain an integrated view of behavior and causation. We may have left supernatural beliefs behind, but we have moved into something far more complex in trying to determine the role of natural factors—be they biological, psychological, or sociocultural—in abnormal behavior. For a recap of some of the key contributors to the field of abnormal psychology, see Table 2.1.

#### in review

- Compare the views of the Nancy School with those of Charcot. How did this debate influence modern psychology?
- Evaluate the impact of the work of Freud and that of Watson on psychology today.
- How did early experimental science help to establish brain pathology as a causal factor in mental disorders?
- Describe the historical development of the behavioral view in psychology.

**TABLE 2.1**  
**Major Figures in the Early History of Abnormal Psychology**

Hippocrates

#### The Ancient World

*Hippocrates* (460–377 B.C.) A Greek physician who believed that mental disease was the result of natural causes and brain pathology rather than demonology.

*Plato* (429–347 B.C.) A Greek philosopher who believed that mental patients should be treated humanely and should not be held responsible for their actions.

*Aristotle* (384–322 B.C.) A Greek philosopher and a pupil of Plato who believed in the Hippocratic theory that various agents, or humors, within the body, when imbalanced, were responsible for mental disorders. Aristotle rejected the notion of psychological factors as causes of mental disorders.

*Galen* (A.D. 130–200) A Greek physician who contributed much to our understanding of the nervous system. Galen divided the causes of mental disorders into physical and mental categories.

Galen

**Avicenna**

### The Middle Ages

**Avicenna** (980–1037) An ancient Persian physician who promoted principles of humane treatment for the mentally disturbed at a time when Western approaches to mental illness were inhumane.

**Hildegard** (1098–1179) A remarkable woman, known as the “Sybil of the Rhine,” who used curative powers of natural objects for healing and wrote treatises about natural history and medicinal uses of plants.

**Benjamin Rush**

### The Sixteenth Through the Eighteenth Centuries

**Paracelsus** (1490–1541) A Swiss physician who rejected demonology as a cause of abnormal behavior. Paracelsus believed in psychic causes of mental illness.

**Teresa of Avila** (1515–1582) A Spanish nun, since canonized, who argued that mental disorder was an illness of the mind.

**Johann Weyer** (1515–1588) A German physician who argued against demonology and was ostracized by his peers and the Church for his progressive views.

**Robert Burton** (1576–1640) An Oxford scholar who wrote a classic, influential treatise on depression, *The Anatomy of Melancholia*, in 1621.

**William Tuke** (1732–1822) An English Quaker who established the York Retreat, where mental patients lived in humane surroundings.

**Philippe Pinel** (1745–1826) A French physician who pioneered the use of moral management in La Bicêtre and La Salpêtrière hospitals in France, where mental patients were treated in a humane way.

**Benjamin Rush** (1745–1813) An American physician and the founder of American psychiatry, who used moral management, based on Pinel's humanitarian methods, to treat the mentally disturbed.

### The Nineteenth and Early Twentieth Centuries

**Dorothea Dix**

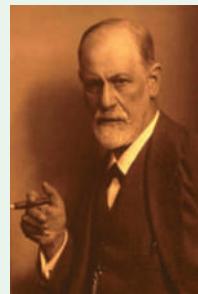

**Dorothea Dix** (1802–1887) An American teacher who founded the mental hygiene movement in the United States, which focused on the physical well-being of mental patients in hospitals.

**Clifford Beers** (1876–1943) An American who campaigned to change public attitudes toward mental patients after his own experiences in mental institutions.

**Franz Anton Mesmer** (1734–1815) An Austrian physician who conducted early investigations into hypnosis as a medical treatment.

**Emil Kraepelin** (1856–1926) A German psychiatrist who developed the first diagnostic system.

**Sigmund Freud** (1856–1939) The founder of the school of psychological therapy known as psychoanalysis.

**Sigmund Freud**

**Wilhelm Wundt** (1832–1920) A German scientist who established the first experimental psychology laboratory in 1879 and subsequently influenced the empirical study of abnormal behavior.

**J. McKeen Cattell** (1860–1944) An American psychologist who adopted Wundt's methods and studied individual differences in mental processing.

**Lightner Witmer** (1867–1956) An American psychologist who established the first psychological clinic in the United States, focusing on problems of mentally deficient children. He also founded the journal *The Psychological Clinic* in 1907.

**John B. Watson**

**William Healy** (1869–1963) An American psychologist who established the Chicago Juvenile Psychopathic Institute and advanced the idea that mental illness was due to environmental, or sociocultural, factors.

**Ivan Pavlov** (1849–1936) A Russian physiologist who published classical studies in the psychology of learning.

**John B. Watson** (1878–1958) An American psychologist who conducted early research into learning principles and came to be known as the father of behaviorism.

**B. F. Skinner** (1904–1990) An American learning theorist who developed the school of learning known as operant conditioning and was influential in incorporating behavioral principles into influencing behavioral change.

**B. F. Skinner**

## UNRESOLVED issues

### Interpreting Historical Events

Understanding current events and phenomena depends to a substantial degree on having an accurate understanding of the historical development of knowledge. Many psychologists hold the view that psychological theorizing can be advanced by greater use of historical data (McGuire, 1994). This chapter has attempted to provide a historical perspective on some of the concepts you will encounter in the chapters that follow. You might think that looking back in history to get a picture of events that occurred long ago would not be a difficult task—that it would be a simple matter of reviewing some history books and some publications from the time in question. However, different and conflicting views as to the importance and relevance of historical events in contemporary psychology have emerged. The traditional view maintains that historical events are stepping stones for understanding contemporary events, while a “New History” approach minimizes this cumulative and often celebratory approach and questions the cumulative knowledge aspect. Instead, this approach favors considering history as “national habits or characteristics of a culture that does not necessarily serve as cumulative force in the advancement of knowledge” (for an interesting discussion of historical approaches see Lovett, 2006). The distinction here is whether past developments in acquiring knowledge and understanding build on each other to create a more accurate picture or whether such developments should be viewed independently in their own context.

Regardless of one’s view of the historical approach, those who try to understand the historical context of particular phenomena or ideas are sometimes confronted with what Burton (2001) referred to as the tenacity of historical misinformation. He pointed out that there is one discouraging theme in the history of science—the widespread acceptance of false accounts. He noted that it is not uncommon for psychological findings and theories to be exaggerated or distorted and that the exaggerations frequently spread much further through public sources than do the authentic facts. For example, he noted the widespread acceptance, and inclusion in many textbooks, of inaccurate restatements of the widely cited study of Little Albert’s fear of furry objects:

#### LITTLE ALBERT

Little Albert was the famous toddler who, originally unafraid of rats, exhibited such a fear when J. B. Watson and Rayner (1920) paired the presence of a rat with a loud noise. Harris (1979), Samelson (1980), and Gilovich (1991) are among the critics who have noted how frequently and consistently this case is misrepresented and exaggerated. J. B. Watson and Rayner described pairing the loud noise with the rat and later testing Albert’s reaction to a rat and a rabbit, as well as to blocks, a seal coat, cotton wool, the hair of Watson and some assistants, and a Santa Claus mask. Albert never reacted to the blocks or the assistants’ hair, always reacted

to the rat, and reacted to the other objects with various degrees of agitation that were sometimes vividly described but sometimes merely (and vaguely) termed “negative reaction.” According to Harris (1979, p. 153), secondary sources have erroneously reported the testing of “a fur pelt, . . . a man’s beard, . . . a cat, a pup, a fur muff, . . . a white furry glove, . . . Albert’s aunt, who supposedly wore fur, . . . either the fur coat or the fur neckpiece of Albert’s mother, . . . and even a teddy bear.” (pp. 228–229)

Another factor that can affect the quality of historical information is that our views of history and our understanding of events are sometimes open to reinterpretation. As Schudson (1995) points out, “Collective memory, more than individual memory, at least in liberal pluralistic societies, is provisional. It is always open to contestation” (p. 16). Any number of obstacles can stand in the way of our gaining an accurate picture of the attitudes and behaviors of people who lived hundreds of years ago. This has certainly been the case with our views of the Middle Ages (Kroll & Bachrach, 1984).

The foremost problem in retrospective psychological analysis is that we cannot rely on direct observation, a hallmark of psychological research. Instead, we must turn to written documents or historical surveys of the times. Although these sources are often full of fascinating information, they may not reveal directly the information we seek; we must therefore extrapolate “facts” from the information we have, which is not always an easy task. We are restricted in our conclusions by the documents or sources available to us. Attempting to learn about people’s attitudes and subtle social perceptions hundreds of years ago by examining surviving church documents or biographical accounts is less than ideal. First, we inevitably view these documents out of the context in which they were written. Second, we do not know whether the authors had ulterior motives or what the real purposes of the documents were. For example, some historians have concluded erroneously that people of the Middle Ages considered sin to be a major causal factor in mental illness. This misconception may have been due in part to zealous authors invoking “God’s punishment” against the victims of mental illnesses who happened to be their enemies. Apparently, if the victims happened to be friends, sin was typically not mentioned as a causal factor (Kroll & Bachrach, 1984). Such writings, of course, are biased, but we may have no way of knowing this. The fewer the sources surveyed, the more likely that any existing bias will go undetected.

In other cases, concepts important to historical interpretation may have quite a different meaning to us today than they had in the past, or the meaning may simply be unclear. Kroll and Bachrach (1984) point out that the concept of “possession,” so critical to our views of the Middle Ages, is a very vague and complex concept for which we have no helpful natural models.

Our language fails us, except for colorful analogies and metaphors. Just as the term *nervous breakdown* means different things to different people, so too *possession* means and meant many different things and undoubtedly had a different range of meanings to medieval persons from what it has to us. This kind of uncertainty can make definitive assessments of things that happened during the Middle Ages difficult, if not impossible (Phillips, 2002).

Bias can come into play during interpretation also. Our interpretations of historical events or previously held beliefs can be colored by our own views of what is normal and what is abnormal. In fact, it is difficult to conduct a retrospective analysis without taking current perspectives and values as a starting point. For example, our modern beliefs about the Middle Ages have led, says Schoeneman (1984), to our contemporary misinterpretation

that during the fifteenth and sixteenth centuries the mentally ill were typically accused of being witches. For most of us, this mistaken interpretation makes sense simply because we do not understand the medieval perspective on witchcraft.

Although reevaluations of the Middle Ages have discredited the view that demonology, sin, and witchcraft played key roles in the medieval understanding of mental illness, it is also clear that in some cases these concepts were associated with mental illness. Where does the truth lie? It appears that the last word has not been written on the Middle Ages, nor on any period of our history for that matter. At best, historical views—and, therefore, retrospective psychological studies—must be regarded as working hypotheses that are open to change as new perspectives are applied to history and as “new” historical documents are discovered.

## summary

### 2.1 How has abnormal behavior been viewed throughout history?

- Understanding of abnormal behavior has not evolved smoothly or uniformly over the centuries; the steps have been uneven, with great gaps in between, and unusual—even bizarre—views or beliefs have often sidetracked researchers and theorists.
- The dominant social, economic, and religious views of the times have had a profound influence over how people have viewed abnormal behavior.
- In the ancient world, superstitious explanations for mental disorders were followed by the emergence of medical concepts in many places such as Egypt and Greece; many of these concepts were developed and refined by Roman physicians.
- After the fall of Rome near the end of the fifth century A.D., superstitious views dominated popular thinking about mental disorders for over 1,000 years. In the fifteenth and sixteenth centuries, it was still widely believed, even by scholars, that some mentally disturbed people were possessed by a devil.

### 2.2 What effect did the emergence of humanism have on abnormal psychology?

- Great strides have been made in our understanding of abnormal behavior. For example, during the latter part of the Middle Ages and the early Renaissance, a spirit of scientific questioning reappeared in Europe, and several noted physicians spoke out against inhumane treatments. There was a general movement away from superstitions and “magic” toward reasoned, scientific studies.

- With recognition of a need for the special treatment of disturbed people came the founding of various “asylums” toward the end of the sixteenth century. However, institutionalization brought the isolation and maltreatment of mental patients. Slowly this situation was recognized, and in the eighteenth century further efforts were made to help afflicted individuals by providing them with better living conditions and humane treatment, although these improvements were the exception rather than the rule.
- The nineteenth and early twentieth centuries witnessed a number of scientific and humanitarian advances. The work of Philippe Pinel in France, of William Tuke in England, and of Benjamin Rush and Dorothea Dix in the United States prepared the way for several important developments in contemporary abnormal psychology, such as moral management. Among these were the gradual acceptance of mental patients as afflicted individuals who need and deserve professional attention; the successful application of biomedical methods to disorders; and the growth of scientific research into the biological, psychological, and socio-cultural roots of abnormal behavior.
- The reform of mental hospitals continued into the twentieth century, but over the last four decades of the century there has been a strong movement to close mental hospitals and release people into the community. This movement remains controversial in the early part of the twenty-first century.

### 2.3 What developments led to the contemporary view of abnormal psychology?

- In the nineteenth century, great technological discoveries and scientific advancements that were made in the biological sciences enhanced the understanding and treatment of disturbed individuals. One major biomedical breakthrough came with the discovery of the organic factors underlying general paresis—syphilis of the brain—one of the most serious mental illnesses of the day.

- Beginning in the early part of the eighteenth century, knowledge of anatomy, physiology, neurology, chemistry, and general medicine increased rapidly. These advances led to the identification of the biological, or organic, pathology underlying many physical ailments.
- The development of a psychiatric classification system by Kraepelin played a dominant role in the early development of the biological viewpoint. Kraepelin's work (a forerunner to the *DSM* system) helped to establish the importance of brain pathology in mental disorders and made several related contributions that helped establish this viewpoint.
- The first major steps toward understanding psychological factors in mental disorders occurred with mesmerism and the Nancy School, followed by the work of Sigmund Freud. During five decades of observation, treatment, and writing, he developed a theory of psychopathology, known as "psychoanalysis," that emphasized the inner dynamics of unconscious motives. Over the last half-century, other clinicians have modified and revised Freud's theory, which has thus evolved into new psychodynamic perspectives.
- Scientific investigation into psychological factors and human behavior began to make progress in the latter part of the nineteenth century. The end of the nineteenth century and the early twentieth century saw experimental psychology evolve into clinical psychology with the development of clinics to study, as well as intervene in, abnormal behavior.
- Paralleling this development was the work of Pavlov in understanding learning and conditioning. Behaviorism emerged as an explanatory model in abnormal psychology. The behavioral perspective is organized around a central theme—that learning plays an important role in human behavior. Although this perspective was initially developed through research in the laboratory (unlike psychoanalysis, which emerged out of clinical practice with disturbed individuals), it has been shown to have important implications for explaining and treating maladaptive behavior.
- Understanding the history of psychopathology—its forward steps and missteps alike—helps us understand the emergence of modern concepts of abnormal behavior.

## learning objectives

### 3.1

What are the causes and risk factors for abnormal behavior?

### 3.2

What viewpoints can we take to help us understand the causes of abnormal behavior?

### 3.3

What does the biological viewpoint tell us about abnormal behavior and what are the biological causal factors of abnormal behavior?

### 3.4

What are the psychological viewpoints on abnormal psychology?

### 3.5

What are the psychological causal factors behind abnormal behavior?

### 3.6

How does the sociocultural viewpoint help us understand abnormal behavior?

### 3.7

What are the sociocultural causal factors of abnormal behavior?

We saw in the last chapter that speculation about the causes of abnormal behavior goes back very far in human history. From early times, those who observed disordered behavior grappled with the question of its cause. Hippocrates, for example, had a type of disease model and suggested that an imbalance in the four bodily humors produced abnormal behavior, with each humor connected with certain kinds of behavior. To other observers, the cause was possession by demons or evil spirits. Later, bodily dysfunction was suggested as a cause.

Each attempt at identifying a cause brought with it a theory, or model, of abnormal behavior. Today we are still puzzling over the causes of abnormal behavior, and speculation about causes continues to give rise to new models of abnormality. Since about 1900, several important schools of thought have developed elaborate models to explain the origins of abnormal behavior and to suggest how it might be treated. We will discuss the most influential of these theoretical perspectives in this chapter, paying special attention to the different types of causal factors that each

perspective has identified. First, however, we need to address the very nature of the concept of causation as it is applied to abnormal behavior.

## Causes and Risk Factors for Abnormal Behavior

Central to the field of abnormal psychology are questions about what causes people to experience mental distress and to behave maladaptively. If we knew the causes for given disorders, we might be able to prevent conditions that lead to them and perhaps reverse those that maintain them. We could also classify and diagnose disorders better if we clearly understood their causes rather than relying on clusters of symptoms, as we usually must do now.

Although understanding the causes of abnormal behavior is clearly a desirable goal, it is enormously difficult to achieve because human behavior is so complex. Even the simplest human behavior, such as speaking or writing a single word, is the product of thousands of prior events—the connections among which are not always clear. Attempting to understand a person's life in causal terms is a task of enormous magnitude, whether it be a fairly normal or adaptive life or a life characterized by severe mental disorders. As a result, many investigators now prefer to speak of *risk factors* (variables correlated with an abnormal outcome) rather than of causes (Rutter, 2006a). Although understanding causes remains the ultimate goal, this is particularly difficult to achieve when straightforward scientific approaches such as experiments using random assignment are generally not feasible for ethical reasons.

## Necessary, Sufficient, and Contributory Causes

Regardless of one's theoretical perspective, several terms can be used to specify the role a factor plays in the **etiology**, or causal pattern, of abnormal behavior. A **necessary cause** (e.g., cause X) is a condition that must exist for a disorder (e.g., disorder Y) to occur. For example, general paresis (Y)—a degenerative brain disorder—cannot develop unless a person has previously contracted syphilis (X). Or more generally, if Y occurs, then X must have preceded it. Another example is Huntington's chorea—a rare degenerative brain disorder of the central nervous system—which can develop only if the person has the necessary gene (IT 15, or the Huntington's gene—see Chapter 14). To date, most mental disorders have not been found to have necessary causes, although there continues to be a search for such causes.

A **sufficient cause** (e.g., cause X) of a disorder is a condition that guarantees the occurrence of a disorder (e.g., disorder Y). For example, one current theory hypothesizes that hopelessness (X) is a sufficient cause of depression (Y) (Abramson et al., 1995; Abramson et al., 1989). Or, more generally, if X occurs, then Y will also occur. According to this theory, if you are hopeless

enough about your future, then you will become depressed. However, a sufficient cause may not be a necessary cause. Continuing with the depression example, Abramson and colleagues (1989) acknowledge that hopelessness is not a necessary cause of depression; there are other causes of depression as well. Finally, what we study most often in psychopathology research are **contributory causes**. A contributory cause (e.g., cause X) is one that increases the probability of a disorder (e.g., disorder Y) developing but is neither necessary nor sufficient for the disorder to occur. Or, more generally, if X occurs, then the probability of Y occurring increases. For example, parental rejection could increase the probability that a child will later have difficulty in handling close personal relationships or could increase the probability that being rejected in a relationship in adulthood will precipitate depression. We say here that parental rejection is a contributory cause for the person's later difficulties, but it is neither necessary nor sufficient (Abramson et al., 1989, 1995). See Figure 3.1 for a summary.

In addition to distinguishing among necessary, sufficient, and contributory causes of abnormal behavior, we must also consider the time frame under which the different causes operate. Some causal factors occurring relatively early in life may not show their effects for many years; these would be considered *distal causal factors* that may contribute to a predisposition to develop a disorder. For example, loss of a parent early in life, or having abusive or neglectful parents as a child or adolescent, may serve as a distal contributory cause predisposing a person to depression or antisocial behaviors later in life. By contrast, other causal factors operate shortly before the occurrence of the symptoms of a disorder; these would be considered *proximal causal factors*. Sometimes a proximal causal factor may be a condition that proves too much for a child or adult and triggers the onset of a disorder. A crushing disappointment at school or work or severe difficulties with a school friend or a marital partner are examples of more proximal causal factors that could lead to depression. In other cases, proximal factors might involve biological changes such as damage to certain parts of the left hemisphere of the brain, which can lead to depression.

A *reinforcing contributory cause* is a condition that tends to maintain maladaptive behavior that is already occurring. An example is the extra attention, sympathy, and relief from unwanted responsibility that may come when a person is ill; these pleasant experiences may unintentionally discourage recovery. Another example occurs when a depressed person's behavior alienates friends and family, leading to a greater sense of rejection

The loss of a parent at an early age may be a contributory cause for a child to develop depression in adulthood. Factors that may not show their effects for many years are called distal causal factors.

that reinforces the existing depression (Joiner, 2002; Joiner & Timmons, 2009).

For many forms of psychopathology, we do not yet have a clear understanding of whether there are necessary or sufficient causes, although answering this question remains the goal of much current research. We do, however, have a good understanding of many of the contributory causes for most forms of psychopathology. Some of the distal contributory causes, to be discussed later in this chapter, set up vulnerability during childhood to some disorder later in life. Other more proximal contributory causes appear to bring on a disorder directly, and still others may contribute to maintenance of a disorder. This complex causal picture is further complicated by the fact that what may be a proximal cause for a problem at one stage in life may also serve as a distal contributory cause that sets up a predisposition for another disorder later in life. For example, the death of a parent can be a proximal cause of a child's subsequent grief reaction, which might last a few months or a year; however, the parent's death may also serve as a distal contributory factor that increases the probability that when the child grows up he or she will become depressed in response to certain stressors.

## Feedback and Bidirectionality in Abnormal Behavior

Traditionally in the sciences, the task of determining cause-and-effect relationships has focused on isolating the condition X (cause) that can be demonstrated to lead to condition

Necessary Cause	If Disorder Y occurs, then Cause X must have preceded it.
Sufficient Cause	If Cause X occurs, then Disorder Y will also occur.
Contributory Cause	If X occurs, then the probability of Disorder Y increases.

**FIGURE 3.1**  
Abnormal Behavior: Types of Causes.

Y (effect). For example, when the alcohol content of the blood reaches a certain level, alcoholic intoxication occurs. When more than one causal factor is involved, as is often the case, the term *causal pattern* is used. Here, conditions A, B, C, and so on lead to condition Y. In either case, this concept of cause follows a simple linear model in which a given variable or set of variables leads to a result either immediately or later. In the behavioral sciences, however, not only do we usually deal with a multitude of interacting causes but we also often have difficulty distinguishing between what is cause and what is effect because effects can serve as feedback that can in turn influence the causes. In other words, the effects of feedback and the existence of mutual, two-way (bidirectional) influences must be taken into account.

Consider the following example, which illustrates that our concepts of causal relationships must take into account the complex factors of bidirectionality of feedback.

→ **Perceived Hostility** A boy with a history of disturbed interactions with his parents routinely misinterprets the intentions of his peers as being hostile. He develops defensive strategies to counteract the supposed hostility of those around him such as rejecting the efforts of others to be friendly, which he misinterprets as patronizing. Confronted by the boy's prickly behavior, those around him become defensive, hostile, and rejecting, thus confirming and strengthening the boy's distorted expectations. In this manner, each opportunity for new experience and new learning is in fact subverted and becomes yet another encounter with a social environment that seems perversely and persistently hostile—exactly in line with the boy's expectations.

## Diathesis-Stress Models

A predisposition toward developing a disorder is termed a **diathesis**. It can derive from biological, psychological, or sociocultural causal factors, and the different viewpoints that we will be discussing tend to emphasize the importance of different kinds of diatheses. Many mental disorders are believed to develop when some kind of stressor operates on a person who has a diathesis or *vulnerability* for that disorder. Hence we will discuss what are commonly known as **diathesis-stress models** of abnormal behavior (e.g., Ingram & Luxton, 2005; Meehl, 1962; Monroe & Simons, 1991).

To translate these terms into the types of causal factors described earlier, the diathesis or vulnerability results from one or more relatively distal necessary or contributory causes, but is generally not sufficient to cause the disorder. Instead, there generally must be a more proximal undesirable event or situation (the stressor), which may also be contributory or necessary but is generally not sufficient by itself to cause the disorder except in someone with the diathesis.

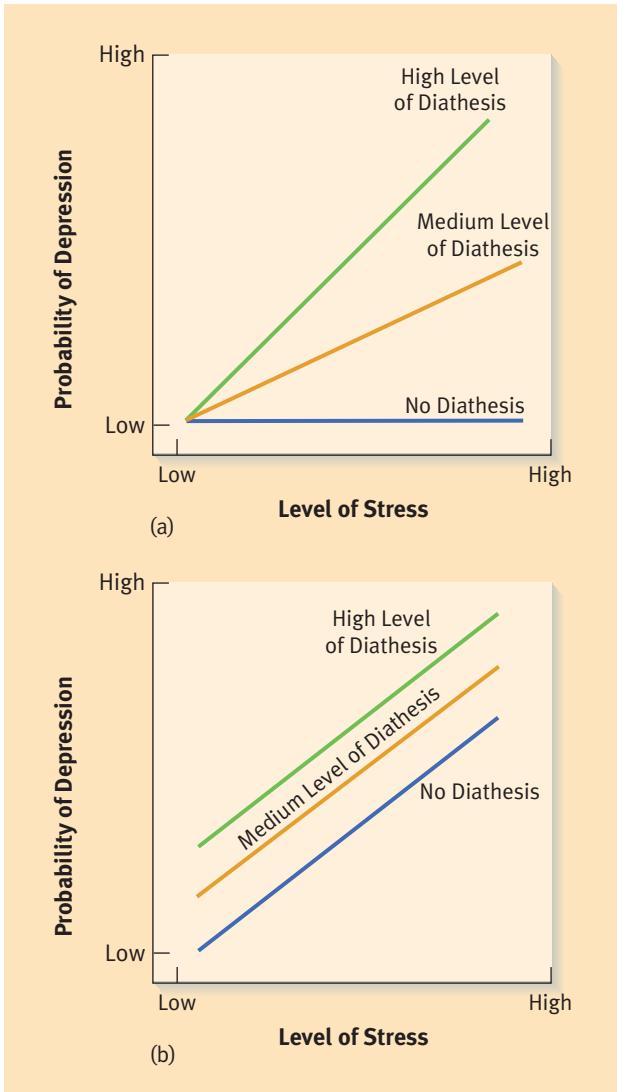

**Stress**, the response or experience of an individual to demands that he or she perceives as taxing or exceeding his or her personal resources (Folkman & Moskowitz, 2004;

Monroe et al., 2009; Taylor & Stanton, 2007), will be the focus of Chapter 5. It usually occurs when an individual experiences chronic or episodic events that are undesirable and lead to behavioral, physiological, and cognitive accommodations (Baum & Poslusny, 1999). It is important to note that factors contributing to the development of a diathesis are themselves sometimes highly potent stressors, as when a child experiences the death of a parent and may thereby acquire a predisposition or diathesis for becoming depressed later in life.

Researchers have proposed several different ways that a diathesis and stress may combine to produce a disorder (Ingram & Luxton, 2005; Monroe & Simons, 1991). In what is called the *additive model*, individuals who have a high level of a diathesis may need only a small amount of stress before a disorder develops, but those who have a very low level of a diathesis may need to experience a large amount of stress for a disorder to develop. In other words, the diathesis and the stress sum together, and when one is high the other can be low, and vice versa; thus, a person with no diathesis or a very low level of diathesis could still develop a disorder when faced with truly severe stress. In what is called an *interactive model*, some amount of diathesis must be present before stress will have any effect. Thus, in the interactive model, someone with no diathesis will never develop the disorder, no matter how much stress he or she experiences, whereas someone with the diathesis will show increasing likelihood of developing the disorder with increasing levels of stress. More complex models are also possible because diatheses often exist on a continuum, ranging from zero to high levels. Each of these possibilities is illustrated in Figure 3.2.

Since the late 1980s, attention has been focused on the concept of **protective factors**, which are influences that modify a person's response to environmental stressors, making it less likely that the person will experience the adverse consequences of the stressors (Cicchetti & Garmezy, 1993; Masten et al., 2004; Rutter, 2006a, 2011). One important protective factor in childhood is having a family environment in which at least one parent is warm and supportive, allowing the development of a good attachment relationship between the child and parent that can protect against the harmful effects of an abusive parent (Masten & Coatsworth, 1998). Ordinarily, protective factors operate only to help resist against the effects of a risk factor rather than to provide any benefits to people without risk factors (Rutter, 2006a).

Protective factors are not necessarily positive experiences. Indeed, sometimes exposure to stressful experiences that are dealt with successfully can promote a sense of self-confidence or self-esteem and thereby serve as a protective factor; thus some stressors paradoxically promote coping. This “steeling” or “inoculation” effect is more likely to occur with moderate stressors than with mild or extreme stressors (Barlow, 2002; Hetherington, 1991; Rutter, 1987). And some protective factors have nothing to do with experiences at all but are simply some quality or attribute of a person. For example, some protective

**FIGURE 3.2**

**Diathesis-Stress Model.** (a) Interactive model of diathesis-stress interaction. (b) Additive model of diathesis-stress interaction.

attributes include an easygoing temperament, high self-esteem, high intelligence, and school achievement, all of which can help protect against a variety of stressors (Masten, 2001; Rutter, 1987; Sapienza & Masten, 2011).

Protective factors most often, but not always, lead to **resilience**—the ability to adapt successfully to even very difficult circumstances. An example is the child who perseveres and does well in school despite his or her parent's drug addiction or physical abuse (Garmezy, 1993; Luthar, 2003; Sapienza & Masten, 2011). More generally, the term *resilience* has been used to describe the phenomenon that “some individuals have a relatively good outcome despite suffering risk experiences that would be expected to bring about serious sequelae” (Rutter, 2007, p. 205). A more everyday way of thinking of resilience is in terms

A child growing up under conditions of adversity may be protected from problems later in life if he or she has a warm and supportive relationship with some adult—such as a grandmother. Encouraging children to ask questions, taking the time to listen to their problems and concerns, and trying to understand the conflicts and pressures they face are the important elements of such a supportive and protective relationship.

of “overcoming the odds” against you. There is increasing evidence that if a child’s fundamental systems of adaptation (such as intelligence and cognitive development, ability to self-regulate, motivation to achieve mastery, effective parenting, and well-functioning neurobiological systems for handling stress) are operating normally, then most threatening circumstances will have minimal impact on him or her (Masten, 2001; Sapienza & Masten, 2011). Problems tend to arise when one or more of these systems of adaptation is weak to begin with (e.g., low intelligence or poorly functioning neurobiological systems for handling stress; Lester et al., 2006) or when a serious stressor damages one or more of these systems (e.g., when a parent dies). Problems can also arise when the level of challenge far exceeds human capacity to adapt (e.g., exposure to chronic trauma in war or chronic maltreatment in abusive families; Cicchetti, 2004; Cicchetti & Toth, 2005; Masten & Coatsworth, 1998; Sapienza & Masten, 2011). We should also note, however, that resilience should not be thought of as an all-or-none capacity, and some research has shown that resilient children (that is, those who show high social competence despite high stress) may nonetheless also experience considerable self-reported emotional distress. Moreover, children who show resilience in one domain may show significant difficulties in other domains.

In sum, we can distinguish between causes of abnormal behavior that lie within and are part of the biological makeup or prior experience of a person—diatheses, vulnerabilities, or predispositions—and causes that pertain to current challenges in a person’s life—stressors. Typically, neither the diathesis nor the stress is by itself sufficient to cause the disorder, but in combination they can sometimes lead the individual to behave abnormally. In addition, we can also examine protective factors, which may derive either from particular types of experiences or from certain qualities of the person, that can promote

resilience in the face of vulnerability and stress. The following hypothetical but highly plausible scenario nicely illustrates these concepts.

→ **Nature and Nurture** Melinda and Tracy were identical twins whose parents were killed in a car accident when they were a year old. Their mother and grandmother both had histories of recurrent clinical depression. The twins were adopted into two loving middle-class families without a history of depression. Melinda's adoptive family provided a loving and supportive environment and supported her through school and college. Tracy's adoptive parents, by contrast, soon divorced, and she was raised by her adoptive mother, who developed a serious dependence on alcohol and who could not hold a job. Her mother's living circumstances deteriorated and Tracy was forced to change schools four times. Because of her adoptive mother's alcohol and other mental problems, she was unable to provide Tracy with a consistently loving and supportive environment, and when she was drunk she frequently punished Tracy for no good reason. Tracy somehow managed to graduate from high school and supported herself through a state college. Both Tracy and Melinda married after they graduated from college but, by age 27, both marriages resulted in divorce. Although Melinda developed some depressive symptoms for the first 6 weeks following the divorce, the depression was not severe and she quickly recovered. Tracy, by contrast, developed a major depressive episode that lasted for over a year.

In this example, both Tracy and Melinda have identical genetic makeup and therefore the same genetic diathesis for depression. Both had experienced the same distal stressor (death of parents at an early age), and the same proximal stressor (divorce) at age 27. But Melinda had many protective factors growing up (loving and supportive family and adequate resources) that Tracy did not have (lack of a loving and supportive mother and inadequate resources). Thus Melinda showed resilience in the face of her divorce but Tracy did not.

Different models of abnormal behavior, as we shall see in the sections that follow, identify different diatheses and different stressors as the route to abnormality and different protective factors as the route to resilience in the face of adversity.

This discussion should make it very clear that diathesis-stress models need to be considered in a broad framework of *multicausal developmental models*. Specifically, in the course of development a child may acquire a variety of cumulative risk factors that may interact in determining his or her risk for psychopathology. These risk factors also interact, however, with a variety of protective processes, and sometimes with stressors, to determine whether the child develops in a normal and adaptive way—as opposed to showing signs of maladaptive behavior and psychopathology—in childhood, adolescence, or adulthood (e.g., Rutter, 2001, 2006a; Sapienza & Masten, 2011).

It is also important to note, however, that to understand what is abnormal, one must always have a good understanding of normal human development at biological, psychological, and sociocultural levels of analysis. This has been the focus of the rapidly growing field of **developmental psychopathology**, which focuses on determining what is abnormal at any point in development by comparing and contrasting it with the normal and expected changes that occur in the course of development (e.g., Masten, 2006; Rutter, 2001). For example, an intense fear of the dark in a 3- to 5-year-old child may not be considered abnormal, given that most children have at least one specific fear that they bring into early adolescence (Antony et al., 1997; Barlow, 2002). However, an intense fear of the dark that causes considerable distress and avoidance behavior in a high school or college-age student would be considered a phobia.

- Define the terms *protective factors* and *resilience*. Give examples of each.
- Explain why diathesis-stress models need to be considered as multicausal developmental models.

## Viewpoints for Understanding the Causes of Abnormal Behavior

Students are often perplexed by the fact that in the behavioral sciences there often are several competing explanations for the same thing. In general, the more complex the phenomenon being investigated, the greater the number of viewpoints that develop in an attempt to explain it, although inevitably they are not all equally valid. In each case, a particular viewpoint helps researchers and theoreticians to organize the observations they have made, provides a system of thought in which to place the observed data, and suggests areas of focus for research and treatment. In a fundamental way, viewpoints also help determine the kinds of potential causes that are even examined in the first place. It is important to remember, however, that each of these viewpoints is a theoretical construction devised to orient psychologists in the study of abnormal (and normal) behavior. One potential problem is that when adherents of a particular viewpoint are overly confident about the validity of that viewpoint, they may become blind to alternative interpretations.

As we saw in Chapter 2, Sigmund Freud helped shift the focus of abnormal psychology from biological illness or moral infirmity to unconscious mental processes within the person. In recent years, three other shifts in focus seem to have been occurring in parallel in the study of abnormal behavior. First, a newer, slightly different biological viewpoint is having a significant

impact; it is the dominant force in psychiatry and has become very influential in clinical science more generally. Second, the behavioral and cognitive-behavioral viewpoints have become very influential paradigms among many empirically oriented clinical psychologists and some psychiatrists. Third, a sociocultural viewpoint has also become influential among psychologists and psychiatrists interested in the effects of sociocultural factors on abnormal behavior. In the long run, however, we also know from biological, psychological, and sociocultural research that only an integrated approach is likely to provide anything close to a full understanding of the origins of various forms of psychopathology or the form that a long-lasting cure for many serious forms of psychopathology might take. Thus, in recent years, many theorists have come to recognize the need for a more integrative, **biopsychosocial viewpoint** that acknowledges that biological, psychological, and sociocultural factors all interact and play a role in psychopathology and treatment.

With this in mind, we now turn to the major different viewpoints themselves. We will present the key ideas of each perspective, along with information about attempts to evaluate its validity. We will also describe the kinds of causal factors that each model tends to emphasize.

- What are the three traditional viewpoints that have dominated the study of abnormal behavior in recent years?
- What is the central idea of the more current biopsychosocial viewpoint?

## The Biological Viewpoint and Biological Causal Factors

As we saw in Chapter 2 in the discussion of general paresis and its link to syphilis, the traditional biological viewpoint focuses on mental disorders as diseases, many of the primary symptoms of which are cognitive, emotional, or behavioral. Mental disorders are thus viewed as disorders of the central nervous system, the autonomic nervous system, and/or the endocrine system that are either inherited or caused by some pathological process. At one time, people who adopted this viewpoint hoped to find simple biological explanations. Today, however, most clinical psychologists and psychiatrists recognize that such explanations are rarely simple, and many also acknowledge that psychological and sociocultural causal factors play important roles as well.

The disorders first recognized as having biological or organic components were those associated with gross destruction of brain tissue. These disorders are neurological diseases—that is, they result from the disruption of brain functioning by physical or biochemical means and often involve psychological or behavioral aberrations. For example, damage to certain areas in the brain can cause memory loss, and damage to the left hemisphere that occurs during a stroke can cause depression.

- ▶ Neurotransmitter and hormonal abnormalities
- ▶ Genetic vulnerabilities
- ▶ Temperament
- ▶ Brain dysfunction and neural plasticity

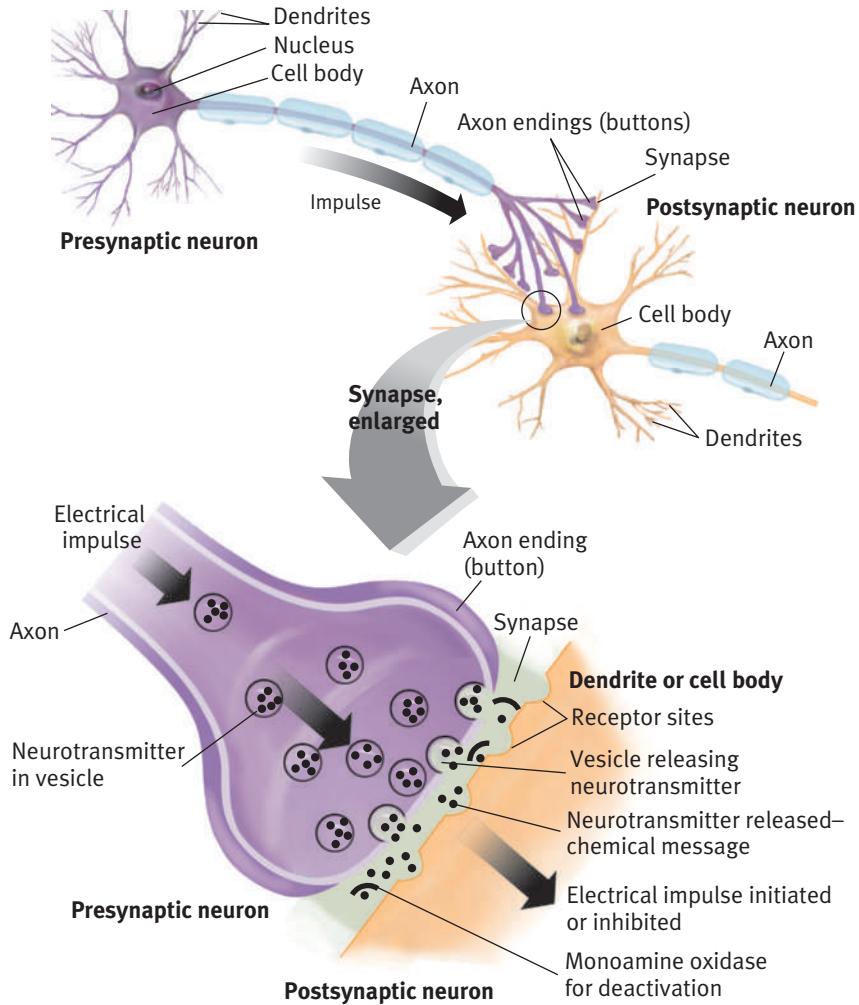

**FIGURE 3.3**  
Biological Causal Factors.

However, most mental disorders are not caused by neurological damage per se. For example, abnormalities in neurotransmitter systems in the brain can lead to mental disorders without causing damage to the brain. Moreover, the bizarre content of delusions and other abnormal mental states like hallucinations can never be caused simply and directly by brain damage. Consider the example of a person with schizophrenia or general paresis who claims to be Napoleon. The content of such delusions must be the byproduct of some sort of functional integration of different neural structures, some of which have been “programmed” by personality and learning based on past experience (e.g., having learned who Napoleon was).

We will focus here on four categories of biological factors (summarized in Figure 3.3) that seem particularly relevant to the development of maladaptive behavior: (1) neurotransmitter and hormonal abnormalities in the brain or other parts of the central nervous system, (2) genetic vulnerabilities, (3) temperament, and (4) brain dysfunction and neural plasticity. Each of these categories encompasses a number of conditions that influence the quality and functioning of our bodies and our behavior. They are often not independent of each other but rather interact with one another. Moreover, different factors may play more or less important roles in different people.

### Imbalances of Neurotransmitters and Hormones

In order for the brain to function adequately, neurons, or nerve cells, need to be able to communicate effectively with one another. This communication is done through the transmission of nerve impulses which are electrical in nature. Nerve impulses travel from the cell body or dendrites of one neuron (nerve cell) down the axon. Although there is only one axon for each neuron, axons have branches at their ends called axon endings. These are the sites where neurotransmitter substances are released into the **synapse**—a tiny fluid-filled space between the axon endings of one neuron (the presynaptic neuron) and the dendrites or cell body of another neuron (the postsynaptic neuron). The synapse is the site of communication between the axon of one neuron and the dendrites or cell body of another. These interneuronal transmissions are accomplished by **neurotransmitters**—chemical substances that are released into the synapse by the presynaptic

**FIGURE 3.4**

Neurotransmission and Abnormal Behavior. Watch the Video

The Basics: How the Brain Works in MyPsychLab

neuron when a nerve impulse occurs (for details, see Figure 3.4). The neurotransmitter substances released into the synapse then act on the postsynaptic membrane of the dendrite (or cell body) of the receiving neuron, which has specialized receptor sites where the neurotransmitter substances pass on their message. The neurotransmitters can stimulate that postsynaptic neuron to either initiate an impulse or inhibit impulse transmission. Both kinds of messages are important.

Once the neurotransmitter substance is released into the synapse, it does not stay around indefinitely (otherwise, the receiving neuron would continue firing in the absence of a real impulse). Sometimes the neurotransmitters are quickly destroyed by an enzyme such as monoamine oxidase, and sometimes they are returned to storage vesicles in the axon endings by a reuptake mechanism—a process of reabsorption by which the neurotransmitters are reabsorbed or effectively sucked back up into the axon ending. The enzyme monoamine oxidase is also present in the presynaptic terminal and can destroy excess neurotransmitter there too.

There are many different kinds of neurotransmitters; some increase the likelihood that the postsynaptic neuron will “fire” (produce an impulse), and others inhibit the impulse. Whether the neural message is successfully transmitted to the postsynaptic neuron depends, among other things, on the concentration of certain neurotransmitters within the synapse.

### IMBALANCES OF NEUROTRANSMITTER SYSTEMS

The belief that imbalances in neurotransmitters in the brain can result in abnormal behavior is one of the basic tenets of the biological perspective today, although currently most researchers agree that this is only part of the causal pattern involved in the etiology of most disorders. Sometimes psychological stress can bring on *neurotransmitter imbalances*. These imbalances can be created in a variety of ways:

- There may be excessive production and release of the neurotransmitter substance into the synapses, causing a functional excess in levels of that neurotransmitter.
- There may be dysfunctions in the normal processes by which neurotransmitters, once released into the synapse, are deactivated. Ordinarily this deactivation occurs either through a process of reuptake of the released neurotransmitter from the synapse into the axon endings or through a process of degradation by certain enzymes that may be present in the synapse and in the presynaptic axon endings.
- Finally, there may be problems with the receptors in the postsynaptic neuron, which may be either abnormally sensitive or abnormally insensitive.

Neurons that are sensitive to a particular neurotransmitter tend to cluster together, forming neural paths between different parts of the brain known as *chemical circuits*. As we will see, different disorders are thought to stem from different patterns of neurotransmitter imbalances in various brain areas (e.g., Lambert & Kinsley, 2005; Thompson, 2000). Different medications used to treat various disorders are often believed to operate by correcting these imbalances. For example, the widely prescribed antidepressants Prozac and Zoloft appear to slow the reuptake of the neurotransmitter serotonin, thereby prolonging how long serotonin remains in the synapse (see Chapters 7 and 16).

Although over a hundred neurotransmitters have been discovered to date, five different kinds of neurotransmitters have been most extensively studied in relationship to psychopathology: (1) norepinephrine, (2) dopamine, (3) serotonin, (4) glutamate, and (5) gamma aminobutyric acid (known as GABA; Carlson, 2007; Lambert & Kinsley, 2005; Thompson, 2000). The first three belong to a class of neurotransmitters called *monoamines*.

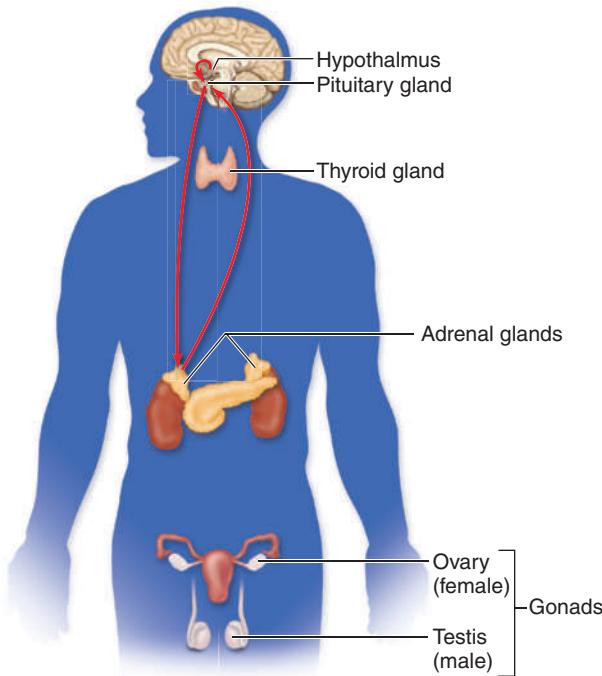

because each is synthesized from a single amino acid (*monoamine* means “one amine”). Norepinephrine has been implicated as playing an important role in the emergency reactions our bodies show when we are exposed to an acutely stressful or dangerous situation, as well as in attention, orientation, and basic motives (see Chapters 5 and 6). Some of the functions of dopamine include pleasure and cognitive processing, and it has been implicated in schizophrenia (see Chapter 13) as well as in addictive disorders (see Chapter 11). Serotonin has been found to have important effects on the way we think and process information from our environment as well as on behaviors and moods. Not surprisingly, then, it seems to play an important role in emotional disorders such as anxiety and depression, as well as in suicide, as we will see in Chapters 6 and 7. In Chapter 13 we discuss the excitatory neurotransmitter glutamate, which has been implicated in schizophrenia. Finally, in Chapter 6, we discuss the neurotransmitter GABA, which is strongly implicated in reducing anxiety as well as other emotional states characterized by high levels of arousal. Each will be discussed at greater length when the relevant disorders are discussed.

Given that many forms of psychopathology have been associated with various abnormalities in neurotransmitter functioning and with altered sensitivities of receptor sites, it is not surprising that many of the medications used to treat various disorders have the synapse as their site of action. For example, certain medications act to increase or decrease the concentrations of pertinent neurotransmitters in the synaptic gap. They may do so by blocking the reuptake process, by altering the sensitivity of the receptor sites, or by affecting the actions of the enzymes that ordinarily break down the neurotransmitter substances. Medications that facilitate the effects of a neurotransmitter on the postsynaptic neuron are called *agonists*, and those that oppose or inhibit the effects of a neurotransmitter on a postsynaptic neuron are called *antagonists*.

**HORMONAL IMBALANCES** Some forms of psychopathology have also been linked to *hormonal imbalances*. **Hormones** are chemical messengers secreted by a set of endocrine glands in our bodies. Each of the endocrine glands produces and releases its own set of hormones directly into our bloodstream. The hormones then travel and directly affect target cells in various parts of our brain and body, influencing diverse events such as fight-or-flight reactions, sexual responses, physical growth, and many other physical expressions of mental states. Our central nervous system is linked to the endocrine system (in what is known as the *neuroendocrine system*) by the effects of the hypothalamus on the **pituitary gland**, which is the master gland of the body, producing a variety of hormones that regulate or control the other endocrine glands (see Figure 3.5).

One particularly important set of interactions occurs in the **hypothalamic-pituitary-adrenal axis (HPA axis)**. Activation of this axis involves:

1. Messages in the form of corticotrophin-releasing hormone (CRH) travel from the hypothalamus to the pituitary.

**FIGURE 3.5**

**Major Glands of the Endocrine System.** This figure illustrates some of the major glands of the endocrine system, which produce and release hormones into the bloodstream. The hypothalamic-pituitary-adrenal axis is also shown (blue arrows). The hypothalamus and pituitary are closely connected, and the hypothalamus periodically sends hormone signals to the pituitary (the master gland), which in turn sends another hormone to the cortical part of the adrenal glands (above the kidneys) to release epinephrine and the stress hormone cortisol. [Simulate the Experiment The Endocrine System in MyPsychLab](#)

2. In response to CRH, the pituitary releases adrenocorticotrophic hormone (ACTH), which stimulates the cortical part of the adrenal gland (located on top of the kidney) to produce epinephrine (adrenaline) and the stress hormone **cortisol**, which are released into general circulation. Cortisol mobilizes the body to deal with stress.
3. Cortisol in turn provides negative feedback to the hypothalamus and pituitary to decrease their release of CRH and ACTH, which in turn reduces the release of adrenaline and cortisol. This negative feedback system operates much as a thermostat does to regulate temperature.

As we will see, malfunctioning of this negative feedback system has been implicated in various forms of psychopathology such as depression and posttraumatic stress disorder.

Sex hormones are produced by the gonadal glands, and imbalance in these (such as the male hormones, the *androgens*) can also contribute to maladaptive behavior. Moreover, gonadal hormonal influences on the developing nervous system also seem to contribute to some of the differences between behavior in men and in women (e.g., Hayward, 2003; Hines, 2004; Money & Ehrhardt, 1972).

## Genetic Vulnerabilities

The biochemical processes described above are themselves affected by **genes**, which consist of very long molecules of DNA (deoxyribonucleic acid) and are present at various locations on chromosomes. **Chromosomes** are the chain-like structures within a cell nucleus that contain the genes. Genes are the carriers of genetic information that we inherit from our parents and other ancestors, and each gene exists in two or more alternate forms called *alleles*. Although neither behavior nor mental disorders are ever determined exclusively by genes, there is substantial evidence that most mental disorders show at least some genetic influence ranging from small to large (e.g., Plomin et al., 2008; Rutter, 2006a). Some of these genetic influences, such as broad temperamental features, are first apparent in newborns and children. For example, some children are just naturally more shy or anxious, whereas others are more outgoing (e.g., Carey & DiLalla, 1994; Fox et al., 2010; Kagan & Fox, 2006). However, some genetic sources of vulnerability do not manifest themselves until adolescence or adulthood, when most mental disorders appear for the first time.

Healthy human cells have 46 chromosomes containing genetic materials that encode the hereditary plan for each individual, providing the potentialities for development and behavior of that individual throughout a lifetime. The normal inheritance consists of 23 pairs of chromosomes, one of each pair from the mother and one from the father. Twenty-two of these chromosome pairs determine, by their biochemical action, an individual's general anatomical and other physiological characteristics. The remaining pair, the *sex chromosomes*, determine the individual's sex. In a female, both of these sex chromosomes—one from each parent—are designated as X chromosomes. In a male, the sex chromosome from the mother is an X, but that from the father is a Y chromosome (see Figure 3.6).

Research in developmental genetics has shown that abnormalities in the structure or number of the chromosomes can be associated with major defects or disorders. For example, Down syndrome is a type of intellectual disability (also associated with recognizable facial features such as a flat face and slanted eyes) in which there is a trisomy (a set of three chromosomes instead of two) in chromosome 21 (see Chapter 15). Here the extra chromosome is the primary cause of the disorder. Anomalies may also occur in the sex chromosomes, producing a variety of complications, such as ambiguous sexual characteristics, that may predispose a person to develop abnormal behavior.

More typically, however, personality traits and mental disorders are not affected by chromosomal abnormalities per se. Instead they are more often influenced either by abnormalities in some of the genes on the chromosomes or by naturally occurring variations of genes known as *polymorphisms*. Although you will often hear about discoveries that "the gene" for a particular disorder has been discovered, vulnerabilities to mental disorders are almost always **polygenic**, which means they are influenced by multiple genes or by multiple polymorphisms of genes, with any one gene having only very small effects (Kendler, 2005; Plomin et al., 2008). In other words, a genetically vulnerable person has usually inherited a large number of genes, or polymorphisms of genes, that operate together in some sort of additive or interactive fashion to increase vulnerability (e.g., Kendler, 2005; Plomin et al., 2008; Rutter, 2006b). Collectively these genes may, for example, lead to structural abnormalities in the central nervous system, to abnormalities in the regulation of brain chemistry and hormonal balance, or to excesses or deficiencies in the reactivity of the autonomic nervous system, which is involved in mediating many of our emotional responses.

In the field of abnormal psychology, genetic influences rarely express themselves in a simple and straightforward manner. This is because behavior, unlike some physical characteristics such as eye color, is not determined exclusively by genetic endowment; it is a product of the organism's interaction with

**FIGURE 3.6**

**Human Chromosome Pairs.** A normal human male has 23 pairs of chromosomes, including an X chromosome and a Y chromosome.

Source: "Human Chromosome Pairs," from Thomas D. Gelehrter et al. (1998). *Principles of Medical Genetics*. Reprinted with permission of Lippincott/Williams & Wilkins and Dr. Thomas D. Gelehrter.

the environment. In other words, genes can affect behavior only indirectly. Gene “expression” is normally not a simple outcome of the information encoded in DNA but is, rather, the end product of an intricate process that may be influenced by the internal (e.g., intrauterine) and external environment. Indeed, certain genes can actually be “turned on,” or activated, and “turned off,” or deactivated, in response to environmental influences such as stress (e.g., Plomin et al., 2008; Rutter, 2006b).

**THE RELATIONSHIP OF GENOTYPES TO PHENOTYPES** A person’s total genetic endowment is referred to as her or his **genotype** and, except for identical twins, no two humans ever begin life with the same endowment. The observed structural and functional characteristics that result from an interaction of the genotype and the environment are referred to as a person’s **phenotype**. In some cases, the genotypic vulnerability present at birth does not exert its effect on the phenotype until much later in life. In many other cases, the genotype may shape the environmental experiences a child has, thus affecting the phenotype in yet another very important way. For example, a child who is genetically predisposed to aggressive behavior may be rejected by his or her peers in early grades because of the aggressive behavior. Such rejection may lead the child to go on to associate with similarly aggressive and delinquent peers in later grades, leading to an increased likelihood of developing a full-blown pattern of delinquency in adolescence. When the genotype shapes the environmental experiences a child has in this way, we refer to this phenomenon as a **genotype–environment correlation** (Plomin et al., 2008; Rutter, 2006, 2007).

**GENOTYPE–ENVIRONMENT CORRELATIONS** Researchers have found three important ways in which an individual’s genotype may shape his or her environment (Jang, 2005; Plomin et al., 2008, 2013).

1. The child’s genotype may have what has been termed a *passive effect* on the environment, resulting from the genetic similarity of parents and children. For example, highly intelligent parents may provide a highly stimulating environment for their child, thus creating an environment that will interact in a positive way with the child’s genetic endowment for high intelligence. Conversely, parents who exhibit antisocial behavior tend to create a risky environment characterized by family dysfunction, thereby increasing the probability of certain mental disorders in their children (e.g., Rutter, 2006b; see also Chapter 10).
2. The child’s genotype may evoke particular kinds of reactions from the social and physical environment—a so-called *evocative effect*. For example, active, happy babies evoke more positive responses from others than do passive, unresponsive infants (Lyttton, 1980). Similarly, musically talented children may be picked out at school and given special opportunities (Plomin et al., 2008, 2013).

3. The child’s genotype may play a more active role in shaping the environment—a so-called *active effect*. In this case the child seeks out or builds an environment that is congenial—a phenomenon known as “niche building.” For example, extraverted children may seek the company of others, for example, thereby enhancing their own tendencies to be sociable (Baumrind, 1991; Plomin et al., 2008, 2013).

**GENOTYPE–ENVIRONMENT INTERACTIONS** With the type of genotype–environment correlations just discussed, we see the effects that genes have on a child’s exposure to the environment. But an additional, fascinating complication is that people with different genotypes may be differentially sensitive or susceptible to their environments; this is known as a **genotype–environment interaction**. One important example is illustrated by a disorder known as PKU-induced intellectual disability (see Chapter 15). Children with the genetic vulnerability to PKU react very differently to many common foods with phenylalanine than do normal children because they cannot metabolize the phenylalanine (an amino acid), and as its metabolic products build up, they damage the brain (Plomin et al., 2008, 2013; Rutter, 2006b). Fortunately, this mental retardation syndrome can be prevented if the young child’s diet is changed so as to eliminate foods with phenylalanine.

Another example occurs in people at genetic risk for depression, who have been shown to be more likely to respond to stressful life events by becoming depressed than are people without the genetic risk factors who experience the same stressful life events (Kendler, Kessler, et al., 1995; Moffitt, Caspi, & Rutter, 2005, 2006; Silberg, Rutter, Neale & Eaves, 2001). In one landmark study of nearly 850 young adults who had been followed since age 3, investigators found evidence for a genotype–environment interaction involving several variants on a specific gene involved in the transport of the neurotransmitter serotonin. Which of two variants of this gene a person had affected the likelihood that she or he would develop major depression in her or his 20s, but only when considered in interaction with life stress (Caspi et al., 2003). Specifically, individuals with one variant of the gene (two short alleles) who also experienced four or more major life stressors had twice the probability of developing major depression than individuals with another variant of the gene (two long alleles) who also experienced four or more major life stressors (see Chapter 7 for more details). Since then, this basic pattern of results has been replicated in many studies (and not in others), but recent evidence suggests that the effects are robust if sophisticated interview-based measures of life stress (not checklists) are used (Uher & McGuffin, 2010; see also Karg et al., 2011).

**METHODS FOR STUDYING GENETIC INFLUENCES** Although advances are beginning to be made in identifying faulty genetic endowment, for the most part we are not yet able to

isolate, on the genes themselves, specific defects for mental disorders. Therefore, most of the information we have on the role of genetic factors in mental disorders is based not on studies of genes but on studies of people who are related to each other.

Three primary methods have traditionally been used in **behavior genetics**, the field that focuses on studying the heritability of mental disorders (as well as other aspects of psychological functioning): (1) the family history (or pedigree) method, (2) the twin method, and (3) the adoption method. More recently, two additional methods, linkage studies and association studies, have also been developed.

The **family history** (or pedigree) **method** requires that an investigator observe samples of relatives of each *proband* or *index case* (the subject, or carrier, of the trait or disorder in question) to see whether the incidence increases in proportion to the degree of hereditary relationship. In addition, the incidence of the disorder in a normal population is compared (as a control) with its incidence among the relatives of the index cases. The main limitation of this method is that people who are more closely related genetically also tend to share more similar environments, which makes it difficult to disentangle genetic and environmental effects.

The **twin method** is the second approach used to study genetic influences on abnormal behavior. *Identical (monozygotic) twins* share the same genetic endowment because they develop from a single zygote, or fertilized egg. Thus if a given disorder or trait were completely heritable, one would expect the **concordance rate**—the percentage of twins sharing the disorder or trait—to be 100 percent. That is, if one identical twin had a particular disorder, the other twin would as well. However, there are no forms of psychopathology where the concordance rates for identical twins are this high, so we can safely conclude that no mental disorders are completely heritable. Nevertheless, as we will see, there are relatively high concordance rates for identical twins in some more severe forms of psychopathology. These concordance rates are particularly meaningful when they differ from those found for nonidentical twins. *Nonidentical (dizygotic) twins* do not share any more genes than do siblings from the same parents because they develop from two different fertilized eggs. One would therefore expect concordance rates for a disorder to be much lower for dizygotic (DZ) than for monozygotic (MZ) twins if the disorder had a strong genetic component. Thus evidence for genetic transmission of a trait or a disorder can be obtained by comparing the concordance rates between identical and nonidentical twins. For most of the disorders we will discuss, concordance rates are indeed much lower for nonidentical twins than for identical twins.

Some researchers have argued that finding higher concordance rates for a disorder in monozygotic twins than in dizygotic twins is not conclusive evidence of a genetic contribution because it is always possible that identical twins are treated more similarly by their parents and others than are nonidentical twins

This set of identical twins from Bouchard's University of Minnesota Study of Twins Reared Apart pose here with Dr. Nancy Segal, co-director of the project. Mark Newman (left) and Gerry Levey (right) were separated at birth and raised by different parents. Both were dedicated firefighters in different New Jersey towns and met after someone mistook one of them at a firemen's convention for his twin. Both had highly similar patterns of baldness and were 6'4" tall. They both loved Budweiser beer (which they both held by placing their pinky finger under the beer can) as well as Chinese and Italian food. Both had been smokers until recently, when one had quit. They both also liked hunting and fishing and always carried knives. These eerie similarities between identical twins reared apart have been observed in many other such twins as well (Segal, 2005).

(Bouchard & Propping, 1993; Torgersen, 1993). However, research has provided reasonably strong evidence that the genetic similarity is more important than the similarity of the parents' behavior (e.g., Hettema, Neale, & Kendler, 1995; Plomin et al., 2008, 2013; Rutter, 2006). Nevertheless, the ideal study of genetic factors in psychopathology involves identical twins who have been reared apart in significantly different environments. Unfortunately, finding such twins is extremely difficult (there are probably only a few hundred pairs in the United States), and so only a few such small studies have been done.

The third method used to study genetic influences is the **adoption method**. This method capitalizes on the fact that adoption creates a situation in which individuals who do not share a common family environment are nonetheless genetically related (e.g., Plomin et al., 2008, 2013). In one variation on this method, the biological parents of individuals who have a given disorder (and who were adopted away shortly after birth) are compared with the biological parents of individuals without the disorder (who also were adopted away shortly after birth) to determine their rates of disorder. If there is a genetic influence, one expects to find higher rates of the disorder in the biological relatives of those with the disorder than in those without the disorder. In another variation, researchers compare the rates of disorder in the adopted-away offspring of

biological parents who have a disorder with those seen in the adopted-away offspring of normal biological parents. If there is a genetic influence, then there should be higher rates of disorder in the adopted-away offspring of the biological parents who have the disorder.

Although pitfalls can arise in interpreting each of these methods, if the results from studies using all three strategies converge, one can draw reasonably strong conclusions about the genetic influence on a disorder (Plomin et al., 2008; Rutter, 1991). The Developments in Thinking box below considers various misconceptions about studies of genetics and psychopathology.

### SEPARATING GENETIC AND ENVIRONMENTAL

**INFLUENCES** Because all of the three types of heritability studies separate heredity from environment to some extent, they

also allow for testing the influence of environmental factors and even for differentiating “shared” and “nonshared” environmental influences (Plomin & Daniels, 1987; Plomin et al., 2008, 2013; Rutter, 2006). *Shared environmental influences* are those that would make children in a family more similar, whether the influence occurs within the family (e.g., family discord and poverty) or in the environment (e.g., two high-quality schools, with one twin going to each). *Nonshared environmental influences* are those in which the children in a family differ. These would include unique experiences at school and also some unique features of upbringing in the home, such as a parent treating one child in a qualitatively different way from another. An example of nonshared influences occurs when parents who are quarreling and showing hostility to one another draw some children into the conflict while others are able to remain outside it (Plomin

## developments in THINKING

### Nature, Nurture, and Psychopathology: A New Look at an Old Topic

People have abundant misconceptions and stereotypes about studies of genetic influences on behavior, traits, and psychopathology, many stemming from outdated ideas that nature and nurture are separate rather than in constant interplay. Indeed, as we have seen in the examples of genotype–environment correlations and interactions, “In the great majority of cases, both psychological traits and mental disorders are multifactorial in origin—meaning that they involve some kind of combination, and interplay, among several genetic factors providing contributions to susceptibility or liability and several environmental factors that similarly play a part in the causal pathway” (Rutter, 2006, p. 29). Several of the more important misconceptions are presented here (Plomin et al., 2008; Rutter, 1991, 2006).

**1. Misconception:** Strong genetic effects mean that environmental influences must be unimportant. **Fact:** Even if we are discussing a trait or disorder that has a strong genetic influence, environmental factors can have a major impact on the level of that trait (Rutter, 2006). Height, for example, is strongly genetically determined, and yet nutritional factors have a very large effect on the actual height a person attains. Between 1900 and 1960 the average height of boys reared in London increased about 4 inches, thanks only to improvements in diet (Tizard, 1975).

**2. Misconception:** Genes provide a limit to potential. **Fact:** One’s potential can change if one’s environment changes, as the height example above illustrates. Another example comes from children born to socially disadvantaged parents but who are adopted and reared with socially advantaged parents. These children have a mean IQ about 12 points higher than those reared in the socially disadvantaged environment (Capron & Duyme, 1989; see also Duyme et al., 2004).

**3. Misconception:** Genetic strategies are of no value for studying environmental influences. **Fact:** The opposite is true because genetic research strategies provide critical tests of environmental influences on personality and psychopathology (Rutter, 2006). For example, because monozygotic twins have identical genes, concordance rates of less than 100 percent clearly illustrate the importance of environmental influences (Bouchard & Loehlin, 2001; Rutter, 2006a).

**4. Misconception:** Genetic effects diminish with age. **Fact:** Although many people assume that genetic effects should be maximal at birth, with environmental influences getting stronger with increasing age, it is now evident that this is not always true (Plomin, 1986; Rutter, 2006). For height, weight, and IQ, dizygotic twins are almost as alike as monozygotic twins in early infancy, but over time dizygotic twins show greater differences than monozygotic twins. For whatever reasons, many genetic effects on psychological characteristics increase with age up to at least middle childhood or even young adulthood. Moreover, other genetic effects do not appear until much later in life, as in cases like Huntington’s disease, to be discussed in Chapter 14.

**5. Misconception:** Disorders that run in families must be genetic, and those that do not run in families must not be genetic. **Fact:** Many examples contradict these misconceptions. For example, teenage-onset juvenile delinquency tends to run in families, and yet this seems to be due primarily to environmental rather than genetic influences (Plomin et al., 2008; Rutter, 2006a). Conversely, autism is such a rare disorder that it doesn’t appear to run in families (only about 3% of siblings have the disorder), and yet there seems to be a very powerful genetic effect (Plomin et al., 2008; Rutter, 2006a).

et al., 2008, 2013; Rutter, 2006a; Rutter et al., 1993). For many important psychological characteristics and forms of psychopathology, nonshared influences have appeared to be more important—that is, experiences that are specific to a child may do more to influence his or her behavior and adjustment than experiences shared by all children in the family (Plomin et al., 2008, 2013; Rutter, 1991, 2006).

**LINKAGE ANALYSIS AND ASSOCIATION STUDIES** More recent molecular genetic methods used to study genetic influences on mental disorders include *linkage analysis* and *association studies*. Whereas the methods previously described attempt to obtain quantitative estimates of the degree of genetic influence for different disorders, linkage analysis and association studies attempt to determine the actual location of genes responsible for mental disorders. Considerable excitement surrounds such work because identifying the location of genes for certain disorders could provide promising leads for new forms of treatment and even prevention of those disorders.

**Linkage analysis** studies of mental disorders capitalize on several currently known locations on chromosomes of genes for other inherited physical characteristics or biological processes (such as eye color, blood group, etc.). For example, researchers might conduct a large family pedigree study on schizophrenia, looking at all known relatives of a person with schizophrenia going back several generations. At the same time, however, they might also keep track of something like the eye color of each individual (as well as which *DSM* diagnoses they have). Eye color might be chosen because it has a known genetic marker located on a particular chromosome. If the researchers found that the familial patterns for schizophrenia in one family pedigree (a sample of all relatives) were closely linked to the familial patterns for eye color in the same pedigree, they could infer that a gene affecting schizophrenia must be located very nearby on the chromosome that contains the known genetic marker for eye color. In other words, in this case one would expect all members of a particular family pedigree with schizophrenia to have the same eye color (e.g., blue), even though all members of a different family pedigree with schizophrenia might have brown eyes.

A number of published studies over the past 20 years using linkage analysis have provided evidence supporting, for example, the location of a gene for bipolar disorder on chromosome 11 (e.g., Egeland et al., 1987) and the location of genes for schizophrenia on particular parts of chromosomes 22, 6, 8, and 1 (e.g., Heinrichs, 2001). However, numerous other studies have failed to replicate these results. Therefore, most results are considered inconclusive at the present time (e.g., Carey, 2003; Rutter, 2006). Part of the problem in coming up with replicable results in such studies is that most of these disorders are influenced by many different genes spread over multiple chromosomes. To date, these linkage analysis techniques have been most successful in locating the genes for single-gene brain disorders such as Huntington's disease (Plomin et al., 2008, 2013; Rutter, 2006).

**Association studies** start with two large groups of individuals, one group with and one group without a given disorder. Researchers then compare the frequencies in these two groups of certain genetic markers that are known to be located on particular chromosomes (such as eye color, blood group, etc.). If one or more of the known genetic markers occur with much higher frequency in the individuals with the disorder than in the people without the disorder, the researchers infer that one or more genes associated with the disorder are located on the same chromosome. Ideally, the search for gene candidates for a given disorder starts with known genes for some biological process that is disrupted in the disorder (see Moffitt et al., 2005). For example, one study found that the genetic markers for certain aspects of dopamine functioning were present significantly more frequently in the children with hyperactivity than in the children without hyperactivity. This led researchers to infer that some of the genes involved with hyperactivity are located near the known genetic markers for dopamine functioning (Thapar et al., 2006; see also Plomin et al., 2008, 2013). For most mental disorders that are known to be influenced polygenically, association studies are more promising than linkage studies for identifying small effects of any particular gene.

In summary, these molecular genetic studies using linkage and association methodologies hold tremendous promise for identifying new prevention or treatment approaches. However, at present that promise has not been fulfilled because of difficulties in producing replicable results.

## Temperament

**Temperament** refers to a child's reactivity and characteristic ways of self-regulation. When we say that babies differ in temperament, we mean that they show differences in their characteristic emotional and arousal responses to various stimuli and in their tendency to approach, withdraw, or attend to various situations (Rothbart, Derryberry, & Hershey, 2000). Some babies are startled by slight sounds or cry when sunlight hits their faces; others are seemingly insensitive to such stimulation. These behaviors are strongly influenced by genetic factors, but prenatal and postnatal environmental factors also play a role in their development (Goldsmith, 2003; Rothbart et al., 2000).

Our early temperament is thought to be the basis from which our personality develops. Starting at about 2 to 3 months of age, approximately five dimensions of temperament can be identified: fearfulness, irritability and frustration, positive affect, activity level, and attentional persistence and effortful control, although some of these emerge later than others. These seem to be related to the three important dimensions of adult personality: (1) neuroticism or negative emotionality, (2) extraversion or positive emotionality, and (3) constraint (conscientiousness and agreeableness; Rothbart & Ahadi, 1994; Rothbart & Bates, 2006; Watson, Clark, & Harkness, 1994). The infant dimensions of fearfulness and irritability, which show few gender differences (Else-Quest et al., 2006), correspond to the adult

A child with a fearful and anxious temperament can become very distressed with changes in the environment, such as his mother leaving for work.

dimension of neuroticism—the disposition to experience negative affect. The infant dimensions of positive affect and possibly activity level seem related to the adult dimension of extraversion, and the infant dimension of attentional persistence and effortful control seem related to the adult dimension of constraint or control. One quantitative review concluded that, on average, boys show slightly higher levels of activity and intense pleasure than do girls, whereas girls, on average, seem to have greater control of their impulses and greater ability to regulate their attention (e.g., Else-Quest et al., 2006). At least some aspects of temperament show a moderate degree of stability from late in the first year of life through at least middle childhood, although temperament can also change (e.g., Fox et al., 2005; Kagan, 2003; Rothbart et al., 2000).

Just as we saw in the discussion of genotype–environment correlations, the temperament of an infant or young child has profound effects on a variety of important developmental processes (Fox et al., 2010; Rothbart et al., 2000). For example, a child with a fearful temperament has many opportunities for the classical conditioning of fear to situations in which fear is provoked; later the child may learn to avoid entering those feared situations, and evidence suggests that he or she may be especially likely to learn to fear social situations (Fox et al., 2010; Kagan, 2003). In addition, children with high levels of positive affect and activity are more likely to show high levels of mastery motivation, whereas children with high levels of fear and sadness are less likely to show mastery motivation (Posner & Rothbart, 2007).

Finally, children with high levels of negative emotionality are more difficult for parents to be supportive of, and different parents have different styles of parenting such children. This seems to be true especially in families with lower socioeconomic status, which are, on average, less supportive of difficult children than families of mid to high socioeconomic status. The latter families seem to be more resourceful in adapting their parenting styles when faced with such high negative emotionality in a child (Paulussen-Hoogeboom et al., 2007).

Not surprisingly, temperament may also set the stage for the development of various forms of psychopathology later in life. For example, children who are fearful and hypervigilant in many novel or unfamiliar situations have been labeled *behaviorally inhibited* by Kagan, Fox, and their colleagues. This trait has a significant heritable component (Kagan, 2003) and, when it is stable, is a risk factor for the development of anxiety disorders later in childhood and probably in adulthood (e.g., Fox et al., 2005, 2010; Kagan, 2003). Conversely, 2-year-old children who are highly *uninhibited*, showing little fear of anything, may have difficulty learning moral standards for their behavior from parents or society (Frick, Cornell, Bodin, et al., 2003; Rothbart, Ahadi, & Evans, 2000), and they have been shown at age 13 to exhibit more aggressive and delinquent behavior (Schwartz, Snidman, & Kagan, 1996). If these personality ingredients are combined with high levels of hostility, the stage also might be set for the development of conduct disorder and antisocial personality disorder (Harpur et al., 1993).

### Brain Dysfunction and Neural Plasticity

As noted earlier, specific brain lesions with observable defects in brain tissue are rarely a primary cause of psychiatric disorders. However, advances in understanding how more subtle deficiencies of brain structure or function are implicated in many mental disorders have been increasing at a rapid pace in the past few decades. Some of these advances come from the increased availability of sophisticated new neuroimaging techniques to study the function and structure of the brain (see Chapter 4 for more details). These and other kinds of techniques have shown that genetic programs for brain development are not so rigid and deterministic as was once believed (e.g., Gottesman & Hanson, 2005; Nelson & Bloom, 1997; Thompson & Nelson, 2001). Instead, there is considerable *neural plasticity*—flexibility of the brain in making changes in organization and function in response to pre- and postnatal experiences, stress, diet, disease, drugs, maturation, and so forth. Existing neural circuits can be modified, or new neural circuits can be generated (e.g., Fox et al., 2010; Kolb et al., 2003). The effects can be either beneficial or detrimental to the individual, depending on the circumstances.

One example of the positive effects of *prenatal experiences* comes from an experiment in which pregnant rats housed in complex, enriched environments had offspring that were less negatively affected by brain injury that occurred early in development than those without the same positive prenatal experiences (Kolb et al., 2003). One example of negative effects of prenatal experiences comes from an experiment in which pregnant monkeys exposed to unpredictable loud sounds had infants that were jittery and showed neurochemical abnormalities (specifically, elevated levels of circulating catecholamines; Schneider, 1992). Many *postnatal environmental events* also affect the brain development of the infant and child (Nelson & Bloom, 1997; Thompson & Nelson, 2001). For example, the formation of new neural connections (or synapses) after birth is

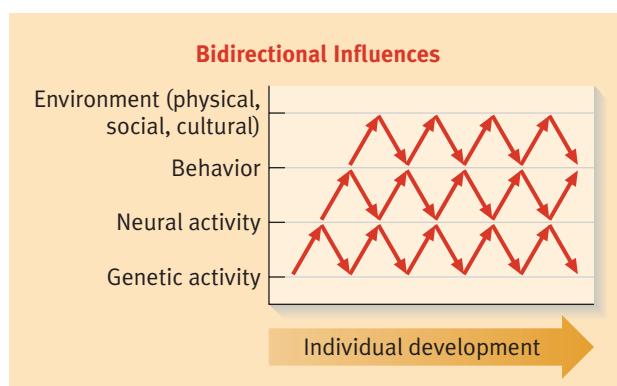

dramatically affected by the experiences a young organism has (e.g., Greenough & Black, 1992; Rosenzweig et al., 2002). Rats reared in enriched environments (as opposed to in isolation) show heavier and thicker cell development in certain portions of the cortex (as well as more synapses per neuron). Similar but less extensive changes can occur in older animals exposed to enriched environments; hence neural plasticity continues to some extent throughout the life span (see Fox et al., 2010; Lambert & Kinsley, 2005).

The early implications of this kind of work were taken to suggest that human infants should be exposed to highly enriched environments. However, subsequent work has shown that normal rearing conditions with caring parents are perfectly adequate. What later work really showed is that unstimulating, deprived environments can cause retarded development (Thompson, 2000; Thompson & Nelson, 2001).

This research on neural and behavioral plasticity, in combination with the work described earlier on genotype-environment correlations, makes it clear why developmental psychopathologists have been devoting increasing attention to a **developmental systems approach** (e.g., Masten, 2006; Spencer et al., 2009). This approach acknowledges not only that genetic activity influences neural activity, which in turn influences behavior, which in turn influences the environment, but also that these influences are bidirectional. Thus Figure 3.7 illustrates this first direction of influence but also shows how various aspects of our environment (physical, social, and cultural) also influence our behavior, which in turn affects our neural activity, and this in turn can even influence genetic activity (Gottlieb, 1992; Gottlieb & Halpern, 2002; see also Gottesman & Hanson, 2005; Masten, 2006).

### The Impact of the Biological Viewpoint

Biological discoveries have profoundly affected the way we think about human behavior. We now recognize the important role of biochemical factors and innate characteristics, many of

**FIGURE 3.7**

**Bidirectional Influences.** A systems view of psychobiological development. Source: From Gilbert Gottlieb. 1992. *Individual Development and Evolution: The Genesis of Novel Behavior*. New York: Oxford University Press. Reprinted by permission of Lawrence Erlbaum Associates.

which are genetically determined, in both normal and abnormal behavior. In addition, since the 1950s we have witnessed many new developments in the use of drugs that can dramatically alter the severity and course of certain mental disorders—particularly the more severe ones such as schizophrenia and manic depressive illness (bipolar disorder). The host of new drugs has attracted a great deal of attention to the biological viewpoint not only in scientific circles but also in the popular media. Biological treatments seem to have more immediate results than other available therapies, and the hope is that they may in most cases lead to a “cure-all”—immediate results with seemingly little effort.

However, as Gorenstein (1992) and others argued two decades ago, there are several common errors in the way many people interpret the meaning of recent biological advances. Gorenstein points out that it is illusory to think—as some prominent biological researchers have—that establishing biological differences between, for example, individuals with schizophrenia and those without schizophrenia in and of itself substantiates that schizophrenia is an illness (e.g., Andreasen, 1984; Kety, 1974). All behavioral traits (introversion and extraversion, for example, or high and low sensation seeking) are characterized by distinctive biological characteristics, yet we do not label these traits as illnesses. Thus the decision about what constitutes a mental illness or disorder ultimately still rests on clinical judgment regarding the functional effects of the disordered behavior—specifically whether it leads to clinically significant distress or impairment in functioning. Establishing the biological substrate does not bear on this issue because all behavior—normal and abnormal—has a biological substrate.

As Gorenstein (1992) also pointed out, the effects of psychological events are always **mediated** through the activities of the central nervous system because all our behaviors, beliefs, emotions, and cognitions are ultimately reducible to a set of biological events in the brain. In actuality, then, if we find some dysfunction of the nervous system, this dysfunction could have arisen from psychological causes as well as from biological causes. In addition, psychological treatments are often as effective as drugs in producing changes in brain structure and function (e.g., Baxter et al., 2000; Linden, 2006).

### research CLOSE-UP

#### Mediate

A mediator (or mediating variable) lies between two other variables and helps explain the relationship between them. You can think of it as being like an intermediate variable, hence the name.

At a more general level, we must remind ourselves again that few, if any, mental disorders are independent of people's personalities or of the problems they face in trying to live their lives. We will examine viewpoints that emphasize these psychological and sociocultural considerations in the pages that follow, keeping in mind that the ultimate challenge will be to integrate these varying perspectives into a theoretically consistent biopsychosocial perspective on psychopathology.

#### in review

- Describe the sequence of events involved in the transmission of nerve impulses.
- Explain how neurotransmitter and hormonal abnormalities might produce abnormal behavior.
- What is the relationship between an individual's genotype and phenotype, and how can genotypes shape and interact with the environment?
- Describe at least two methods for studying genetic influences on abnormal behavior.
- What is temperament, and why is it important for the origins of abnormal behavior?
- What do we mean by "neural plasticity"?

## The Psychological Viewpoints

There are many more psychological than biological interpretations of abnormal behavior, reflecting a wider range of opinions on how best to understand humans as people with motives, desires, perceptions, thoughts, and so on rather than just as biological organisms. We will examine in some depth three perspectives on human nature and behavior that have been particularly influential: psychodynamic, behavioral, and cognitive-behavioral. (See Figure 3.8.) These three viewpoints represent distinct and sometimes conflicting orientations, but they are in many ways

complementary. They all emphasize the importance of early experience and an awareness of psychological processes within an individual, as well as how these are influenced by social factors. The Developments in Thinking Box on page 77 will later present a few of the major themes of two additional psychological perspectives: the humanistic and existential perspectives.

## The Psychodynamic Perspectives

As we noted in Chapter 2, Sigmund Freud founded the *psychoanalytic school*, which emphasized the role of unconscious motives and thoughts and their dynamic interrelationships in the determination of both normal and abnormal behavior. A key concept here is the *unconscious*. According to Freud, the conscious part of the mind represents a relatively small area, whereas the unconscious part, like the submerged part of an iceberg, is the much larger portion. In the depths of the unconscious are the hurtful memories, forbidden desires, and other experiences that have been repressed—that is, pushed out of consciousness. However, Freud believed that unconscious material continues to seek expression and emerges in fantasies, dreams, slips of the tongue, and so forth. Until such unconscious material is brought to awareness and integrated into the conscious part of the mind—for example, through psychoanalysis (a form of psychotherapy Freud developed—see Chapter 16)—it may lead to irrational and maladaptive behavior. For our purposes, a general overview of the principles of classical psychoanalytic theory will suffice (see Alexander, 1948; Arlow, 2000; Luborsky & Barrett, 2006; or any of Freud's original works for more information). We will then discuss several of the newer *psychodynamic perspectives*, which were the second generation of theories that stemmed in some important ways out of Freud's original psychoanalytic theory and yet also departed from it in significant ways.

## FUNDAMENTALS OF FREUD'S PSYCHOANALYTIC THEORY

### The Structure of Personality: Id, Ego, and Superego

Freud theorized that a person's behavior results from the interaction of three key components of the personality or psyche: the id, ego, and superego (e.g., see Arlow, 2000; Engler, 2006). The **id** is the source of instinctual drives and is the first structure to appear in infancy. These drives are inherited and are considered to be of two opposing types: (1) *life instincts*, which are constructive drives primarily of a sexual nature and which constitute the **libido**, the basic emotional and psychic energy of life; and (2) *death instincts*, which are destructive drives that tend toward aggression, destruction, and eventual death. Freud used the term *sexual* in a broad sense to refer to almost anything pleasurable, from eating to painting. The id operates on the **pleasure principle**, engaging in completely selfish and pleasure-oriented behavior, concerned only with the immediate gratification of instinctual needs without reference to reality or moral considerations. Although the id can generate mental images and wish-fulfilling fantasies, referred to as **primary**

- ▶ Psychosocial perspectives attempt to understand humans not just as biological organisms but also as people with motives, desires, and perceptions.
- ▶ There are three major psychosocial perspectives on human nature and behavior:
  1. Psychodynamic
  2. Behavioral

**FIGURE 3.8**

Psychosocial Perspectives.

**process thinking**, it cannot undertake the realistic actions needed to meet instinctual demands.

Consequently, after the first few months of life, a second part of the personality, as viewed by Freud, develops—the **ego**. The ego mediates between the demands of the id and the realities of the external world. For example, during toilet training the child learns to control a bodily function to meet parental and societal expectations, and it is the developing ego that assumes the role of mediating between the physical needs of the body/id and the need to find an appropriate place and time. One of the basic functions of the ego is to meet id demands, but in such a way as to ensure the well-being and survival of the individual. This role requires the use of reason and other intellectual resources in dealing with the external world, as well as the exercise of control over id demands. The ego's adaptive measures are referred to as **secondary process thinking**, and the ego operates on the **reality principle**.

Freud viewed id demands, especially sexual and aggressive strivings, as inherently in conflict with the rules and prohibitions imposed by society. He postulated that as a child grows and gradually learns the rules of parents and society regarding right and wrong, a third part of the personality gradually emerges from the ego—the **superego**. The superego is the outgrowth of internalizing the taboos and moral values of society concerning what is right and wrong. It is essentially what we refer to as the *conscience*. As the superego develops, it becomes an inner control system that deals with the uninhibited desires of the id. Because the ego mediates among the desires of the id, the demands of reality, and the moral constraints of the superego, it is often called the *executive branch of the personality*.

Freud believed that the interplay of id, ego, and superego is of crucial significance in determining behavior. Often inner mental conflicts arise because the three subsystems are striving for different goals. If unresolved, these **intrapsychic conflicts** lead to mental disorder.

**Anxiety, Defense Mechanisms, and the Unconscious**  
The concept of *anxiety*—generalized feelings of fear and apprehension—is prominent in the psychoanalytic viewpoint because it is an almost universal symptom of neurotic disorders. Indeed, Freud believed that anxiety plays a key causal role in most of the forms of psychopathology that will be discussed in this book. He believed that the anxiety is sometimes overtly experienced, and at other times it is repressed and then transformed into and manifested in other overt symptoms such as conversion blindness or paralysis (see Chapter 8).

Anxiety is a warning of impending real or imagined dangers as well as a painful experience, and it forces an individual to take corrective action. Often, the ego can cope with objective anxiety through rational measures. However, neurotic and moral anxiety, because they are unconscious, usually cannot be dealt with through rational measures. In these cases the ego resorts to irrational protective measures that are referred to as **ego-defense**

Anxiety is almost universally experienced at some point. This woman shows her anxiety while awaiting news about the outcome of surgery on her sick child.

**mechanisms**, some of which are described in Table 3.1 on page 72. These defense mechanisms discharge or soothe anxiety, but they do so by helping a person push painful ideas out of consciousness (such as when we “forget” a dental appointment) rather than by dealing directly with the problem. These mechanisms result in a distorted view of reality, although some are clearly more adaptive than others.

**Psychosexual Stages of Development** In addition to his concept of the structure of personality, Freud also conceptualized five **psychosexual stages of development** that we all pass through from infancy through puberty. Each stage is characterized by a dominant mode of achieving libidinal (sexual) pleasure:

1. **Oral stage:** During the first 2 years of life, the mouth is the principal erogenous zone: An infant’s greatest source of gratification is sucking, a process that is necessary for feeding.
2. **Anal stage:** From ages 2 to 3, the anus provides the major source of pleasurable stimulation during the time when toilet training is often going on and there are urges both for retention and for elimination.
3. **Phallic stage:** From ages 3 to 5 or 6, self-manipulation of the genitals provides the major source of pleasurable sensation.
4. **Latency period:** From ages 6 to 12, sexual motivations recede in importance as a child becomes preoccupied with developing skills and other activities.
5. **Genital stage:** After puberty, the deepest feelings of pleasure come from sexual relations.

**TABLE 3.1**  
**Ego-Defense Mechanisms**

Mechanism	Example
<b>Displacement.</b> Discharging pent-up feelings, often of hostility, on objects less dangerous than those arousing the feelings.	A woman harassed by her boss at work initiates an argument with her husband.
<b>Fixation.</b> Attaching oneself in an unreasonable or exaggerated way to some person, or arresting emotional development on a childhood or adolescent level.	An unmarried, middle-aged man still depends on his mother to provide his basic needs.
<b>Projection.</b> Attributing one's unacceptable motives or characteristics to others.	An expansionist-minded dictator of a totalitarian state is convinced that neighboring countries are planning to invade.
<b>Rationalization.</b> Using contrived explanations to conceal or disguise unworthy motives for one's behavior.	A fanatical racist uses ambiguous passages from the scriptures to justify his hostile actions toward minorities.
<b>Reaction formation.</b> Preventing the awareness or expression of unacceptable desires by an exaggerated adoption of seemingly opposite behavior.	A man troubled by homosexual urges initiates a zealous community campaign to stamp out gay bars.
<b>Regression.</b> Retreating to an earlier developmental level involving less mature behavior and responsibility.	A man with shattered self-esteem reverts to childlike "showing off" and exhibits his genitals to young girls.
<b>Repression.</b> Preventing painful or dangerous thoughts from entering consciousness.	A mother's occasional murderous impulses toward her hyperactive 2-year-old are denied access to awareness.
<b>Sublimation.</b> Channeling frustrated sexual energy into substitutive activities.	A sexually frustrated artist paints wildly erotic pictures.

Source: Based on A. Freud (1946) and DSM-IV-TR (2000).

Freud believed that appropriate gratification during each stage is important if a person is to avoid being stuck, or *fixated*, at that level. For example, he maintained that an infant who does not receive adequate oral gratification may, in adult life, be prone to excessive eating or other forms of oral stimulation, such as biting fingernails, smoking, or drinking.

**The Oedipus Complex and the Electra Complex** In general, each psychosexual stage of development places demands on a child and arouses conflicts that Freud believed must be resolved in order to avoid later fixations. One of the most important conflicts occurs during the phallic stage, when the pleasures of self-stimulation and accompanying fantasies pave the way for the **Oedipus complex**. According to Greek mythology, Oedipus unknowingly killed his father and married his mother. Each young boy, Freud thought, symbolically relives the Oedipus drama. He longs for his mother sexually and views his father as a hated rival; however, each young boy also fears that his father will punish his son's lust by cutting off his penis. This **castration anxiety** forces the boy to repress his sexual desire for his mother and his hostility toward his father. Eventually, if all goes well, the boy identifies with his father and comes to have only harmless affection for his mother, channeling his sexual impulses toward another woman.

The **Electra complex** is the female counterpart of the Oedipus complex and is also drawn from a Greek tragedy. It is based on the view that each girl desires to possess her father and

The demands of the id are evident in early childhood. According to Freud, babies pass through an oral stage, in which sucking is a dominant pleasure.

to replace her mother. Freud also believed that each girl at this stage experiences *penis envy*, wishing she could be more like her father and brothers. She emerges from the complex when she comes to identify with her mother and settles for a promissory note: One day she will have a man of her own who can give her a baby—which unconsciously serves as a type of penis substitute.

Resolution of this conflict is considered essential if a young adult of either sex is to develop satisfactory heterosexual relationships. The psychoanalytic perspective holds that the best we can hope for is to effect a compromise among our warring inclinations—and to realize as much instinctual gratification as possible with minimal punishment and guilt. This perspective thus presents a deterministic view of human behavior that minimizes rationality and freedom of self-determination. On a group level, it interprets violence, war, and related phenomena as the inevitable products of the aggressive and destructive instincts present in human nature.

**NEWER PSYCHODYNAMIC PERSPECTIVES** In seeking to understand his patients and develop his theories, Freud was chiefly concerned with the workings of the id, its nature as a source of energy, and the manner in which this id energy could be channeled or transformed. He also focused on the superego and the role of conscience but paid relatively little attention to the importance of the ego. Later theorists developed some of Freud's basic ideas in three somewhat different directions.

**Ego Psychology** One new direction was that taken by his daughter Anna Freud (1895–1982), who was much more concerned with how the *ego* performs its central functions as the “executive” of personality. She and some of the other influential second-generation psychodynamic theorists refined and elaborated on the ego-defense mechanisms and put the ego in the foreground, giving it an important organizing role in personality development (e.g., A. Freud, 1946). According to this view, psychopathology develops when the ego does not function adequately to control or delay impulse gratification or does not make adequate use of defense mechanisms when faced with internal conflicts. This school became known as **ego psychology**.

Anna Freud (1895–1982) studied the important role of the ego in normal and abnormal development and elaborated the theory of ego-defense reactions.

Margaret Mahler (1897–1985) elaborated the object-relations approach, which many see as the main focus of contemporary psychoanalysis.

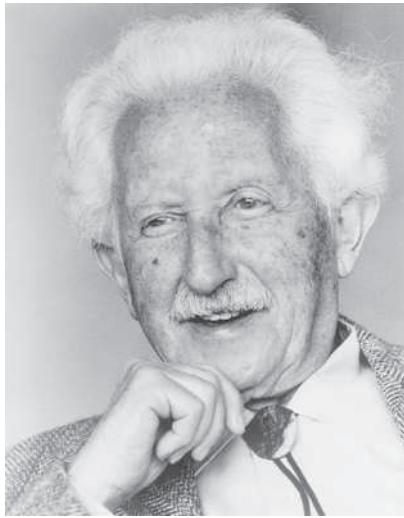

**Object-Relations Theory** A second new psychodynamic perspective was object-relations theory, developed by a number of prominent theorists including Melanie Klein, Margaret Mahler, W. R. D. Fairburn, and D. W. Winnicott, starting in the 1930s and 1940s. Although there are many variations on **object-relations theory**, they share a focus on individuals' interactions with real and imagined other people (external and internal objects) and on the relationships that people experience between their external and internal objects (Engler, 2006; Greenberg & Mitchell, 1983). *Object* in this context refers to the symbolic representation of another person in the infant's or child's environment, most often a parent. Through a process of *introduction*, a child symbolically incorporates into his or her personality (through images and memories) important people in his or her life. For example, a child might internalize images of a punishing father; that image then becomes a harsh self-critic, influencing how the child behaves. The general notion is that internalized objects could have various conflicting properties—such as exciting or attractive versus hostile, frustrating, or rejecting—and also that these objects could split off from the central ego and maintain independent existences, thus giving rise to inner conflicts. An individual experiencing such splitting among internalized objects is, so to speak, “the servant of many masters” and cannot therefore lead an integrated, orderly life.

Otto Kernberg, for example, is an influential American analyst who has a theory that people with a *borderline personality*, whose chief characteristic is instability (especially in personal relationships), are individuals who are unable to achieve a full and stable personal identity (self) because of an inability to integrate and reconcile pathological internalized objects (Kernberg 1985, 1996; Kernberg & Caligor, 2005; Kernberg & Michels, 2009). Because of their inability to structure their internal world in such a way that the people they know (including themselves) can have a mixture of both good and bad traits, they also perceive the external world in abrupt extremes. For example, a person may be “all good” one moment and “all bad” the next (Koenigsberg et al., 2000).

**The Interpersonal Perspective** A third set of second-generation psychodynamic theorists focused on social determinants of behavior. We are social beings, and much of what we

Erich Fromm (1900–1980) focused on the orientations that people adopt in their interactions with others. He believed that these basic orientations to the social environment were the bases of much psychopathology.

Erik Erikson (1902–1994) elaborated and broadened Freud's psychosexual stages into more socially oriented concepts. Erikson described conflicts that occurred at eight stages, each of which could be resolved in a healthy or unhealthy way.

are is a product of our relationships with others. It is logical to expect that much of psychopathology reflects this fact—that psychopathology is rooted in the unfortunate tendencies we have developed while dealing with our interpersonal environments. This is the focus of the **interpersonal perspective**, which began with the defection in 1911 of Alfred Adler (1870–1937) from the psychoanalytic viewpoint of his teacher, Sigmund Freud, and emphasizes social and cultural forces rather than inner instincts as determinants of behavior. In Adler's view, people are inherently social beings motivated primarily by the desire to belong to and participate in a group (see Engler, 2006; Mosak, 2000, for recent reviews).

Over time, a number of other psychodynamic theorists also took issue with psychoanalytic theory for its neglect of crucial social factors. Among the best known of these theorists are Erich Fromm (1900–1980) and Karen Horney (1885–1952). Fromm focused on the orientations, or dispositions (exploitive, for example), that people adopted in their interactions with others. He believed that when these orientations to the social environment were maladaptive, they served as the bases of much psychopathology. Horney independently developed a similar view and, in particular, vigorously rejected Freud's demeaning psychoanalytic view of women (for instance, the idea that women experience penis envy).

Erik Erikson (1902–1994) also extended the interpersonal aspects of psychoanalytic theory. He elaborated and broadened Freud's psychosexual stages into more socially oriented concepts, describing crises or conflicts that occurred at eight stages, each of which could be resolved in a healthy or unhealthy way. For example, Erikson believed that during what Freud called the "oral stage," when a child is preoccupied with oral gratification, a child's real development centers on learning either "basic trust" or "basic mistrust" of her or his social world. Achieving a certain level of trust, for instance, is necessary for later competence in many areas of life.

**Attachment Theory** Finally, John Bowlby's **attachment theory**, which can in many ways be seen as having its roots in the interpersonal and object-relations perspectives, has become

an enormously influential theory in child psychology and child psychiatry as well as in adult psychopathology. Drawing on Freud and others from these perspectives, Bowlby's theory (1969, 1973, 1980) emphasizes the importance of early experience, especially early experience with attachment relationships, as laying the foundation for later functioning throughout childhood, adolescence, and adulthood. He stresses the importance of the quality of parental care to the development of secure attachments, but he also sees the infant as playing a more active role in shaping the course of his or her own development than had most of the earlier theorists (Carlson & Sroufe, 1995; Rutter et al., 2009; Sroufe et al., 2003).

**IMPACT OF THE PSYCHOANALYTIC PERSPECTIVE** Freud's psychoanalytic theory can be seen as the first systematic approach to showing how human psychological processes can result in mental disorders. Much as the biological perspective had replaced superstition with organic pathology as the suspected cause of mental disorders for many psychiatrists and psychologists, the psychoanalytic perspective replaced brain pathology with intrapsychic conflict and exaggerated ego defenses as the suspected cause of at least some mental disorders.

Freud greatly advanced our understanding of both normal and abnormal behavior. Many of his original concepts have become fundamental to our thinking about human nature and behavior and have even had an important influence on the intellectual history of Western civilization. Two of Freud's contributions stand out as particularly noteworthy:

1. He developed therapeutic techniques such as free association and dream analysis for becoming acquainted with both the conscious and the unconscious aspects of mental life (see Chapter 16). The results obtained led Freud to emphasize several points that have been incorporated (in modified forms) into current thinking: (a) the extent to which unconscious motives and defense mechanisms affect behavior, meaning that the causes of human behavior are generally

- not obvious or available to conscious awareness; (b) the importance of early childhood experiences in the development of both normal and abnormal personality; and (c) the importance of sexual factors in human behavior and mental disorders. Although, as we have said, Freud used the term *sexual* in a much broader sense than usual, the idea struck a common chord, and the role of sexual factors in human behavior was finally brought out into the open as an appropriate topic for scientific investigation (see Chapter 12).
2. He demonstrated that certain abnormal mental phenomena occur in the attempt to cope with difficult problems and are simply exaggerations of normal ego-defense mechanisms. This realization that the same psychological principles apply to both normal and abnormal behavior dissipated much of the mystery and fear surrounding mental disorders.

The psychoanalytic perspective came under attack, however, from many directions. Two important criticisms of traditional psychoanalytic theory center on its failure as a scientific theory to explain abnormal behavior. First, many believe that it fails to recognize sufficiently the scientific limits of personal reports of experience as the primary mode of obtaining information. Second, there is a lack of scientific evidence to support many of its explanatory assumptions or the effectiveness of traditional psychoanalysis (Erdelyi, 1992; but see also Westen, 1998). In addition, Freudian theory in particular has been criticized for an overemphasis on the sex drive, for its demeaning view of women, for pessimism about basic human nature, for exaggerating the role of unconscious processes, and for failing to consider motives toward personal growth and fulfillment.

### IMPACT OF NEWER PSYCHODYNAMIC PERSPECTIVES

The second generation of psychodynamic theorists has done much to improve scientific efforts to measure concepts such as a person's core (but unconscious) conflictual relationships (e.g., Henry et al., 1994; Horowitz et al., 1991; Luborsky & Barrett, 2006). Some progress has also been made in understanding how psychodynamic therapy works and in documenting its effectiveness for certain problems (e.g., Crits-Christoph & Barber, 2000; Crits-Christoph et al., 2004; Shedler, 2010). In addition, Bowlby's attachment theory has generated an enormous amount of research supporting many of its basic tenets about normal and abnormal child development and adult psychopathology (e.g., Carlson & Sroufe, 1995; Grossman et al., 2005; Rutter, 2006; Rutter et al., 2009).

The interpersonal perspective has also done a good deal to establish its scientific validity. In the area of diagnosis, many supporters of the interpersonal perspective believe that the reliability and validity of psychological diagnoses could be improved if a new system based on interpersonal functioning were developed, and some progress has been made toward developing such a system (e.g., Benjamin, 1993, 2005; Benjamin et al., 2006). The focus of interpersonal therapy is on alleviating problem-causing relationships and on helping people achieve more satisfactory

relationships. In recent years, major progress has been made in documenting that interpersonal psychotherapy for certain disorders such as depression, bulimia, and some personality disorders can be as effective, or nearly as effective, as cognitive-behavioral treatment—considered by many to be the treatment of choice for these disorders (Benjamin, 2004; Benjamin & Pugh, 2001; Hollon et al., 2002; Wilson & Fairburn, 2007).

The Developments in Thinking box on page 77 presents two further psychological perspectives that developed in the middle of the twentieth century in part because their founders did not believe that psychodynamic theories acknowledged a person's freedom of choice or the concept of free will.

### The Behavioral Perspective

The behavioral perspective arose in the early twentieth century in part as a reaction against the unscientific methods of psychoanalysis. Behavioral psychologists believed that the study of subjective experience (e.g., free association and dream analysis) did not provide acceptable scientific data because such observations were not open to verification by other investigators. In their view, only the study of directly observable behavior and of the stimuli and reinforcing conditions that control it could serve as a basis for understanding human behavior, normal and abnormal.

Although this perspective was initially developed through laboratory research rather than clinical practice with disturbed patients, its implications for explaining and treating maladaptive behavior soon became evident. As we noted in Chapter 2, the roots of the behavioral perspective are in Pavlov's study of classical conditioning and in Thorndike's study of instrumental conditioning (later renamed operant conditioning by Skinner; today both terms are used). In the United States, where the behavioral perspective flourished, Watson did much to promote the behavioral approach to psychology with his book *Behaviorism* (1924).

**Learning**—the modification of behavior as a consequence of experience—is the central theme of the behavioral approach. Because most human behavior is learned, the behaviorists addressed the question of how learning occurs. Behaviorists focus on the effects of environmental conditions (stimuli) on the acquisition, modification, and possible elimination of various types of response patterns, both adaptive and maladaptive.

**CLASSICAL CONDITIONING** A specific stimulus may come to elicit a specific response through the process of **classical conditioning**. For example, although food naturally elicits salivation, a stimulus that reliably precedes and signals the presentation of food will also come to elicit salivation (Pavlov, 1927). In this case, food is the *unconditioned stimulus* (UCS) and salivation the *unconditioned response* (UCR). A stimulus that signals food delivery and eventually elicits salivation is called a *conditioned stimulus* (CS). Conditioning has occurred when presentation of the conditioned stimulus alone elicits salivation—the *conditioned response* (CR). The same general process occurs when a neutral

CS is paired with a painful or frightening stimulus such as a mild electric shock or loud noise, as illustrated in Figure 3.9, although in this case fear rather than salivation is conditioned.

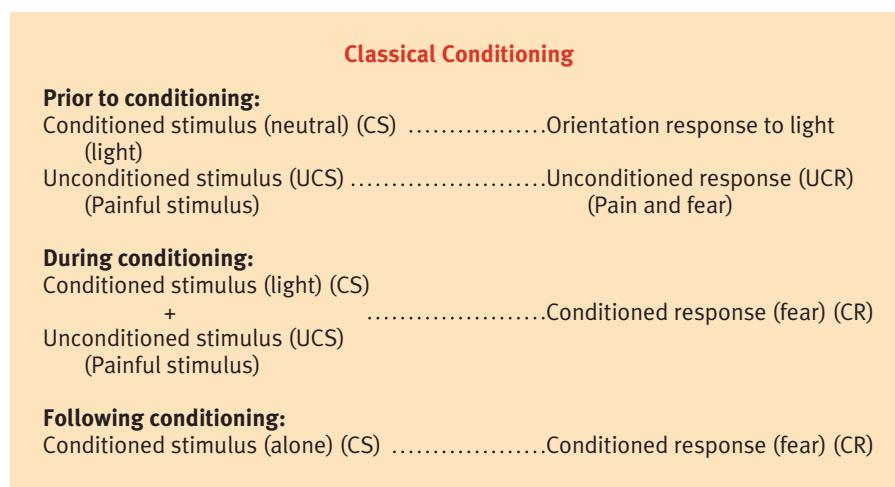

The hallmark of classical conditioning is that a formerly neutral stimulus—the CS—acquires the capacity to elicit biologically adaptive responses through repeated pairings with the UCS (e.g., Bouton, 2007; Domjan, 2009). However, we also now know that this process of classical conditioning is not as blind or automatic as was once thought. Rather, it seems that animals (and people) actively acquire information about what CSs allow them to predict, expect, or prepare for an upcoming biologically significant event (the UCS). That is, they learn what is often called a *stimulus-stimulus expectancy*. Indeed, only CSs that provide reliable and nonredundant information about the occurrence of a UCS acquire the capacity to elicit CRs (Hall, 1994; Rescorla, 1988). For example, if UCSs occur as often without being preceded by a CS as they do with the CS, conditioning will not occur because the CS in this case does not provide reliable information about the occurrence of the UCS.

Classically conditioned responses are well maintained over time; that is, they are not simply forgotten (even over many years). However, if a CS is repeatedly presented without the UCS, the conditioned response gradually extinguishes. This gradual process, known as **extinction**, should not be confused with the idea of unlearning because we know that the response may return at some future point in time (a phenomenon Pavlov called **spontaneous recovery**). Moreover, a somewhat weaker CR may also still be elicited in different environmental contexts than in the one where the extinction process took place (Bouton, 1994, 2002; Bouton et al., 2006). Thus any extinction of fear that has taken place in a therapist's office may not necessarily generalize completely and automatically to other contexts

outside the therapist's office (see Craske & Mystkowsky, 2006; Mystkowsky & Mineka, 2007). As we shall see later, these principles of extinction and spontaneous recovery have important implications for many forms of behavioral treatment.

Classical conditioning is important in abnormal psychology because many physiological and emotional responses can be conditioned, including those related to fear, anxiety, or sexual arousal and those stimulated by drugs of abuse. Thus, for example, one can learn a fear of the dark if fear-producing stimuli (such as frightening dreams or fantasies) occur regularly in the dark, or one can acquire a fear of snakes if bitten by a snake (e.g., Mineka & Sutton, 2006; Mineka & Zinbarg, 2006). In addition, a young man who has his first few powerful sexual experiences (UCR) with a very attractive woman (UCS) wearing some form of distinctive clothing (CS—such as black fishnet stockings) may find in the future that he becomes very sexually aroused (CR) simply upon seeing fishnet stockings.

**INSTRUMENTAL CONDITIONING** In **instrumental** (or **operant**) **conditioning**, an individual learns how to achieve a desired goal. The goal in question may be to obtain something that is rewarding or to escape from something that is unpleasant. Essential here is the concept of **reinforcement**, which refers either to the delivery of a reward or pleasant stimulus, or to the removal of or escape from an aversive stimulus. New responses are learned and tend to recur if they are reinforced. Although it was originally thought that instrumental conditioning consisted of simple strengthening of a stimulus–response connection every time that reinforcement occurred, it is now believed that the animal or person learns a *response–outcome expectancy* (e.g., Domjan, 2005)—that is, learns that a response will lead to a reward outcome. If sufficiently motivated for that outcome

**FIGURE 3.9**

**Classical Conditioning.** Before conditioning, the CS is neutral and has no capacity to elicit fear. However, after being repeatedly followed by a painful or frightening UCS that elicits pain, fear, or distress, the CS gradually acquires the capacity to elicit a fear CR. If there are also interspersed trials in which the UCS occurs without being preceded by the CS, conditioning does not occur because in this case the CS is not a reliable predictor of the occurrence of the UCS.

### The Humanistic and Existential Perspectives

#### THE HUMANISTIC PERSPECTIVE

The *humanistic perspective* views human nature as basically "good." Paying less attention to unconscious processes and past causes, it emphasizes present conscious processes and places strong emphasis on people's inherent capacity for responsible self-direction. Humanistic psychologists think that much of the empirical research designed to investigate causal factors is too simplistic to uncover the complexities of human behavior. Instead, this perspective is concerned with processes such as love, hope, creativity, values, meaning, personal growth, and self-fulfillment. Although these abstract processes are not readily subject to empirical investigation, certain underlying themes and principles of humanistic psychology can be identified, including the self as a unifying theme and a focus on values and personal growth.

In using the concept of *self* as a unifying theme, humanistic psychologists emphasize the importance of individuality. Among humanistic psychologists, Carl Rogers (1902–1987) developed the most systematic formulation of the *self-concept*, based largely on his pioneering research into the nature of the psychotherapeutic process. Rogers (1951, 1959) stated his views in a series of propositions that may be summarized as follows:

- Each individual exists in a private world of experience of which the *I, me, or myself* is the center.
- The most basic striving of an individual is toward the maintenance, enhancement, and actualization of the self, and his or her inner tendencies are toward health and wholeness under normal conditions.
- Perceived threat to the self is followed by a defense, including a tightening of perception and behavior and the introduction of self-defense mechanisms.

Humanistic psychologists emphasize that values and the process of choice are key in guiding our behavior and achieving meaningful and fulfilling lives. Each of us must develop values and a sense of our own identity based on our own experiences rather than blindly accepting the values of others; otherwise, we deny our own experiences and lose touch with our own feelings. Only in this way can we become *self-actualizing*, meaning that we are achieving our full potential. According to this view,

psychopathology is essentially the blocking or distortion of personal growth and the natural tendency toward physical and mental health. Chapter 16 presents the humanistic approach to psychotherapy.

#### THE EXISTENTIAL PERSPECTIVE

The *existential perspective* resembles the humanistic view in its emphasis on the uniqueness of each individual, the quest for values and meaning, and the existence of freedom for self-direction and self-fulfillment. However, it takes a less optimistic view of human beings and places more emphasis on their irrational tendencies and the difficulties inherent in self-fulfillment—particularly in a modern, bureaucratic, and dehumanizing mass society. In short, living is much more of a "confrontation" for the existentialists than for the humanists. Existential thinkers are especially concerned with the inner experiences of an individual in his or her attempts to understand and deal with the deepest human problems. There are several basic themes of existentialism:

- *Existence and essence.* Our existence is a given, but what we make of it—our essence—is up to us. Our essence is created by our choices because our choices reflect the values on which we base and order our lives.
- *Meaning and value.* The will-to-meaning is a basic human tendency to find satisfying values and guide one's life by them.
- *Existential anxiety and the encounter with nothingness.* Nonbeing, or nothingness, which in its final form is death, is the inescapable fate of all human beings. The awareness of our inevitable death and its implications for our living can lead to existential anxiety, a deep concern over whether we are living meaningful and fulfilling lives.

Thus existential psychologists focus on the importance of establishing values and acquiring a level of spiritual maturity worthy of the freedom and dignity bestowed by one's humanness. Avoiding such central issues creates corrupted, meaningless, and wasted lives. Much abnormal behavior, therefore, is seen as the product of a failure to deal constructively with existential despair and frustration.

(e.g., being hungry), the person will make the response that he or she has learned produces the outcome (e.g., opening the refrigerator).

Initially a high rate of reinforcement may be necessary to establish an instrumental response, but lesser rates are usually sufficient to maintain it. In fact, an instrumental response appears to be especially persistent when reinforcement is intermittent—when the reinforcing stimulus does not invariably follow the response—as demonstrated in gambling, when occasional wins seem to

maintain high rates of responding. However, when reinforcement is consistently withheld over time, the conditioned response—whether classical or instrumental—gradually extinguishes. In short, the subject eventually stops making the response.

A special problem arises conditioning a response in situations in which a subject has been conditioned to anticipate an aversive event and to make an instrumental response to avoid it. For example, a boy who has nearly drowned in a swimming pool may develop a fear of water and a *conditioned avoidance*

*response* in which he consistently avoids all large bodies of water. According to one influential theory, when he sees a pond, lake, or swimming pool, he feels anxious; running away and avoiding contact lessens his anxiety and thus is reinforcing. As a result, his avoidance response is highly resistant to extinction. It also prevents him from having experiences with water that could bring about extinction of his fear. In later discussions, we will see that conditioned avoidance responses play a role in many patterns of abnormal behavior.

As we grow up, instrumental learning becomes an important mechanism for discriminating between what will prove rewarding and what will prove unrewarding—and thus for acquiring the behaviors essential for coping with our world. Unfortunately, what we learn is not always useful in the long run. We may learn to value things (such as cigarettes or alcohol) that seem attractive in the short run but that can actually hurt us in the long run, or we may learn coping patterns (such as helplessness, bullying, or other irresponsible behaviors) that are maladaptive rather than adaptive in the long run.

**GENERALIZATION AND DISCRIMINATION** In both classical and instrumental conditioning, when a response is conditioned to one stimulus or set of stimuli, it can be evoked by other, similar stimuli; this process is called **generalization**. A person who fears bees, for example, may generalize that fear to all flying insects. A process complementary to generalization is **discrimination**, which occurs when a person learns to distinguish between similar stimuli and to respond differently to them based on which ones are followed by reinforcement. For example, because red strawberries taste good and green ones do not, a conditioned discrimination will occur if a person has experience with both.

The concepts of generalization and discrimination have many implications for the development of maladaptive behavior. Although generalization enables us to use past experiences in sizing up new situations, the possibility of making inappropriate generalizations always exists, as when a troubled adolescent fails to discriminate between friendly and hostile teasing from peers. In some instances, an important discrimination seems to be beyond an individual's capability (as when a bigoted person deals with others on the basis of stereotypes rather than as individuals) and may lead to inappropriate and maladaptive behavior.

**OBSERVATIONAL LEARNING** Human and nonhuman primates are also capable of **observational learning**—that is, learning through observation alone, without directly experiencing an unconditioned stimulus (for classical conditioning) or a reinforcement (for instrumental conditioning). For instance, children can acquire new fears simply observing a parent or peer behaving fearfully with some object or situation that the child did not initially fear. In this case, they experience the fear of the parent or peer vicariously, and that fear becomes attached to the formerly neutral object (Mineka & Oehlberg, 2008; Mineka &

Continuing to gamble after an occasional unpredictable win is an example of intermittent reinforcement. Behavior that is reinforced in this unpredictable manner occurs at high rates and is highly resistant to extinction.

Cook, 1993; Mineka & Sutton, 2006). For observational instrumental learning, Bandura did a classic series of experiments in the 1960s on how children observationally learned various novel, aggressive responses toward a large Bobo doll after they had observed models being reinforced for these responses (see Bandura, 1969). Although the children themselves were never directly reinforced for showing these novel aggressive responses, they nonetheless showed them when given the opportunity to interact with the Bobo doll themselves. The possibilities for observational conditioning of both classical and instrumental responses greatly expand our opportunities for learning both adaptive and maladaptive behavior.

**IMPACT OF THE BEHAVIORAL PERSPECTIVE** Because there was so much resistance from well-entrenched supporters of psychoanalysis, behavior therapy did not become well established as a powerful way of viewing and treating abnormal behavior until the 1960s and 1970s. By then, the behavioral assault on the prevailing psychodynamic doctrine of the time (Salter, 1949; Wolpe, 1958) was well underway and important evidence had been gathered on the power of behavior therapy techniques.

By means of relatively few basic concepts, the behavioral perspective attempts to explain the acquisition, modification, and extinction of nearly all types of behavior. Maladaptive behavior is viewed as essentially the result of (1) a failure to learn necessary adaptive behaviors or competencies, such as how to establish satisfying personal relationships, and/or (2) the learning of ineffective or maladaptive responses. Maladaptive behavior is thus the result of learning that has gone awry and is defined in terms of specific, observable, undesirable responses.

For the behavior therapist, the focus of therapy is on changing specific behaviors and emotional responses—eliminating undesirable reactions and learning desirable ones. For example, fears and phobias can be successfully treated by prolonged exposure to the feared objects or situations—an extinction procedure

derived from principles of extinction of classical conditioning. Or an inappropriate sexual attraction to a deviant stimulus (such as prepubertal children) can be altered by pairing pictures of the deviant stimuli with a foul odor or another unpleasant stimulus. Classic work using the principles of instrumental conditioning also showed that chronically mentally ill people in institutions can be retaught basic living skills such as clothing and feeding themselves through the use of tokens that are earned for appropriate behavior and that can be turned in for desirable rewards (candy, time watching television, passes to go outside, etc.).

The behavioral approach is well known for its precision and objectivity, for its wealth of research, and for its demonstrated effectiveness in changing specific behaviors. A behavior therapist specifies what behavior is to be changed and how it is to be changed. Later, the effectiveness of the therapy can be evaluated objectively by the degree to which the stated goals have been achieved. Nevertheless, the behavioral perspective has been criticized for several reasons. One early criticism was that behavior therapy was concerned only with symptoms, not underlying causes. However, this criticism has been considered unfair by many contemporary behavior therapists, given that successful symptom-focused treatment often has very positive effects on other aspects of a person's life (e.g., Borkovec et al., 1995; Lenz & Demal, 2000). Still others have argued that the behavioral approach oversimplifies human behavior and is unable to explain all of its complexities. This latter criticism stems at least in part from misunderstandings about current developments in behavioral approaches (e.g., Bouton, 2007; Bouton et al., 2001; Mineka & Oehlberg, 2008; Mineka & Zinbarg, 2006). Whatever its limitations, the behavioral perspective has had a tremendous impact on contemporary views of human nature, behavior, and psychopathology.

### The Cognitive-Behavioral Perspective

Since the 1950s many psychologists, including some learning theorists, have focused on cognitive processes and their impact on behavior. Cognitive psychology involves the study of basic information-processing mechanisms such as attention and memory, as well as higher mental processes such as thinking, planning, and decision making. The current emphasis within psychology as a whole on understanding all of these facets of normal human cognition originally began as a reaction against the relatively mechanistic nature of the traditional, radical behavioral viewpoint (espoused by Watson and Skinner), including its failure to attend to the importance of mental processes—both in their own right and for their influence on emotions and behavior.

Albert Bandura (b. 1925), a learning theorist who developed an early cognitive-behavioral perspective, placed considerable emphasis on the cognitive aspects of learning. Bandura stressed that human beings regulate behavior by internal symbolic processes—thoughts. That is, we learn by *internal reinforcement*. According to Bandura, we prepare ourselves for difficult tasks, for example, by visualizing what

Albert Bandura (b. 1925) stressed that people learn more by internal than external reinforcement. They can visualize the consequences of their actions rather than rely exclusively on environmental reinforcements.

the consequences would be if we did not perform them. Thus we take our automobiles to the garage in the fall and have the antifreeze checked because we can "see" ourselves stranded on a road in winter. We do not always require external reinforcement to alter our behavior patterns; our cognitive abilities allow us to solve many problems internally. Bandura (1974) went so far as to say that human beings have "a capacity for self-direction" (p. 861). Bandura later developed a theory of *self-efficacy*, the belief that one can achieve desired goals (1986, 1997). He posited that cognitive-behavioral treatments work in large part by improving self-efficacy.

Other cognitive-behavioral theorists abandoned the learning theory framework more vigorously than did Bandura and focused almost exclusively on cognitive processes and their impact on behavior. Today the cognitive or **cognitive-behavioral perspective** on abnormal behavior generally focuses on how thoughts and information processing can become distorted and lead to maladaptive emotions and behavior. One central construct for this perspective is the concept of a schema, which was adapted from cognitive psychology by Aaron Beck (b. 1921), another pioneering cognitive theorist (e.g., Beck, 1967; Neisser, 1967, 1982). A **schema** is an underlying representation of knowledge that guides the current processing of information and often leads to distortions in attention, memory, and comprehension. People develop different schemas based on their temperament, abilities, and experiences.

**SCHEMAS AND COGNITIVE DISTORTIONS** Our schemas about the world around us and about ourselves (self-schemas) are our guides, one might say, through the complexities of living in the world as we understand it. For example, we all have schemas about other people (for example, expectations that they are lazy or very career oriented). We also have schemas about social roles (for example, expectations about what the appropriate

Our self-schemas—our frames of reference for what we are, what we might become, and what is important to us—*influence our choice of goals and our confidence in attaining them*. A probable element of this older woman's self-schema was that she could accomplish her life-long goal of obtaining a college education once her children were grown in spite of the fact she was nearly 40 years older than the average college student.

behaviors for a widow are) and about events (for example, what sequences of events are appropriate for a particular situation such as someone coping with a loss; Bodenhausen & Morales, 2013; Clark, Beck, & Alford, 1999; Fiske & Taylor, 1991). Our **self-schemas** include our views on who we are, what we might become, and what is important to us. Other aspects of our self-schemas concern our notions of the various roles we occupy or might occupy in our social environment such as "woman," "man," "student," "parent," "physician," "American," and so on. Most people have clear ideas about at least some of their own personal attributes and less clear ideas about other attributes (Fiske & Taylor, 1991; Kunda, 1999).

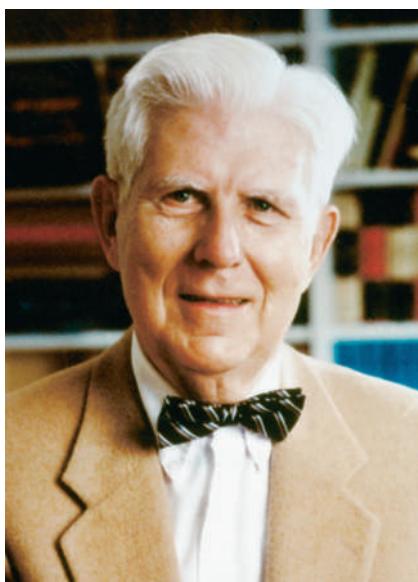

Schemas about the world and self-schemas are vital to our ability to engage in effective and organized behavior because they enable us to focus on the most relevant and important bits of information among the amazingly complex array of information that is available to our senses. However, schemas are also sources of psychological vulnerabilities because some of our schemas or certain aspects of our self-schemas may be distorted and inaccurate. In addition, we often hold some schemas—even distorted ones—with conviction, making them resistant to change. This is in part because we are usually not completely conscious of our schemas. In other words, although our daily decisions and behavior are largely shaped by these frames of reference, we may be unaware of the assumptions on which they are based—or even of making assumptions at all. We think that we are simply seeing things the way they are and often do not consider the fact that other views of the "real" world might be possible or that other rules for what is "right" might exist.

We tend to work new experiences into our existing cognitive frameworks, even if the new information has to be reinterpreted or distorted to make it fit—a process known as *assimilation*.

In other words, we are likely to cling to existing assumptions and to reject or distort new information that contradicts them. *Accommodation*—changing our existing frameworks to make it possible to incorporate new information that doesn't fit—is more difficult and threatening, especially when important assumptions are challenged. Accommodation is, of course, a basic goal of psychological therapies—explicitly in the case of the cognitive and cognitive-behavioral therapies, but deeply embedded in virtually all other approaches as well.

According to Beck (1967; Beck & Weishaar, 2000; Beck et al., 2004; Beck et al., 2005), different forms of psychopathology are characterized by different maladaptive schemas that have developed as a function of adverse early learning experiences. These maladaptive schemas lead to the distortions in thinking that are characteristic of certain disorders such as anxiety, depression, and personality disorders. In addition to studying the nature of dysfunctional schemas associated with different forms of psychopathology, researchers have also studied several different patterns of distorted information processing exhibited by people with various forms of psychopathology. This research has illuminated the cognitive mechanisms that may be involved in causing or maintaining certain disorders. For example, depressed individuals show memory biases favoring negative information over positive or neutral information. Such biases are likely to help reinforce or maintain one's current depressed state (e.g., Joormann, 2009; Mathews & MacLeod, 1994, 2005).

Another important feature of information processing is that a great deal of information is processed *nonconsciously*, or outside of our awareness. Note that the term *nonconscious* does not refer to Freud's concept of the *unconscious*, in which primitive emotional conflicts are thought to simmer. Instead, the term *nonconscious mental activity* as studied by cognitive psychologists is simply a descriptive term for mental processes that are occurring without our being aware of them. One example relevant to

Aaron Beck (b. 1921) pioneered the development of cognitive theories of depression, anxiety, and personality disorders. He also developed highly effective cognitive-behavioral treatments for these disorders.

psychopathology is that anxious people seem to have their attention drawn to threatening information even when that information is presented subliminally (that is, without the person's awareness; e.g., Mathews & MacLeod, 1994, 2005). Another relevant example occurs in the well-known phenomenon of *implicit memory*, which is demonstrated when a person's behavior reveals that she or he remembers a previously learned word or activity even though she or he cannot consciously remember it. For example, if someone asks you for your old home phone number from about 10 years ago, you may not be able to recall it (no explicit memory for it), but if you picked up a phone you might dial it correctly (intact implicit memory for it).

**ATTRIBUTIONS, ATTRIBUTIONAL STYLE, AND PSYCHOPATHOLOGY** *Attribution theory* has also contributed significantly to the cognitive-behavioral approach (Anderson, Krull, & Weiner, 1996; Fiske & Taylor, 1991; Gotlib & Abramson, 1999). An **attribution** is simply the process of assigning causes to things that happen. We may attribute behavior to external events such as rewards or punishments ("He did it for the money"), or we may assume that the causes are internal and derive from traits within ourselves or others ("He did it because he is so generous"). Causal attributions help us explain our own or other people's behaviors and make it possible to predict what we or others are likely to do in the future. A student who fails a test may attribute the failure to a lack of intelligence (a personal trait) or to ambiguous test questions or unclear directions (environmental causes).

Attribution theorists have been interested in whether different forms of psychopathology are associated with distinctive and dysfunctional attributional styles. *Attributional style* is a characteristic way in which an individual tends to assign causes to bad events or good events. For example, depressed people tend to attribute bad events to internal, stable, and global causes ("I failed the test because I'm stupid" as opposed to "I failed the test because the teacher was in a bad mood and graded it unfairly"). However inaccurate our attributions may be, they become important parts of our view of the world and can have significant effects on our emotional well-being (Abramson et al., 1978; Buchanan & Seligman, 1995; Mineka et al., 2003). Interestingly, nondepressed people tend to have what is called a *self-serving bias* in which they are more likely to make internal, stable, and global attributions for positive rather than negative events (e.g., Mezulis et al., 2004).

**COGNITIVE THERAPY** Beck, who is generally considered the founder of cognitive therapy, has been enormously influential in the development of cognitive-behavioral treatment approaches to various forms of psychopathology. Following Beck's lead, cognitive-behavioral theorists and clinicians have simply shifted their focus from overt behavior itself to the underlying cognitions assumed to be producing the maladaptive emotions and behavior. Fundamental to Beck's perspective is the idea that

the way we interpret events and experiences determines our emotional reactions to them. Suppose, for example, that you are sitting in your living room and hear a crash in the adjacent dining room. You remember that you left the window open in the dining room and conclude that a gust of wind must have knocked over your favorite vase, which was sitting on the table. What would your emotional reaction be? Probably you would be annoyed or angry with yourself either for having left the window open or for having left the vase out (or both!). By contrast, suppose you conclude that a burglar must have climbed in the open window. What would your emotional reaction be then? In all likelihood, you would feel frightened. Thus your interpretation of the crash you heard in the next room fundamentally determines your emotional reaction to it. Moreover, certain individuals with prominent danger schemas may be especially prone to making the burglar assumption in this example, leaving them at risk for anxiety and worry.

One central issue for cognitive therapy, then, is how best to alter distorted and maladaptive cognitions, including the underlying maladaptive schemas that lead to different disorders and their associated emotions. For example, cognitive-behavioral clinicians are concerned with their clients' self-statements—that is, with what their clients say to themselves by way of interpreting their experiences. People who interpret what happens in their lives as a negative reflection of their self-worth are likely to feel depressed; people who interpret the sensation that their heart is racing as meaning that they may have a heart attack and die are likely to have a panic attack. Cognitive-behavioral clinicians use a variety of techniques designed to alter whatever negative cognitive biases the client harbors (e.g., see Barlow, 2008; Beck et al., 2004; Hollon & Beck, 1994; Hollon et al., 2006). This is in contrast to, for example, psychodynamic practice, which assumes that diverse problems are due to a limited array of intrapsychic conflicts (such as an unresolved Oedipus complex) and tends not to focus treatment directly on a person's particular problems or complaints. Many widely used cognitive-behavioral therapies will be described in later chapters.

## THE IMPACT OF THE COGNITIVE-BEHAVIORAL PERSPECTIVE

The cognitive-behavioral viewpoint has had a powerful impact on contemporary clinical psychology. Many researchers and clinicians have found support for the principle of altering human behavior through changing the way people think about themselves and others. Many traditional behaviorists, however, have remained skeptical of the cognitive-behavioral viewpoint. B. F. Skinner (1990), in his last major address, remained true to behaviorism. He questioned the move away from principles of operant (instrumental) conditioning. He reminded his audience that cognitions are not observable phenomena and, as such, cannot be relied on as solid empirical data. Although Skinner

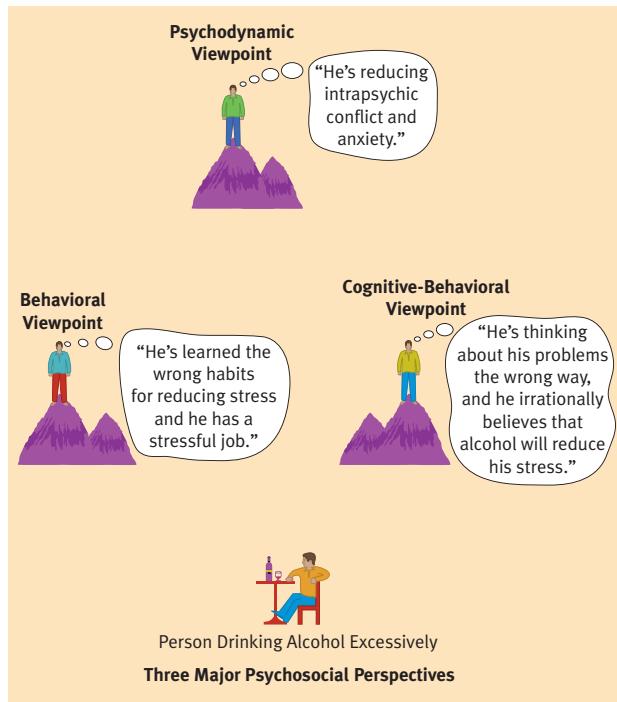

Some interpret terrifying scenes in a horror movie and the sensations of their heart pounding as a sign of excitement and having a good time; others interpret the same scenes and sensations as if something dangerous and scary is really happening. Cognitive-behavioral psychologists emphasize that the way we interpret an event can dramatically color our emotional reactions to it.

is gone, this debate will surely continue in some form. Indeed, Wolpe (1988, 1993), another founder of behavior therapy, also remained highly critical of the cognitive perspective until his death in 1997. However, these criticisms have seemed to be decreasing in recent years as more and more evidence accumulates for the efficacy of cognitive-behavioral treatments for various disorders ranging from schizophrenia to anxiety, depression, and personality disorders (e.g., Barlow, 2008; Butler et al., 2006; Tolin, 2010). This approach has also been greatly advanced by the accumulation of sophisticated information-processing studies of the effects of emotion on cognition and behavior (e.g., Joormann, 2009; Mathews & MacLeod, 2005). This is because such studies do not rely on the self-report techniques that were originally central to this approach, and which are especially open to the kinds of criticisms raised by Skinner and Wolpe.

### What the Adoption of a Perspective Does and Does Not Do

Each of the psychological perspectives on human behavior—psychodynamic, behavioral, and cognitive-behavioral—contributes to our understanding of psychopathology, but none alone can account for the complex variety of human maladaptive behaviors. Because different causal perspectives influence which components of maladaptive behavior the observer focuses on, each perspective depends on generalizations from limited observations and research. For example, in attempting to explain a complex disorder such as alcohol dependence, the more traditional psychodynamic viewpoint focuses on intrapsychic conflict and anxiety that the person attempts to reduce through the intake of alcohol; the more recent interpersonal variant on the psychodynamic perspective focuses on difficulties in a person's

**FIGURE 3.10**

Three major psychological perspectives on alcohol dependence.

past and present relationships that contribute to drinking; the behavioral viewpoint focuses on faulty learning of habits to reduce stress (drinking alcohol) and environmental conditions that may be exacerbating or maintaining the condition; and the cognitive-behavioral viewpoint focuses on maladaptive thinking including deficits in problem solving and information processing, such as irrational beliefs about the need for alcohol to reduce stress.

Thus which perspective we adopt has important consequences: It influences our *perception of maladaptive behavior*, the *types of evidence we look for*, and the *way in which we are likely to interpret data*. A wide range of psychological causal factors have been implicated in the origins of maladaptive behavior, and some of these different viewpoints provide contrasting (or sometimes complementary) explanations for how the causal factors exert their effects. (See Figure 3.10 above.)

### in review

- What is the focus of the cognitive-behavioral perspective, and what has been its impact?

- Why are schemas and self-schemas so important for understanding abnormal behavior and its treatment?
- What role do cognitive distortions and attributions have in psychopathology, according to the cognitive-behavioral perspective?

## Psychological Causal Factors

We begin life with few built-in patterns and a great capacity to learn from experience. What we do learn from our experiences may help us face challenges resourcefully and may lead to resilience in the face of future stressors. Unfortunately, some of our experiences may be much less helpful in our later lives, and we may be deeply influenced by factors in early childhood over which we have no control. One good example of ways in which the events in one child's life may be vastly different from those in another child's life is whether they are *predictable* or *controllable*. At one extreme are children who grow up in stable and lovingly indulgent environments, buffered to a large extent from the harsher realities of the world; at the other extreme are children whose experiences consist of constant exposure to unpredictable and uncontrollable frightening events or unspeakable cruelties. Such different experiences have corresponding effects on the adults' schemas about the world and about the self: Some suggest a world that is uniformly loving, unthreatening, and benign, which of course it is not; others suggest a jungle in which safety and perhaps even life itself are constantly in the balance. Given a preference in terms of likely outcomes, most of us would opt for the former of these sets of experiences. However, these actually may not be the best blueprint for engaging the real world, because it may be important to encounter some stressors and learn ways to deal with them in order to gain a sense of control (e.g., Barlow, 2002; Seligman, 1975) or self-efficacy (Bandura, 1986, 1997).

Exposure to multiple uncontrollable and unpredictable frightening events is likely to leave a person vulnerable to anxiety and negative affect, a central problem in a number of mental disorders such as anxiety and depression. For example, Barlow's (1988, 2002) and Mineka's (1985b; Mineka & Zinbarg, 1996, 2006) models emphasize the important role that experience with unpredictable and uncontrollable negative outcomes has in creating stress, anxiety, and depression (see also Abramson et al., 1978; Chorpita, 2001; Chorpita & Barlow, 1998; Seligman, 1975). It is important to note that a person exposed to the same frequency and intensity of negative outcomes that are predictable and/or controllable will experience less stress and be less likely to develop anxiety or depression.

In this section we will examine the types of psychological factors that make people vulnerable to disorder or that may precipitate disorder. Psychological factors are those developmental influences—often unpredictable and uncontrollable negative events—that may handicap a person psychologically, making him or her less resourceful in coping with events. (However,

it is important to remember that psychological causal factors are always ultimately mediated by changes that take place in our nervous systems when emotions are activated and when new learning takes place.) We will focus on four categories of psychological causal factors that can each have important detrimental effects on a child's socioemotional development: (1) early deprivation or trauma, (2) inadequate parenting styles, (3) marital discord and divorce, and (4) maladaptive peer relationships, also shown in Figure 3.11. Such factors typically do not operate alone. Rather, they interact with each other and with other psychological factors, as well as with particular genetic and temperamental factors and with particular sociocultural settings or environments. In other words, although psychological factors are often studied independently of genetic, temperamental, and sociocultural factors, a more comprehensive biopsychosocial understanding should be the ultimate goal.

We now turn to the four different categories of psychological causal factors.

### Early Deprivation or Trauma

Children who do not have the resources that are typically supplied by parents or parental surrogates may be left with deep and sometimes irreversible psychological scars. The needed resources range from food and shelter to love and attention. Deprivation of such resources can occur in several forms. The most severe manifestations of deprivation are usually seen among abandoned or orphaned children, who may be either institutionalized or placed in a succession of unwholesome and inadequate foster homes. However, it can also occur in intact families where, for one reason or another, parents are unable (for instance, because of mental disorder) or unwilling to provide close and frequent human attention and nurturing.

We can interpret the consequences of parental deprivation from several psychological viewpoints. Such deprivation might result in fixation at the oral stage of psychosexual development (Freud); it might interfere with the development of basic trust (Erikson); it might retard the attainment of needed skills because of a lack of available reinforcements (Skinner); or it might result in the child's acquiring dysfunctional schemas and self-schemas in which relationships are represented as unstable, untrustworthy, and without affection (Beck). Any of these viewpoints might be the best way of conceptualizing the problems that arise

- ▶ Early deprivation or trauma
- ▶ Inadequate parenting styles
- ▶ Marital discord and divorce
- ▶ Maladaptive peer relationships

**FIGURE 3.11**  
Psychological Causal Factors.

in a particular case, or some combination of them might be superior to any single one because, as we have noted, the causal pathways are usually multidimensional. (See Figure 3.12.)

**INSTITUTIONALIZATION** In some cases children are raised in an institution where, compared with an ordinary home, there is likely to be less warmth and physical contact; less intellectual, emotional, and social stimulation; and a lack of encouragement and help in positive learning. Current estimates are that worldwide up to 8 million children live in orphanages (Bos et al., 2011). Research done when institutionalization was more common in the United States and the United Kingdom makes it clear that the long-range prognosis for most children who suffer early and prolonged environmental and social deprivation through institutionalization is unfavorable, especially if the institutionalization lasts longer than 6 months (Beckett et al., 2006; Kreppner et al., 2007; Wiik et al., 2011). Many children institutionalized in infancy and early childhood show severe emotional, behavioral, and learning problems and are at risk for disturbed attachment relationships and psychopathology (e.g., Bos et al., 2011; Ellis et al., 2004; Smyke et al., 2007). At least some of these problems may be the result of delayed maturation in brain electrical activity (McLaughlin et al., 2010).

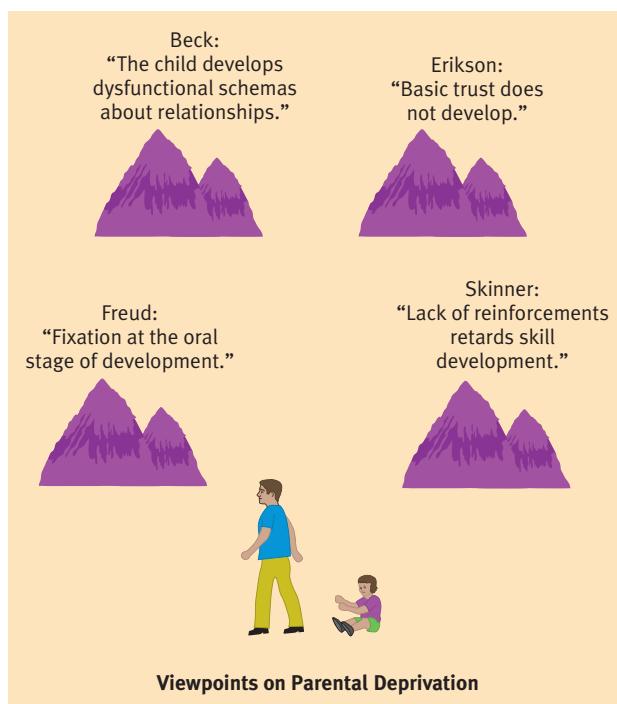

Institutionalization later in childhood of a child who has already had good attachment experiences was not found to be so damaging (Rutter, 1987). However, even some of the children institutionalized at an early age show resilience and do well in adolescence and adulthood (Kreppner et al., 2007; Rutter et al., 2001). In some cases this is because of influential

These Romanian orphans spend most of their days in their cribs. The lack of physical contact and social stimulation and support causes many children who are often institutionalized starting in infancy and early childhood to show severe emotional, behavioral, and learning problems. They are also at elevated risk for psychopathology.

protective factors, which include having some positive experiences at school, whether in the form of social relationships or athletic or academic success, and having a supportive marital partner in adulthood; these successes probably contribute to a better sense of self-esteem or self-efficacy (Quinton & Rutter, 1988; Rutter, 1985; Rutter et al., 2001).

Fortunately, the results of this line of research have had a major impact on public policy in this and some other societies, which have recognized the need to place such children in foster or adoptive families rather than in institutions (see Johnson, 2000; Rutter, 2006). Accordingly, conducting research on the effects of institutionalization in Western societies is less urgent today—and less feasible—than it once was. Unfortunately, however, enlightened policies have not been implemented in some Eastern European countries and in some other parts of the world, where the plight of children in orphanages has often been deplorable (e.g., Johnson, 2000). We focus here on research conducted on children adopted from these Eastern European orphanages because they have been most widely studied (e.g., McLaughlin et al., 2010). Many children whose infancy was spent in these Eastern European orphanages were later adopted into homes in North America and the United Kingdom. For children who spent a significant period of time in one of these deplorable institutions in their first year or two of life, there were very significant intellectual, language, and growth deficits, and even more time spent in the institution was related to more severe deficits. Serious physiological, behavioral, psychological, and social problems also arose (e.g., Bos et al., 2011; Gunnar et al., 2001; Rutter, 2006). At least in one study the physiological changes extended to brain development, with children with severe institutional deprivation showing reduced overall brain volume, although the volumes of their amygdala, which is involved in emotion regulation were enhanced (Mehta et al., 2009). When retested several years after being placed in good adoptive homes, most such children showed significant improvement in most of these areas, although they still showed deficits compared to adoptive infants who had not been

**FIGURE 3.12**  
Viewpoints on Parental Deprivation.

institutionalized. For one of these studies, a more recent follow-up of Romanian adoptees in the United Kingdom when the children were 11 years of age has shown a wide variety of outcomes. About half of the children continued to show multiple impairments, and only about one-quarter showed fairly normal functioning across many domains (Kreppner et al., 2007; see also Wiik et al., 2011). Generally, the earlier the children were adopted (and therefore the less time they spent in the deplorable orphanages), the better they did (see Johnson, 2000, for a review; Rutter et al., 1999).

**NEGLECT AND ABUSE IN THE HOME** Most infants subjected to parental deprivation are not separated from their parents but, rather, suffer from maltreatment at home. In the United States, approximately 2.6 to 3.4 million reports of abuse and neglect are made annually, and about 33 to 40 percent are found to be accurate (Cicchetti & Toth, 2005; Watts-English et al., 2006). This means that about 12 out of every 1,000 children are known to be victims of abuse or neglect, with countless numbers of other unreported cases. Parents can neglect a child in various ways—by physical neglect, denial of love and affection, lack of interest in the child's activities and achievements, or failure to spend time with the child or to supervise his or her activities. Cases of parental abuse (which are less common than neglect; De Bellis, 2005) involve cruel treatment in the form of emotional, physical, or sexual abuse. Parental neglect and abuse may be partial or complete, passive or active, or subtly or overtly cruel.

Outright parental abuse (physical or sexual or both) of children has been associated with many negative effects on their emotional, intellectual, and physical development, although some studies have suggested that, at least among infants, gross neglect may be worse than having an abusive relationship. Abused children often have a tendency to be overly aggressive (both verbally and physically), even to the extent of bullying. Some even respond with anger and aggression to friendly overtures from peers (e.g., Cicchetti & Toth, 2005; Emery & Laumann-Billings, 1998). Researchers have also found that maltreated children often have difficulties in linguistic development and significant problems in behavioral, emotional, and social functioning, including conduct disorder, depression and anxiety, and impaired relationships with peers, who tend to avoid or reject them (Collishaw, Pickles, et al., 2007; Shonk & Cicchetti, 2001). Such adverse consequences are perhaps not surprising given the multitude of very long-lasting negative neurobiological effects that maltreatment has on the developing nervous system (Gunnar & Quevedo, 2007; Watts-English et al., 2006). For example, an important 30-year follow-up study of individuals born on the Isle of Wight in the 1960s who reported having been physically or sexually abused as children found that about two-thirds of them had elevated rates of both adolescent and adult psychopathology compared to individuals who did not report such abuse. A recent quantitative review also reported adverse effects of childhood abuse on numerous adult physical health outcomes (Wegman & Stetler, 2009).

Abused and maltreated infants and toddlers are also quite likely to develop atypical patterns of attachment—most often a *disorganized* and *disoriented style of attachment* (Barnett, Ganiban, & Cicchetti, 1999; Crittenden & Ainsworth, 1989), characterized by insecure, disorganized, and inconsistent behavior with the primary caregiver. For example, such a child might at one point act dazed and show frozen behavior when reunited with his or her caregiver. However, at another point he or she might actually approach the caregiver but then immediately reject and avoid her. A significant portion of these children continue to show these confused patterns of relating to their caregiver up to at least age 13. Moreover, because such children's internal models of themselves in relationships to important others often generalize to new relationships, they are likely to expect others to treat them in a similar negative manner and to not expect that they will fare well in such relationships. Consequently, they may selectively avoid new experiences that could correct their expectations (Cicchetti & Toth, 1995a; Shields et al., 2001).

These effects of early abuse may endure into adolescence and adulthood. For example, previously abused or neglected children have, on average, lower levels of education, employment, and earnings (Currie & Widom, 2010). Several reviews have concluded that childhood physical abuse predicts both familial and nonfamilial violence in adolescence and adulthood, especially in abused men (Cicchetti & Toth, 1995a; Serbin & Karp, 2004). Thus, a significant proportion of parents who reject or abuse their children have themselves been the victims of parental rejection. Their early history of rejection or abuse would clearly have had damaging effects on their schemas and self-schemas, and they were probably unable to internalize good models of parenting (e.g., Serbin & Karp, 2004; Shields et al., 2001). Kaufman and Zigler (1989) estimated that there is about a 30 percent chance of this pattern of intergenerational transmission of abuse (see also Cicchetti & Toth, 1995a).

Nevertheless, it is important to remember that maltreated children—whether the maltreatment comes from abuse or from deprivation—can improve to at least some extent when the caregiving environment improves (Cicchetti & Toth, 1995a; Emery & Laumann-Billings, 1998). Moreover, there are always a range of effects, and those children who are least likely to show these negative outcomes tend to have one or more protective factors such as a good relationship with some adult during childhood, a higher IQ, positive school experiences, or physical attractiveness.

**SEPARATION** Bowlby (1960, 1973) first summarized the traumatic effects, for children from 2 to 5 years old, of being separated from their parents during prolonged periods of hospitalization. First, there are the short-term or acute effects of the separation, which can include significant despair during the separation as well as detachment from the parents upon reunion; Bowlby considered this to be a normal response to prolonged separation, even in infants with a *secure attachment*. However, he also found evidence that children who undergo a number of such separations may

develop an *insecure attachment*. In addition, there can be longer-term effects of early separation from one or both parents. For example, such separations can cause an increased vulnerability to stressors in adulthood, making it more likely that the person will become depressed (Bowlby, 1980) or show other psychiatric symptoms (Canetti et al., 2000; Carlson et al., 2003). As with other early traumatic experiences, the long-term effects of separation depend heavily on whether support and reassurance are given a child by parents or other significant people, which is most likely if the child has a secure relationship with at least one parent (Canetti et al., 2000; Carlson & Sroufe, 1995). Interestingly, many children who experience even a parent's death do not exhibit discernible long-term effects (Brown et al., 1985; Canetti et al., 2000).

## Inadequate Parenting Styles

Even in the absence of severe deprivation, neglect, or trauma, many kinds of deviations in parenting can have profound effects on a child's subsequent ability to cope with life's challenges and thus can create a child's vulnerability to various forms of psychopathology. Therefore, although their explanations vary considerably, the psychological viewpoints on causes of psychopathology all focus on the behavioral tendencies a child acquires in the course of early social interaction with others—chiefly parents or parental surrogates (e.g., Parke, 2004; Sroufe et al., 2000).

You should keep in mind that a parent-child relationship is always bidirectional: As in any continuing relationship, the behavior of each person affects the behavior of the other. Some children are easier to love than others; some parents are more sensitive than others to an infant's needs (e.g., Parke, 2004). For example, parents who have babies with difficult temperaments (who are very prone to negative moods) find it difficult and stressful to deal with their babies (e.g., Putnam et al., 2002; Rutter, 2006). For a second example, in an early study, Rutter and Quinton (1984) found that parents tended to react with irritability, hostility, and criticism to children who were high in negative mood and low on adaptability (see also Crouter & Booth, 2003). This in turn may set such

children at risk for psychopathology because they become a "focus for discord" in the family (Rutter, 1990, p. 191).

**PARENTAL PSYCHOPATHOLOGY** In general, it has been found that parents who have various forms of psychopathology (including schizophrenia, depression, antisocial personality disorder, and alcohol use problems) tend to have one or more children who are at heightened risk for a wide range of developmental difficulties (unless protective factors are also present; Brennan et al., 2003; Masten, 2007). The focus of most research in this area has been on mothers, but there is good evidence that fathers with mental disorders or others who are minimally involved in caretaking in infancy can also make significant contributions to child and adolescent psychopathology, especially to problems such as depression, conduct disorder, delinquency, and attention-deficit disorder (e.g., Boyce, et al., 2006; Hammen, 2009; Phares et al., 2002). Although some of these effects undoubtedly have a genetic component, many researchers believe that genetic influences cannot account for all of the adverse effects that parental psychopathology can have on children (e.g., Hammen, 2009; Sher et al., 2005; Speranza et al., 2006).

Consider some examples. Although many children of people with serious alcohol abuse problems do not have difficulties, others have elevated rates of truancy, substance abuse, and a greater likelihood of dropping out of school, as well as higher levels of anxiety and depression and lower levels of self-esteem (Leonard & Eiden, 2007; Marmorstein et al., 2009; Sher et al., 2005). In addition, the children of seriously depressed parents are at enhanced risk for depression and other disorders themselves (Burt et al., 2005; Cicchetti & Toth, 1998; Hammen, 2009), at least partly because depression makes for unskillful parenting—notably including either intrusive or withdrawn behavior (Field et al., 2006), excessive criticism, and ineffectiveness in managing and disciplining the children (Cicchetti & Toth, 1998; Rogosch et al., 2004). Not surprisingly, children of depressed mothers are also more likely than children of nondepressed mothers to have insecure attachment relationships (Cicchetti & Toth, 1995b) and to live in environments with high levels of stress (e.g., Hammen, 2009).

**PARENTING STYLES: WARMTH AND CONTROL** Less extreme differences in parenting styles than those that may occur with various forms of parental psychopathology or parental abuse can also have a significant impact on children's development and increase their risk for psychopathology. In the past, discipline was conceived of as a method for both punishing undesirable behavior and preventing or deterring such behavior in the future. Discipline is now thought of more positively as providing needed structure and guidance for promoting a child's healthy growth. Such guidance provides a child with schemas similar to outcomes actually meted out by the world, which are contingent on a person's behavior. This allows the child a sense of control over these outcomes and her or his freedom to make deliberate choices. When punishment is deemed necessary, it is important that a

Inadequate parenting styles can have profound effects on a child's subsequent ability to cope with life's challenges and thus create vulnerability to various forms of psychopathology.

Healthy parenting styles are those that reflect warmth and clear limits and restrictions regarding certain kinds of behaviors while allowing considerable freedom within certain boundaries. The children raised in these environments tend to be energetic and friendly and show general competencies for dealing with others.

parent make clear exactly what behavior is inappropriate and what behavior is expected, and that positive and consistent methods of discipline be worked out for dealing with infractions.

Researchers have been interested in how parenting styles—including their disciplinary styles—affect children’s behavior over the course of development. A parenting style reflects an attitude and values that are expressed toward a child across a wide range of settings (L. R. Williams et al., 2009). Four types of parenting styles have been identified that seem to be related to different developmental outcomes for the children: (1) authoritative, (2) authoritarian, (3) permissive/indulgent, and (4) neglectful/uninvolved. These styles vary in the degree of *parental warmth* (amount of support, encouragement, and affection versus shame, rejection, and hostility) and in the degree of *parental control* (extent of discipline and monitoring versus leaving the children largely unsupervised; Emery & Kitzmann, 1995; Manzeske & Stright, 2009; Morris, 2001). (See Figure 3.13 on p. 88.) Parental control includes both behavioral control (rewards and punishments) and psychological control (e.g., expression of approval versus disapproval, or guilt induction).

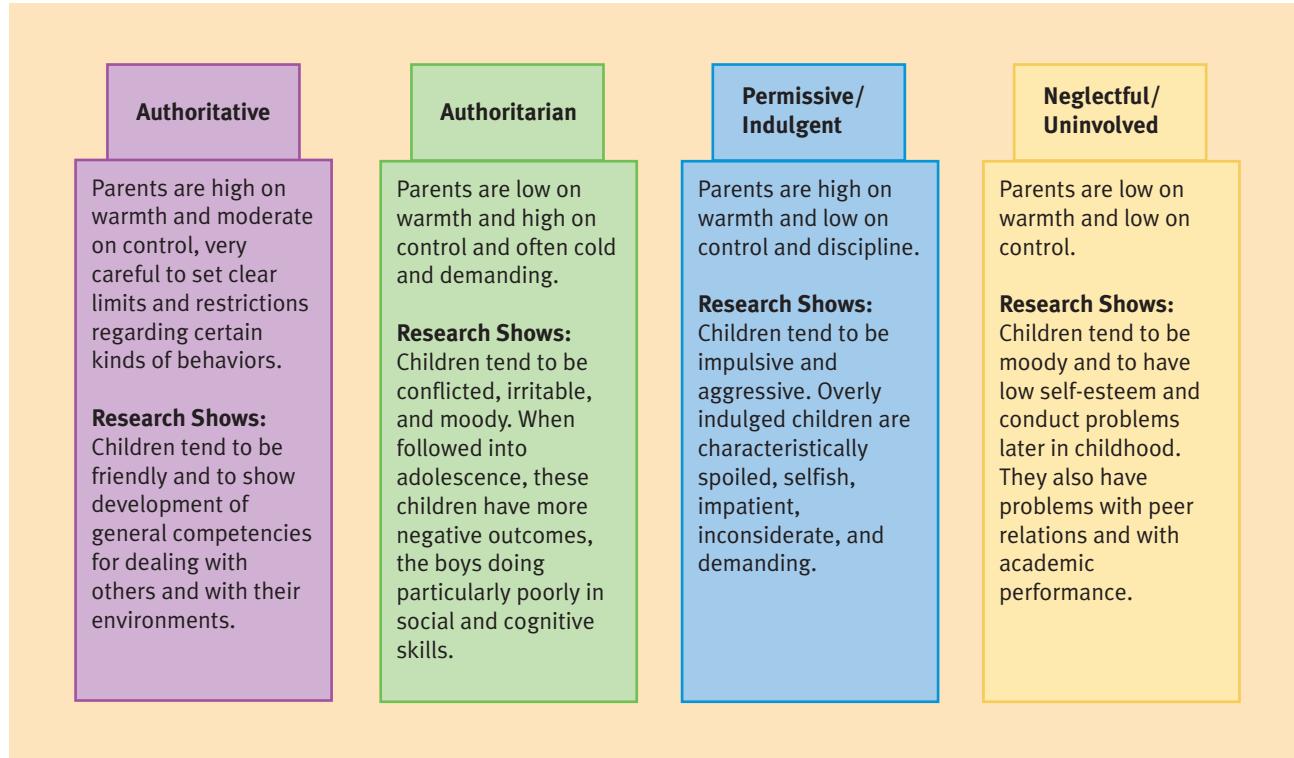

**Authoritative Parenting** The *authoritative style* is one in which the parents are both very warm and very careful to set clear standards and limits on certain kinds of behaviors while allowing

considerable freedom within these limits. They tend to be attentive and sensitive to their needs while still enforcing their limits. This style of parenting is associated with the most positive early social development; the children tend to be energetic and friendly and to show development of general competencies for dealing with others and with their environments (Baumrind, 1993; Siegler et al., 2003; Simons et al., 2005). They also usually have secure attachment relationships (Karavasilis et al., 2003) and show high levels of overall well-being, as well as good school performance when followed into late adolescence (Berk, 2003; Slicker & Thornberry, 2002). Not surprisingly they also are less likely to exhibit either emotional disorders (e.g., anxiety and depression) or behavioural problem such as conduct problems and delinquency (L. R. Williams et al., 2009). Recent work has also shown that authoritative parenting is often effective in promoting resilience in children living in highly stressful contexts induced by war, conflict, and displacement (Salem-Pickartz & Donnelly, 2007).

**Authoritarian Parenting** Parents with an *authoritarian style* are high on control but low on warmth. They often appear quite cold and demanding, favoring punitive methods if their children disobey. Their children tend to be conflicted, irritable, and moody (Baumrind, 1975, 1993; Berk, 2003; Siegler et al., 2003). When followed into adolescence, these children tend to be lower in social and academic competence than children of authoritative parents, with boys doing particularly poorly in social and cognitive skills. Boys with authoritarian fathers—especially those high on hostility—are also at heightened risk of engaging in substance abuse and other delinquent activity (Bronte-Tinkew et al., 2006; Hoeve et al., 2009). If such authoritarian parents also use overly severe discipline in the form of physical punishment—as opposed to the withdrawal of approval and privileges—the result tends to be increased aggressive behavior on the part of the child (Berk, 2003; Emery & Kitzmann, 1995).

**Permissive/Indulgent Parenting** Parents with a *permissive/indulgent style* are high on warmth but low on discipline and control. This lenient style of parenting is associated with impulsive and aggressive behavior in childhood and adolescence (Baumrind, 1967; Hetherington & Parke, 1993; Siegler et al., 2003). Overly indulged children are characteristically spoiled, selfish, impatient, inconsiderate, and demanding (Baumrind, 1971, 1975). In adolescence, they tend to do less well academically and to show more antisocial behaviors (e.g., Steinberg et al., 2006). Confusion and difficulties in adjustment may occur when “reality” forces them to reassess their assumptions about themselves and the world.

**Neglectful/Uninvolved Parenting** Finally, parents who are low both on warmth and on control exhibit the *neglectful/uninvolved style*. They tend to be disengaged and not supportive of their children. This style of parental uninvolved is associated with disruptions in attachment during early childhood (Egeland & Sroufe, 1981; Karavasilis et al., 2003) and with moodiness, low

**FIGURE 3.13**  
Parenting Styles.

self-esteem, and conduct problems later in childhood (Baumrind, 1991; Hetherington & Parke, 1993). These children of uninvolved parents also have problems with peer relations and with academic performance (Hetherington & Parke, 1993; see also Berk, 2003).

### Marital Discord and Divorce

Disturbed parent-child patterns such as parental rejection are rarely found in severe form unless the total familial context is also abnormal. Thus disturbed family structure is an overarching risk factor that increases an individual's vulnerability to particular stressors. We will distinguish between intact families where there is significant marital discord and families that have been disrupted by divorce or separation.

**MARITAL DISCORD** Whatever the reasons for marital discord, when it is long-standing it is likely to be frustrating, hurtful, and generally damaging in its effects on both adults and their children (e.g., Amato, 2006; Amato & Booth, 2001; Parke, 2004). More severe cases of marital discord may expose children to one or more of the stressors we have already discussed: child abuse or neglect, the effects of living with a parent with a serious mental disorder, authoritarian or neglectful/uninvolved parenting, and spouse abuse. But even less severe cases of marital discord also have negative effects on many children. For example, one study showed that children of parents with high levels of overt conflict showed a greater disposition to behave aggressively toward both their peers and their parents than children from less conflictual marriages (Cummings et al., 2004; Du Rocher et al., 2004; see also Amato, 2006). Another

study found that college students who reported high levels of marital conflict in their parents also showed elevated conflict in their own romantic relationships, which in turn was linked to poorer quality of their own romantic relationships (Cui & Fincham, 2010). Interestingly, one study found that children could be buffered against many of the damaging effects of marital conflict if one or both parents had the following characteristics: warmth, proneness to giving praise and approval, and ability to inhibit rejecting behavior toward their children (Katz & Gottman, 1997).

Several recent longitudinal studies have clearly documented that the damaging effects of serious marital discord on children continue into adulthood: The offspring's own marriages are more likely to be marked by discord (whether or not the parents divorced). Some of this intergenerational transmission of marital discord may be the result of the offspring having learned negative interaction styles by observing their own parents' marital interactions (Amato, 2006; Amato & Booth, 2001).

**DIVORCED FAMILIES** Partly as a consequence of a growing cultural acceptance of divorce, approximately a million divorces now occur yearly in the United States, according to the National Center for Health Statistics (as cited in Divorce Statistics Collection, 2005). Estimates are that about 20 percent of children under the age of 18 are living in a single-parent household—some with unwed parents and some with divorced parents. Nearly half of all marriages end in divorce, and it has been estimated that 50 to 60 percent of children born in the

1990s would live at some point in single-parent families (Amato, 2010; Hetherington et al., 1998).

**Effects of Divorce on Parents** Unhappy marriages are difficult, but ending a marital relationship can also be enormously stressful for the adults, both mentally and physically. The negative effects are often temporary, with most people being able to adapt constructively within 2 to 3 years, but some adults never fully recover (Amato, 2000; Hetherington, 2003a). Divorced and separated persons are overrepresented among psychiatric patients, although the *direction of the causal relationship* is not always clear. In their original comprehensive reviews of the effects of divorce on adults, Amato and Keith (1991a) concluded that it is a major source of psychopathology as well as of physical illness, death, suicide, and homicide. It should also be recognized, however, that divorce actually benefits some individuals (Amato, 2000, 2010)—with some evidence that women are more likely to benefit than men (Hetherington, 2003a). There is also some evidence that individuals who were in high-distress marriages before divorce are more likely to show an increase in happiness than are individuals who were in low-distress marriages before divorce (Amato & Hohmann-Marriott, 2007). In addition, favorable adjustment after divorce is positively associated with higher income, dating someone steadily, remarriage, having had relatively favorable attitudes toward divorce before it happened, and being the partner who initiated the divorce (Amato, 2000).

**Effects of Divorce on Children** Divorce can have traumatic effects on children, too. Feelings of insecurity and rejection may be aggravated by conflicting loyalties and, sometimes, by the spoiling the children may receive while staying with one of the parents. Not surprisingly, some children do develop serious maladaptive responses. Temperamentally difficult children are likely to have a more difficult time adjusting than are temperamentally easy children (Hetherington et al., 1989). Somewhat ironically, difficult children may be the ones whose parents are more likely to divorce, perhaps because having difficult children is likely to exacerbate marital problems (Block et al., 1986; Hetherington, 1999).

Delinquency and a wide range of other psychological problems such as anxiety and depression are much more frequent

among children and adolescents from divorced families than among those from intact families, although it is likely that a contributing factor here is prior or continuing parental strife (Chase-Lansdale et al., 1995; Strohschein, 2005). However, findings also show that, on average, such children had shown these problems to some degree even before their parents divorced (Amato, 2010; Strohschein, 2005). In addition, a number of studies have demonstrated that the adverse effects of divorce on adaptive functioning may persist into adulthood. On average, compared to young adults from families without divorce, young adults from divorced families have somewhat lower educational attainment, lower incomes, lower life satisfaction, and an increased probability of being on welfare and having children out of wedlock (Chase-Lansdale et al., 1995; Hetherington et al., 1998). Children from divorced families are also more likely to have their own marriages end in divorce (Amato & DeBoer, 2001; Hetherington, 2003b). One particularly interesting study found that these long-lasting effects even occurred in a subsequent third generation. Specifically, in a study of nearly 700 grandparents and their grandchildren, Amato and Cheadle (2005) found that divorce in the grandparents was associated with lower education, more marital discord, and weaker parental ties in the grandchildren.

Nevertheless, many children adjust quite well to the divorce of their parents. Indeed, a quantitative review of 92 studies on parental divorce and the well-being of children, conducted on 13,000 children from 1950 to 1990, concluded that the average negative effects of divorce on children are actually quite modest (Amato, 2010; Amato & Keith, 1991b; see also Emery, 1999; Hetherington, 2003b), as are the negative effects persisting into adulthood (Amato & Keith, 1991b). Amato and Keith (1991a, 1991b) also found that the negative effects of divorce seemed to decrease from the 1950s through the 1980s (particularly since 1970), perhaps because the stigma of divorce was decreasing. However, a follow-up review of 67 such studies published in the 1990s showed no further decreases in these negative effects since 1990 (Amato, 2001).

The effects of divorce on children are often more favorable than the effects of remaining in a home torn by marital conflict and dissension (Amato, 2010; Amato & Keith, 1991b; Hetherington et al., 1998). At one time it was thought that the detrimental effects of divorce might be minimized if a successful remarriage provided an adequate environment for childrearing. Unfortunately, however, the Amato and Keith (1991b) review revealed that children living with a stepparent were often no better off than children living with a single parent, although this was more true for girls than for boys. Other studies have shown that children—especially very young children—living with a stepparent are at increased risk for physical abuse (injury and even death) by the stepparent relative to children living with two biological parents (Daly & Wilson, 1988, 1996).

### Maladaptive Peer Relationships

Important peer relationships usually begin in the preschool years. Children at this stage are hardly masters of the fine points of human relationships or diplomacy. Empathy—the appreciation

#### research CLOSE-UP

##### Direction of the Causal Relationship

Recall that, in a correlational or observational study, an association between two variables does not allow us to make inferences about causal direction. For example, divorce could precipitate psychological problems. Alternatively, people with psychological disorders might be more likely to have problematic marriages and end up divorced.

of another's situation, perspective, and feelings—is at best only primitively developed. We can see this in a child who rejects a current playmate when a more favored playmate arrives. The child's own immediate satisfaction tends to be the primary goal of any interaction, and there is only an uncertain recognition that cooperation and collaboration may bring even greater benefits. A substantial minority of children seem somehow ill equipped for the rigors and competition of the school years, often because of temperamental factors in the child or dysfunctional family situations. A significant number of them withdraw from their peers and become loners. A significant number of others (especially males) adopt physically intimidating and aggressive lifestyles, often becoming schoolyard or neighborhood bullies. Being either a loner or a bully does not bode well for good mental health outcomes (e.g., Dodge et al., 1997; Heilbron & Prinstein, 2010; Reijntjes et al., 2011). This is in part because both often lead to peer exclusion and peer abuse. Chronic peer exclusion is particularly likely to lead to decreased classroom participation and declining school performance, whereas peer abuse is particularly likely to lead to actual avoidance of school (Buhs et al., 2006).

Several studies have found bullies to show high levels of both proactive aggression (where they initiate the aggressive behavior) and reactive aggression (where they overreact when confronted; e.g., Salmivalli & Nieminen, 2002; Salmivalli, 2010). Although some bullies probably behave this way because of deficits in social skills, others (often the ringleader in a group of bullies) have a more sophisticated understanding of social behavior, which enables them to manipulate and organize their peers (often driven by status goals) so that they can avoid being caught while making others suffer (Salmivalli, 2010; Sutton et al., 1999). Although most children profess attitudes against bullying, when bullying actually occurs, most students do nothing to intervene or support the victim (and as

many as 20 to 30% actually encourage the bully; Salmivalli, 2010; Salmivalli & Voeten, 2004). A small percentage (approximately 20%), however, do take the side of the victim and may even help defend him or her. Victims who have one or more classmates defend them show less distress and higher self-esteem.

In recent years a new form of particularly insidious bullying has emerged as an enormous problem in many North American schools. *Cyberbullying*, as it is called, includes sending offensive, harassing, or intimidating messages over the Internet, spreading ugly rumors on certain Internet sites, and spreading someone's very personal information (Willard, 2007). Some estimate that as many as one-third of teenagers who use the Internet engage in cyberbullying (Li, 2007; Scharnberg, 2007). The psychological consequences of cyberbullying on the victims can be very serious—including anxiety, school phobia, lower self-esteem, suicidal ideation, and occasional cases of suicide (Thomas, 2006).

Fortunately, there is another side to this coin. Peer relations can be difficult, but they can also be sources of key learning experiences that stand an individual in good stead for many years. For a resourceful child, the winning and losing and the successes and failures of the school years provide excellent training in coming to grips with the real world and with her or his developing self—its capabilities and limitations, its attractive and unattractive qualities. The experience of intimacy with a friend has its beginning in this period of intense social involvement. If all goes well, a child emerges into adolescence with a considerable repertoire of social knowledge and skills that add up to social competence. Such resources can be strong protective factors against parental rejection, frustration, demoralization, despair, and mental disorder (Masten, 2007; Sentse et al., 2010).

**SOURCES OF POPULARITY VERSUS REJECTION** What determines which children will be popular and which will be rejected? There seem to be two types of popular children—the prosocial and the antisocial types. *Prosocial* popular children communicate with their peers in friendly and assertive yet cooperative ways. They tend to be good students relative to their less popular peers (Zettergreen, 2003). *Antisocial* popular children—usually boys—tend to be “tough boys” who may be athletically skilled but who do poorly academically. They tend to be highly aggressive and defiant of authority (see Berk, 2003).

Far more attention has been devoted to determining why some children are persistently rejected by their peers and what the consequences are of such rejection. There also appear to be two types of rejected children—those who are too aggressive and those who are very withdrawn (Ladd, 2006). The rejected children who are aggressive take an excessively demanding or aggressive approach when interacting with their peers. They often take offense too readily and attribute hostile intent to the teasing of their peers, thus escalating confrontations to unintended levels (Dodge, 2006; Reijntjes et al., 2011). Indeed, the tendency to attribute hostile intent to others in grade 8 has been shown to predict levels of antisocial behavior in grade 11

Juvenile socializing is a risky business in which a child's hard-won prestige in a group is probably perceived as being constantly in jeopardy. Actually, reputation and status in a group tend to be stable, and a child who has been rejected by peers is likely to continue to have problems in peer relationships.

(Lansford et al., 2006). Such children also tend to take a more punitive and less forgiving attitude toward such situations (Coie et al., 1991; Crick & Dodge, 1994; Reijntjes et al., 2011). This may be especially likely in children who have been maltreated by their parents and have therefore developed maladaptive mental representations of caregivers and expect maltreatment. Expecting maltreatment, they may approach social situations with hyperarousal, anxiety, and angry reactivity, which may be consistent with what they have experienced at home but is out of sync with the context they share with peers (Cicchetti & Toth, 2005; Shields et al., 2001). In addition, having a poor ability to understand a peer's emotions (such as fear and sadness) in kindergarten also predicts aggressive behavior toward peers in the third grade (Dodge et al., 2002).

Being rejected and being aggressive at one point in childhood greatly increases the probability of aggressive and delinquent behavior later on, especially in boys (Coie, 2004; Ladd, 2006; Reijntjes et al., 2011). For example, one study followed 585 children from kindergarten through the eighth grade. Results showed that those who had hostile knowledge structures (schemas) early in childhood were more likely to develop consistent aggressive behaviors over an 8-year follow-up period (Burks et al., 1999; see also Laird et al., 2001).

The second subset of children who may become chronic victims of rejection are not aggressive but, rather, are highly unassertive and quite submissive toward their peers, often because of social anxiety and fear of being scorned or attacked (Schwartz et al., 1993). Such isolation is likely to have serious consequences because it often leads to peer rejection, which in turn deprives a child of further opportunities to learn the rules of social behavior and interchange, rules that become more sophisticated and subtle with increasing age (Coie, 1990; Ladd, 2006). Repeated social failure or becoming the victim of bullies is the usual result, which has further damaging effects on self-confidence and self-esteem and sometimes leads to loneliness, depression, and anxiety, especially during the elementary school years (Burks et al., 1995; Ladd, 2006).

In summary, both logic and research findings suggest the same conclusion: A child who fails to establish satisfactory relationships with peers during the developmental years is deprived of a crucial set of background experiences and is at higher-than-average risk for a variety of negative outcomes in adolescence and adulthood including depression, school dropout, suicidal ideation, and delinquency (Coie, 2004; Heilbron & Prinstein, 2010; Ladd, 2006). However, one should also remember that the peer social problems may also be early markers of disorders that have a heritable component but do not become full blown until later in adolescence or adulthood. What is often going on in such cases is that the peer social problems indeed reflect some heritable diathesis, but they also serve as stressors that make it more likely that the underlying vulnerability will lead to full-blown disorder later (Parker et al., 1995; see also Coie, 2004; Rutter, 2006).

### in review

- What are the most important effects of a child's being exposed to early deprivation or abuse?
- What kinds of effects does parental psychopathology have on children?
- What kinds of influences do different parenting styles tend to have on children's development? (Consider especially the variables of parental warmth and parental control.)
- What is the typical range of effects that divorce and marital discord can have on children? What about effects on adults?
- What are two different types of popular children and two different types of rejected children?

## The Sociocultural Viewpoint

By the beginning of the twentieth century, sociology and anthropology had emerged as independent scientific disciplines and were making rapid strides toward understanding the role of sociocultural factors in human development and behavior. Early sociocultural theorists included such notables as Ruth Benedict, Abram Kardiner, Margaret Mead, and Franz Boas. Their investigations and writings showed that individual personality development reflects the larger society—its institutions, norms, values, and ideas—as well as the immediate family and other groups. Studies also made clear the relationship between various sociocultural conditions and mental disorders (for example, the relationship between the particular stressors in a given society and the types of mental disorders that typically occur in it). Further studies showed that the patterns of both physical and mental disorders within a given society could change over time as sociocultural conditions change. These discoveries have added important new dimensions to modern perspectives on abnormal behavior (Fabrega, 2001; Tsai et al., 2001; Westermeyer & Janca, 1997).

### Uncovering Sociocultural Factors Through Cross-Cultural Studies

The sociocultural viewpoint is concerned with the impact of culture and other features of the social environment on mental disorders. The relationships are complex. It is one thing to observe that a person with a psychological disorder has come from a harsh environment. It is quite another to show empirically that these circumstances were contributory causes of the disorder as opposed to being mere correlates of the disorder. Yet people raised in different societies and exposed to very different environments have provided natural "laboratories" of sorts, and cross-cultural research can enhance our knowledge about the range of variation that is possible in human behavioral and emotional development. It can also generate ideas about what causes normal and abnormal behavior—ideas that can later be tested more rigorously in the laboratory (e.g., Rothbaum, Weisz et al., 1997; Weisz, et al., 2000, 2001).

**UNIVERSAL AND CULTURE-SPECIFIC SYMPTOMS OF DISORDERS** Research supports the view that many psychological disturbances—in both adults and children—are universal, appearing

in most cultures studied (Butcher, 1996b; Butcher, 2005; Kleinman, 1988; Verhulst & Achenbach, 1995). Studying such issues is, of course, never easy because of the need to adapt psychological tests across barriers of language and culture and to validate their use in other cultures. One example of such research has shown that when some tests are translated into the language of different cultures, they need to be adapted so that they are appropriate for the new cultural context. In addition, care must be taken not to miss what may be culture-specific elements of various disorders such as anxiety and depression (e.g., Sue & Chang, 2003; Weisz et al., 2006).

The Minnesota Multiphasic Personality Inventory (MMPI-2; see Chapter 4) is the best validated and most widely used test that has been adapted for use in many cultures (e.g., Butcher, 2011). For example, the basic pattern of disturbed thoughts and behaviors that we call schizophrenia can be found among nearly all peoples, although the prevalence and symptoms vary to some degree (Woo & Oei, 2007). Moreover, certain psychological symptoms, as measured, are consistently found among similarly diagnosed clinical groups in many other countries. For example, Butcher (1996a) found that psychiatric patients from Italy, Switzerland, Chile, India, Greece, and the United States who were diagnosed with paranoid schizophrenia produced similar general personality and symptom patterns on the MMPI. The same MMPI-2 pattern was also found to occur among patients with schizophrenia in Japan (Hayama, 1999).

Nevertheless, although some universal symptoms and patterns of symptoms appear, sociocultural factors often influence which disorders develop, the forms they take, how prevalent they are, and their courses. For example, the prevalence of major depressive disorder varies widely across the cultures of the world. In one study conducted in 10 countries around the world, the prevalence ranged from 3 percent in Japan to nearly 17 percent in the United States (Andrade et al., 2004).

Sociocultural factors influence the form and course of certain disorders. For example, in Western societies people suffering from stress frequently will become depressed. In China, stress is not manifested as depression but in physical problems such as fatigue and weakness.

Differences can also emerge in the prognosis or outcomes of several severe mental disorders in different countries. Several international studies have found a more favorable course of schizophrenia in developing countries than in developed countries (Kulhara & Chakrabarti, 2001).

In another example, Kleinman (1986, 1988) compared the ways in which Chinese people (in Taiwan and the People's Republic of China) and Westerners deal with stress. He found that in Western societies, depression was a frequent reaction to individual stress. In China, on the other hand, he noted a relatively low rate of reported depression (Kleinman, 2004; see also Kirmayer & Groleau, 2001). Instead, the effects of stress were more typically manifested in physical problems such as fatigue, weakness, and other complaints. Moreover, Kleinman and Good (1985) surveyed the experience of depression across cultures. Their data show that important elements of depression in Western societies—for example, the acute sense of guilt typically experienced—do not appear in many other cultures. They also point out that the symptoms of depression, such as sadness, hopelessness, unhappiness, and a lack of pleasure in the things of the world and in social relationships, have dramatically different meanings in different societies. For Buddhists, seeking pleasure from things of the world and social relationships is the basis of all suffering; a willful disengagement is thus the first step toward achieving enlightenment. For Shi'ite Muslims in Iran, grief is a religious experience associated with recognition of the tragic consequences of living justly in an unjust world; the ability to experience grief fully is thus a marker of depth of personality and understanding.

In addition to the influence of culture on the symptoms experienced in different cultures, there are also entire patterns of symptoms in certain cultures that are unlike the patterns experienced in most other parts of the world. Although a variety of these “culture-bound syndromes” will be discussed in various parts of this book, a few will serve to illustrate the general idea. In recent years, for example, a phenomenon known as **Hikikomori** has emerged as quite common in Japan, affecting as many as 700,000 individuals. This is a disorder of acute social withdrawal in which young people just remain in their room in their parents’ house and refuse social interactions for at least 6 months, but often for many years. The social withdrawal is ego-syntonic. Another example is **Zar** which occurs in both North Africa and the Middle East. With Zar a person who believes he or she is possessed by a spirit may experience a dissociative episode during which shouting, laughing, singing, or weeping may occur. The person may also show apathy and withdrawal, not eating or working. Numerous other examples of culture bound syndromes will be covered in subsequent chapters (such as *Koro* and *Taijin Kyofusho* discussed in Chapter 6).

## CULTURE AND OVER- AND UNDERCONTROLLED

**BEHAVIOR** Studies of the prevalence of different kinds of childhood psychopathology in different cultures raise some fascinating issues. In cultures such as that of Thailand, adults are highly intolerant of *undercontrolled behavior* such as aggression, disobedience,

In Thailand, children tend to exhibit overcontrolled behavior and are explicitly taught by their parents to be polite and deferential and to inhibit any expression of anger. This is in contrast to American children, whose parents tend to tolerate undercontrolled behavior to a greater extent.

and disrespectful acts in their children (e.g., Weisz et al., 2003). Children are explicitly taught to be polite and deferential and to inhibit any expression of anger. This raises interesting questions about whether childhood problems stemming from undercontrolled behavior are lower in Thailand than in the United States, where such behavior seems to be tolerated to a greater extent. It also raises the question of whether problems related to *overcontrolled behavior* such as shyness, anxiety, and depression would be overrepresented in Thailand relative to the United States.

Two cross-national studies (Weisz et al., 1987, 1993) confirmed that Thai children and adolescents do indeed have a greater prevalence of overcontrolled problems than do American children. Although there were no differences in the rate of undercontrolled behavior problems between the two countries, there were differences in the kinds of undercontrolled behavior problems reported. For example, Thai adolescents had higher scores than American adolescents on indirect and subtle forms of undercontrol not involving interpersonal aggression such as having difficulty concentrating or being cruel to animals; American adolescents, on the other hand, had higher scores than Thai adolescents on behaviors like fighting, bullying, and disobeying at school (Weisz et al., 1993). In addition, these investigators found that Thai and American parents differ a good deal in which problems they will bring for treatment. In general, Thai parents seem less likely than American parents to refer their children for psychological treatment (Weisz & Weiss, 1991; Weisz et al.,

1997). This may be in part because of their Buddhist belief in the transience of problems and their optimism that their child's behavior will improve. Alternatively, Thai parents may not refer their children with undercontrolled problems for treatment simply because these problems are so unacceptable that the parents are embarrassed to go public with them (Weisz et al., 1997).

Cultural differences in psychopathology may also result from differences in what cultures consider to be the ideal kinds of parent-child attachment relationships. The World Around Us box on page 95 discusses research on cultural differences in what Japanese and Western cultures believe to be the nature of ideal versus disordered attachment relationships.

### in review

- Give some examples of universal and culture-specific symptoms of disorders.
- What cultural factors help account for differences in problems involving overcontrolled and undercontrolled behavior in Thai versus American children?
- Briefly describe three examples of culture-bound syndromes.

## Sociocultural Causal Factors

We all receive a sociocultural inheritance that is the end product of thousands of years of social evolution, just as we receive a genetic inheritance that is the end product of millions of years of biological evolution. Because each sociocultural group fosters its own cultural patterns by systematically teaching its offspring, all its members tend to be somewhat alike. Children reared among headhunters tend to become headhunters; children reared in societies that do not sanction violence usually learn to settle their differences in nonviolent ways. The more uniform and thorough the education of the younger members of a group, the more alike they will become. Thus, in a society characterized by a limited and consistent point of view, there are not the wide individual differences that are typical in a society like ours, where children have contact with diverse, often conflicting beliefs. Even in our society, however, there are certain core values that most of us consider essential.

There are many sources of pathogenic social influences (see Figure 3.14). Some of these stem from socioeconomic factors.

- ▶ Low socioeconomic status and unemployment
- ▶ Prejudice and discrimination in race, gender, and ethnicity
- ▶ Social change and uncertainty
- ▶ Urban stressors: Violence and homelessness

**FIGURE 3.14**

Sociocultural Causal Factors.

Others stem from sociocultural factors regarding role expectations and from the destructive forces of prejudice and discrimination. We will briefly look at some of the more important ones here.

## Low Socioeconomic Status and Unemployment

In our society the lower the socioeconomic class, the higher the incidence of mental and physical disorders (e.g., Caracci & Mezzich, 2001; Conger & Donnellan, 2007). The strength of this inverse correlation varies with different types of mental disorder, however. For example, antisocial personality disorder is strongly related to socioeconomic status (SES), occurring about three times as often in the lowest income category as in the highest income category, whereas depressive disorders occur only about 1.5 times as often in the lowest income category as in the highest income category (Kessler et al., 1994; Kessler & Zhao, 1999; see also Monroe et al., 2009).

There are many reasons for this general inverse relationship (Conger & Donnellan, 2007). There is evidence that some people with mental disorders slide down to the lower rungs of the economic ladder and remain there, sometimes because they do not have the economic or personal resources to climb back up (e.g., Gottesman, 1991) and sometimes because of prejudice and stigma against those with mental illness (e.g., Caracci & Mezzich, 2001). At the same time, more affluent people are better able to get prompt help or to conceal their problems. However, it is also true that, on average, people who live in poverty encounter more—and more severe—stressors in their lives, than do more affluent people, and they usually have fewer resources for dealing with them (e.g., Twenge & Campbell, 2002). Thus lower socioeconomic groups may show increased prevalence of mental and physical disorders due at least partly to increased stress on the people at risk (Conger & Donnellan, 2007; Eaton & Muntaner, 1999; Monroe et al., 2009).

Children and adolescents from lower-SES families also tend to have more problems (see Conger & Donnellan, 2007, for a review). A number of studies have documented a strong relationship between the parents' poverty and lower IQs in their children at least up to age 5. Persistent poverty has the most adverse effects (Duncan et al., 1994; McLoyd, 1998), including greater mental distress as well as greater risk taking and affiliating with deviant peers (Sampson et al., 2002). Children from low-SES families who were assessed when they were in preschool showed more acting-out and aggressive behaviors over the next 4 years (Dodge et al., 1994), perhaps in part because their parents are more likely to have an authoritarian parenting style and to experience marital conflict (Conger & Donnellan, 2007). Nevertheless, many inner-city children from high-risk socioeconomic backgrounds do very well, especially those with higher IQs and those with adequate relationships at home, in school, and with peers (Felsman & Valliant, 1987; Long & Valliant, 1984; Masten & Coatsworth, 1995).

Other studies have examined the effects of unemployment per se on adults and children. Since the 1970s, there

have been a number of severe economic recessions experienced worldwide, and significant rates of unemployment have accompanied each. Studies have repeatedly found unemployment—with its financial hardships, self-devaluation, and emotional distress—to be associated with emotional distress and enhanced vulnerability to psychopathology (e.g., Dooley et al., 2000; Grzywacz & Dooley, 2003). Recent evidence suggests that it is the financial difficulties often resulting from unemployment that lead to the elevated levels of distress and mental disorders (Thomas et al., 2007).

In particular, rates of depression, marital problems, and somatic (bodily) complaints increase during periods of unemployment but usually normalize when employment rates recover (Dew et al., 1991; Jones, 1992; Murphy & Athanasou, 1999). It is not simply that people who are mentally unstable tend to lose their jobs. These effects occur even when mental health status before unemployment is taken into account. Not surprisingly, the wives of unemployed men are also adversely affected, exhibiting higher levels of anxiety, depression, and hostility, which seem to be at least partially caused by the distress of the unemployed husband (Dew et al., 1987). Children too can be seriously affected. In the worst cases, unemployed fathers are much more likely to engage in child abuse (Cicchetti & Lynch, 1995; Dew et al., 1991).

Finally, economic crises since 1990 have centered not only on unemployment but also on the effects that corporate restructuring and downsizing have had on upper-middle-class people, many of whom find themselves having to look for jobs requiring lower skills and paying much lower incomes than they earned in the past. In other cases people are forced to work only part time and often do not make enough to live on. In such cases of underemployment (or inadequate employment), several large studies of people who were underemployed found that rates of depression were comparable or nearly comparable to those seen in unemployed individuals (Dooley & Prause, 2004; Dooley et al., 2000; Grzywacz & Dooley, 2003).

## Prejudice and Discrimination in Race, Gender, and Ethnicity

Vast numbers of people in our society have been subjected to demoralizing stereotypes as well as to both overt and covert discrimination in areas such as employment, education, and housing. We have made progress in race relations since the 1960s, but the lingering effects of mistrust and discomfort among various ethnic and racial groups can be clearly observed in many places (e.g., Eagly, 2004; Mays, Cochran, & Barnes, 2007). For example, on most college campuses, many students socialize informally only with members of their own subcultures, despite the attempts of many well-meaning college administrators to break down the barriers. These tendencies needlessly limit students' educational experiences and probably contribute to continued misinformation about, and prejudice toward, others. There are also very large health disparities between African Americans and Caucasian Americans

## Culture and Attachment Relationships

Recently, research has shown that there are significant cross-cultural differences in views of ideal parent-child attachment relationships. Accordingly, there are different views of what constitutes disordered attachment relationships that can increase risk for psychopathology. Views on the function of good attachment relationships (and the nature of disordered attachment) in Western cultures have been found to differ rather dramatically from those seen in Japan (Rothbaum, Weisz, et al., 2000, 2001). In Western societies, secure attachment relationships are thought to occur when a mother responds in a sensitive fashion to a child's signals (e.g., signs of hunger or discomfort) yet gradually allows the child to explore the environment and develop some autonomy. In the United States one study found that teachers similarly prefer to respond to explicit expression of needs and to foster children's independence and self-expression, which would also foster secure attachments (Rothbaum et al., 2006). Importantly, securely attached children (relative to insecurely attached children) are thought to be less anxious and depressed, better able to cope with negative emotional states, and better able to form close relationships with peers.

However, in Japan, parents' goals are to anticipate all the child's needs and thereby avoid any exposure to stress such as hunger or discomfort and to foster dependency (Rothbaum, Weisz, et al., 2000, 2001). Recent findings suggest that

Japanese teachers also prefer to anticipate their students' needs and to foster dependency on other tasks (Rothbaum et al., 2006). Accordingly, children who are considered securely attached in Japan are very dependent on their mothers (and teachers), and independent children are thought to have disturbed attachments. Moreover, because the Japanese value social harmony, children who are dependent and emotionally restrained and who express their feelings only indirectly are the ones viewed as competent; they also tend to be self-critical and self-effacing. This is very different from Western cultures, where children who show exploration and autonomy and are willing to express strong feelings and even disagreement openly are considered to be socially competent. Such children in Western cultures also tend to have positive self-views (Rothbaum, Weisz, et al., 2000).

Given such differences, it is not surprising that different clinical interventions are viewed as appropriate for children with behavior problems in these two cultures. For example, American therapists often help their clients to develop their own separate identities and assume that expression of negative feelings toward others (including parents) may be necessary. By contrast, Japanese therapists are more likely to encourage clients to be grateful to others (especially their parents) and encourage devotion (see Rothbaum, Weisz, et al., 2000, 2001).

that may at least in part be a result of various forms of discrimination (Mays et al., 2007). Perceived discrimination seems to predict lower levels of well-being for women on dimensions relating to a sense of growth, autonomy, and self-acceptance (Ryff et al., 2003). Prejudice against minority groups may also explain why these groups sometimes show increased prevalence of certain mental disorders such as depression (Cohler et al., 1995; Kessler et al., 1994). One possible reason for this is that perceived discrimination may serve as a stressor that threatens self-esteem, which in turn increases psychological distress (e.g., Cassidy et al., 2004). A recent study of Arab and Muslim Americans two years after the bombing of the World Trade Center in New York found increased psychological distress, lower levels of happiness, and increased health problems in those who had experienced personal or familial prejudice, discrimination, or violence since the World Trade Center disaster (Padela & Heisler, 2010). Finally, another study showed that African American men who experience and perceive high levels of racial discrimination are more likely to report involvement in both street violence and intimate partner violence (Reed et al., 2010).

We have made progress in recognizing the demeaning and often disabling social roles our society has historically assigned to women. Again, though, much remains to be done. Many more women than men suffer from certain emotional disorders,

most notably depression and anxiety disorders, which are two of the three most common categories of disorders (Blehar, 2006). This may be at least partly a consequence of the vulnerabilities (such as passivity and dependence) intrinsic to the traditional roles assigned to women and of the sexual discrimination that still occurs in the workplace (Eagly & Carli, 2007). There are two primary types of discrimination that occur in the workplace: *access discrimination*, wherein women are not hired because they are women, and *treatment discrimination*, wherein women who have a job are paid less and receive fewer opportunities for promotion (Eagly & Carli, 2007; Eagly & Karau, 2002). Sexual harassment in the workplace is another type of stress that women may experience. In addition, the special stressors with which many modern women must cope (being full-time mothers, full-time homemakers, and full-time employees) as their traditional roles rapidly change have also been implicated in higher rates of depression, anxiety, and marital dissatisfaction in women than in the past. This is especially true if a woman works long hours (over 40 hours a week), has a higher income than her husband, and has children at home. However, it should also be noted that under at least some circumstances, working outside the home has also been shown to be a protective factor against depression and marital dissatisfaction (e.g., Brown & Harris, 1978; Helgeson, 2002).

## Social Change and Uncertainty

The rate and pervasiveness of change today are different from anything our ancestors ever experienced. All aspects of our lives are affected—our education, our jobs, our families, our health, our leisure pursuits, our finances, and our beliefs and values. Constantly trying to keep up with the numerous adjustments demanded by these changes is a source of considerable stress. Simultaneously, we confront inevitable crises as the earth's consumable natural resources dwindle, as our environment becomes increasingly noxious with pollutants, and as global warming occurs. No longer are Americans confident that the future will be better than the past or that technology will solve all our problems. On the contrary, our attempts to cope with existing problems seem increasingly to create new problems that are as bad or worse. The resulting despair, demoralization, and sense of helplessness are well-established predisposing conditions for abnormal reactions to stressful events (Dohrenwend, 2000; Seligman, 1990, 1998). This sense of helplessness was also exacerbated for Americans by the September 11, 2001, terrorist attacks on the World Trade Center in New York and the Pentagon, with many people now living under increased worry and uncertainty over the possibility of terrorist attacks. Yet in other parts of the world, such as Israel and Palestine, people have lived with this uncertainty and worry over terrorist attacks for decades.

## Urban Stressors: Violence and Homelessness

Rapid urban growth is occurring worldwide—especially in less developed countries. Unfortunately, it is frequently unregulated and chaotic, and growing numbers of people are unemployed, homeless, or involved with illicit activities (Caracci, 2006).

Perhaps not surprisingly, these areas are also plagued by a high prevalence of mental disorders. Moreover, vast numbers of people in the big cities of both developed and developing countries are direct or second-hand victims of *urban violence* (Caracci, 2006; Caracci & Mezzich, 2001). More than a decade ago it was estimated that at least 3.5 million people worldwide lose their lives to violence each year (World Health Organization, 1999), and there is no reason to think this number has declined. Domestic violence against women and children is especially widespread (e.g., Caracci, 2003). Such violence takes its toll on the victims not only in the areas of medical care and lost productivity but also in increased rates of anxiety, posttraumatic stress disorder, depression, and suicidality (e.g., Caracci, 2006; Caracci & Mezzich, 2001). One recent study of young African American mothers exposed to violence found not only increased levels of depression but also elevated levels of aggressive behavior and harsh discipline of their children (Lewin et al., 2010).

Another severe stress in urban areas worldwide is *homelessness*, which has been rapidly growing for the past few decades. Estimates are that approximately one-third of homeless people are affected by severe mental illness, but many people who are not mentally ill also become homeless because they are victims

of violence or poverty (e.g., Caracci & Mezzich, 2001). Needless to say, the major stressors experienced by being homeless create mental distress including anxiety, depression, suicidality, and physical illness, even in those who started out healthy.

## The Impact of the Sociocultural Viewpoint

With our increased understanding of sociocultural influences on mental health, what was previously an almost exclusive concern with individuals has broadened to include a concern with societal, communal, familial, and other group settings as factors in mental disorders. Sociocultural research has led to programs designed to improve the social conditions that foster maladaptive behavior and mental disorder, and to community facilities for the early detection, treatment, and long-range prevention of mental disorder. In Chapter 17 we will examine some clinical facilities and other programs—both governmental and private—that have been established as a result of community efforts.

There is strong evidence of cultural influences on abnormal behavior, and this area of research may yet answer many questions about the origins and courses of behavior problems as well as their treatment (Cohler et al., 1995; Miranda et al., 2005; Sue, 1999). Nevertheless, in spite of increasing research showing that patients may do better when treated by therapists from their own ethnic group (or at least by someone familiar with the patient's culture),

Today many major metropolitan areas in the United States have problems with gangs and urban violence.

many professionals may fail to adopt an appropriate cultural perspective when dealing with mental illness. Instead, many simply assume that the treatments that have been shown to be useful with one culture will fare as well with other cultures, when in fact this is always an empirical question (e.g., Lam & Sue, 2001; Miranda et al., 2005; Sue, 1998). In a world of instant communication with people from any country, it is crucial for our sciences and professions to take a worldview.

## UNRESOLVED issues

### Theoretical Viewpoints and the Causes of Abnormal Behavior

The viewpoints described in this chapter are theoretical constructions devised to orient psychologists in the study of abnormal behavior. As a set of hypothetical guidelines, each viewpoint emphasizes the importance and integrity of its own position to the exclusion of other explanations. Most psychodynamically oriented clinicians, for example, value those traditional writings and beliefs consistent with Freudian or later psychodynamic theories, and they minimize or ignore the teachings of opposing viewpoints. They usually adhere to prescribed practices of psychodynamic therapy and do not use other methods such as exposure therapy.

#### ADVANTAGES OF HAVING A THEORETICAL VIEWPOINT

Theoretical integrity and adherence to a systematic viewpoint have a key advantage: They ensure a consistent approach to one's practice or research efforts. Once mastered, the methodology can guide a practitioner or researcher through the complex web of human problems. But such adherence to a theory has its disadvantages. By excluding other possible explanations, it can blind researchers to other factors that may be equally important. The fact is that none of the theories devised to date addresses the whole spectrum of abnormality—each is limited in some way in its focus.

Two general trends have occurred as a result. First, the original model or theory may be revised by expanding or modifying some elements of the system. The many examples of such modified interpretations include Adler's and Erikson's modifications of Freudian theory and the more recent cognitive-behavioral approach's modification of behavior therapy. But many of the early Freudian theorists did not accept the neo-Freudian additions, and some classical behavior therapists today still do not accept the revisions proposed by cognitive behaviorists. Therefore, the second trend has been for theoretical viewpoints to multiply and coexist—each with its own proponents—rather than being assimilated into previous views.

#### THE ECLECTIC APPROACH

Alternatively, aspects of two or more diverse approaches may be combined in a more general, eclectic approach. In practice, many psychologists have responded to the existence of many perspectives by adopting an eclectic stance; that is, they accept working ideas from several viewpoints

#### in review

- What effects do low SES and unemployment have on adults and children?
- Describe how prejudice and discrimination, social change and uncertainty, and urban stress can have adverse effects on the development of abnormal behavior.
- Why is it necessary to acknowledge the role of sociocultural factors in mental disorders?

and incorporate whichever they find useful. For example, a psychologist using an eclectic approach might accept causal explanations from psychodynamic theory while applying techniques of anxiety reduction from behavior therapy. Another psychologist might combine techniques from the cognitive-behavioral approach with those from the interpersonal approach. Purists in the field—those who advocate a single viewpoint—are skeptical about eclecticism, claiming that the eclectic approach tends to lack integrity and produces a "crazy quilt" of inconsistent practice with little rationale. This criticism may be true, but the approach certainly seems to work for many psychotherapists.

Typically, those who use an eclectic approach to treatment make no attempt to synthesize the theoretical perspectives. Although this approach can work in practical settings, it is not successful at a theoretical level because the underlying principles of many of the theoretical perspectives are incompatible as they now stand. Thus the eclectic approach still falls short of the final goal, which is to tackle the theoretical clutter and develop a single, comprehensive, internally consistent viewpoint that accurately reflects what we know empirically about abnormal behavior.

#### THE BIOPSYCHOSOCIAL UNIFIED APPROACH

At present, the only attempt at such a unified perspective that has been developing is called the *biopsychosocial viewpoint*. This viewpoint reflects the conviction that most disorders are the result of many causal factors—biological, psychological, and sociocultural—interacting with one another. Moreover, for any given person, the particular combination of causal factors may be unique, or at least not widely shared by large numbers of people with the same disorder. For example, some children may become delinquents primarily because of having a heavy genetic loading for antisocial behavior, whereas others may become delinquent primarily because of environmental influences such as living in an area with a large number of gangs. Therefore, we can still hope to achieve a scientific understanding of many of the causes of abnormal behavior even if we cannot predict such behavior with exact certainty in each individual case and are often left with some "unexplained" influences.

# 3

## summary

### 3.1 What are the causes and risk factors for abnormal behavior?

- In considering the causes of abnormal behavior, it is important to distinguish among necessary, sufficient, and contributory causal factors, as well as between relatively distal causal factors and those that are more proximal.
- Usually the occurrence of abnormal or maladaptive behavior is considered to be the joint product of a person's predisposition or vulnerability (diathesis) to disorder and of certain stressors that challenge his or her coping resources.
- The concept of protective factors is important for understanding why some people with both a diathesis and a stressor may remain resilient and not develop a disorder.

### 3.2 What viewpoints can we take to help us understand the causes of abnormal behavior?

- Both the distal (long-ago) and proximal (immediate) risk factors for mental disorder may involve biological, psychological, and sociocultural factors. These three classes of factors can interact with each other in complicated ways during the development of mental disorders.
- This chapter discusses biological, psychological, and sociocultural viewpoints, each of which tends to emphasize the importance of causal factors of a characteristic type. Ultimately we strive for an integrative biopsychosocial viewpoint.

### 3.3 What does the biological viewpoint tell us about abnormal behavior and what are the biological causal factors of abnormal behavior?

- In examining biologically based vulnerabilities, we must consider abnormalities in neurochemical and hormonal systems, genetic vulnerabilities, temperament, and brain dysfunction and neural plasticity.
- Many different neurotransmitter and hormonal abnormalities contribute to the development of mental disorders because of the effects they exert on different relevant brain and body areas for different disorders.
- Genetic vulnerabilities can affect the development of mental disorders through multiple mechanisms, including ways in which the genotype may affect the phenotype (genotype–environment correlations) and in which they affect an individual's susceptibility to environmental influences (genotype–environment interactions).
- Methods for studying the extent of genetic versus environmental influences include the family history method, the twin method, and the adoption method. More recently, linkage analysis and association studies are beginning to contribute knowledge about the exact location of genes contributing to mental disorders.

- Temperament is strongly influenced by genetic factors and refers to a baby's characteristic ways of reacting to the environment and his or her ways of self-regulation. It forms the basis of our adult personality, which in turn influences our vulnerability to different disorders.
- Studies of neural plasticity have shown that genetic programs for brain development are not as fixed as once believed and that existing neural circuits can often be modified based on experience.

### 3.4 What are the psychological viewpoints on abnormal psychology?

- In examining psychologically based vulnerabilities, there are three primary perspectives that have developed since the end of the nineteenth century: psychodynamic, behavioral, and cognitive-behavioral.
- The oldest psychological viewpoint on abnormal behavior is Freudian psychoanalytic theory. For many years this view was preoccupied with questions about libidinal (*id*) energies and their containment.
- More recently, four second-generation psychodynamic theories departed in significant ways from Freud's original ideas.
- Anna Freud's ego psychology focused on the important role of the ego in normal and abnormal behavior, with special attention focused on ego-defense reactions.
- Object-relations theorists focused on the role of the quality of very early (pre-Oedipal) mother–infant relationships for normal development.
- The originators of the interpersonal perspective took exception to the Freudian emphasis on the internal determinants of motivation and behavior and instead emphasized the social and cultural forces that shape behavior.
- Attachment theory, which has roots in both the interpersonal and object-relations perspectives, emphasizes the importance of early experiences with attachment relationships for laying the foundation for later child, adolescent, and adult development.
- Psychoanalysis and closely related therapeutic approaches are termed *psychodynamic* in recognition of their attention to inner, often unconscious forces.
- The behavioral perspective focuses on the role of learning in human behavior and attributes maladaptive behavior either to a failure to learn appropriate behaviors or to the learning of maladaptive behaviors.
- The primary forms of learning studied are classical conditioning and instrumental (operant) learning. The effects of each are modified by principles of generalization and discrimination. Observational learning is also important.
- Adherents of the behavioral viewpoint attempt to alter maladaptive behavior by extinguishing it or providing training in new, more adaptive behaviors.
- The cognitive-behavioral viewpoint attempts to incorporate the complexities of human cognition, and how it can become distorted, into an understanding of the causes of psychopathology.

- People's schemas and self-schemas play a central role in the way they process information, in how they attribute outcomes to causes, and in their values. The efficiency, accuracy, and coherence of a person's schemas and self-schemas and attributions appear to provide an important protection against breakdown.
- Treatments developed from the cognitive-behavioral perspective attempt to alter maladaptive thinking and improve a person's abilities to solve problems and to achieve goals.

### **3.5 What are the psychological causal factors behind abnormal behavior?**

- Sources of psychologically determined vulnerability include early social deprivation or severe emotional trauma, inadequate parenting styles, marital discord and divorce, and maladaptive peer relationships.

### **3.6 How does the sociocultural viewpoint help us understand abnormal behavior?**

- The sociocultural viewpoint is concerned with the contribution of sociocultural variables to mental disorder.

- Although many serious mental disorders are fairly universal, the form that some disorders take and their prevalence vary widely among different cultures.

### **3.7 What are the sociocultural causal factors of abnormal behavior?**

- Low socioeconomic status and unemployment; being subjected to prejudice and discrimination in race, gender, and ethnicity; experiencing social change and uncertainty; and urban violence and homelessness are all associated with greater risk for various disorders.
- The biopsychosocial approach is promising, but in many ways it is merely a descriptive acknowledgment of the complex interactions among biological, psychological, and sociocultural risk factors rather than a clearly articulated theory of how they interact.

## learning objectives

### 4.1

What are the basic elements in assessment?

### 4.2

What is involved in the assessment of the physical organism?

### 4.3

What is psychosocial assessment?

### 4.4

How do practitioners integrate assessment data?

### 4.5

What is the process for classifying abnormal behavior?

The assessment of the personality and motivation of others has been of interest to people since antiquity. Early records show that some individuals used assessment methods to evaluate potential personality problems or behaviors. There are documented attempts at understanding personality characteristics in ancient civilizations. Hathaway (1965) points out that one of the earliest descriptions of using behavioral observation in assessing personality can be found in the Old Testament. Gideon relied upon observations of his men who trembled with fear to consider them fit for duty; Gideon also observed how soldiers chose to drink water from a stream as a means of selecting effective soldiers for battle. In ancient Rome, Tacitus provided examples in which the appraisal of a person's personality entered into their leader's judgments about them. Tacitus (translated by Grant, 1956, p. 36) points out that Emperor Tiberius evaluated his subordinates in his meetings by often pretending to be hesitant in order to detect what the leading men were thinking.

Psychological assessment is one of the oldest and most widely developed branches of contemporary psychology, dating back to the work of Galton (1879) in the nineteenth century (Butcher, 2010; Weiner & Greene, 2008). We will focus in this chapter on the initial clinical assessment and on arriving at a clinical diagnosis according to *DSM-5*. **Psychological assessment** refers to a procedure by which clinicians, using psychological tests, observation, and interviews, develop a summary of the client's symptoms and problems. **Clinical diagnosis** is the process through which a clinician arrives at a general "summary classification" of the patient's symptoms by following a clearly defined system such as *DSM-5* or ICD-10 (International Classification of Diseases), the latter published by the World Health Organization.

Assessment is an ongoing process and may be important at various points during treatment, not just at the beginning—for example, to examine the client's progress in treatment or to evaluate outcome. In the initial clinical assessment, an attempt is usually made to identify the main dimensions of a client's problem and to predict the probable course of events under various conditions. It is at this initial stage that crucial decisions have to be made—such as what (if any) treatment approach is to be offered, whether the problem will require hospitalization, to what extent family members will need to be included as coclients, and so on. Sometimes these decisions must be made quickly, as in emergency conditions, and without critical information. As will be seen, various psychological measurement instruments are employed to maximize assessment efficiency in this type of pretreatment examination process (Harwood & Beutler, 2009).

A less obvious, but equally important, function of pretreatment assessment is establishing baselines for various psychological functions so that the effects of treatment can be measured. Criteria based on these measurements may be established as part of the treatment plan such that the therapy is considered successful and is terminated only when the client's behavior meets these predetermined criteria. Also, as we will see in later chapters, comparison of posttreatment with pretreatment assessment results is an essential feature of many research projects designed to evaluate the effectiveness of various therapies.

In this chapter, we will review some of the more commonly used assessment procedures and show how the data obtained can be integrated into a coherent clinical picture for making decisions about referral and treatment. Our survey will include a discussion of physical, neurological, and neuropsychological assessment; the clinical interview; behavioral observation; and personality assessment through the use of projective and objective psychological tests. Later in this chapter we will examine the process of arriving at a clinical diagnosis using *DSM-5*.

Let us look first at what, exactly, a clinician is trying to learn during the psychological assessment of a client.

## The Basic Elements in Assessment

What does a clinician need to know? First, of course, the **presenting problem**, or major symptoms and behavior the client is experiencing, must be identified. Is it a situational problem precipitated by some environmental stressor such as divorce or unemployment, a manifestation of a more pervasive and long-term disorder, or some combination of the two? Is there any evidence of recent deterioration in cognitive functioning? What is the duration of the current complaint, and how is the person dealing with the problem? What, if any, prior help has been sought? Are there indications of self-defeating behavior and personality deterioration, or is the individual using available personal and environmental resources in a good effort to cope? How pervasively has the problem affected the person's performance of

important social roles? Does the individual's symptomatic behavior fit any of the diagnostic patterns in the *DSM-5*?

## The Relationship Between Assessment and Diagnosis

It is important to have an adequate classification of the presenting problem for a number of reasons. Clinically, knowledge of a person's type of disorder can help in planning and managing the appropriate treatment. Administratively, it is essential to know the range of diagnostic problems that are represented in the client population and for which treatment facilities need to be available. If most clients at a facility have been diagnosed as having personality disorders, for example, then the staffing, physical environment, and treatment facilities should be arranged accordingly, for example, with appropriate security and clearly established rules. In many cases, a formal diagnosis is necessary before insurance claims can be filed to cover the client's treatment costs. Thus the nature of the difficulty needs to be understood as clearly as possible, including a diagnostic categorization if appropriate (see the section "Classifying Abnormal Behavior" at the end of this chapter).

## Taking a Social or Behavioral History

For most clinical purposes, assigning a formal diagnostic classification per se is much less important than having a clear understanding of the individual's behavioral history, intellectual functioning, personality characteristics, and environmental pressures and resources. That is, an adequate assessment includes much more than the diagnostic label. For example, it should include an objective description of the person's behavior. How does the person characteristically respond to other people? Are there excesses in behavior present, such as eating or drinking too much? Are there notable deficits, for example, in social skills? How appropriate is the person's behavior? Is the person manifesting behavior that is plainly unresponsive or uncooperative? Excesses, deficits, and appropriateness are key dimensions to be

noted if the clinician is to understand the particular disorder that has brought the individual to the clinic or hospital.

**PERSONALITY FACTORS** Assessment should include a description of any relevant long-term personality characteristics. Has the person typically responded in deviant ways to particular kinds of situations—for example, those requiring submission to legitimate authority? Are there personality traits or behavior patterns that predispose the individual to behave in maladaptive ways? Does the person tend to become enmeshed with others to the point of losing his or her identity, or is he or she so self-absorbed that intimate relationships are not possible? Is the person able to accept help from others? Is the person capable of genuine affection and of accepting appropriate responsibility for the welfare of others? Such questions are at the heart of many assessment efforts.

**THE SOCIAL CONTEXT** It is also important to assess the social context in which the individual functions. What kinds of environmental demands are typically placed on the person, and what supports or special stressors exist in her or his life situation? For example, being the primary caretaker for a spouse suffering from Alzheimer's disease is so challenging that relatively few people can manage the task without significant psychological impairment, especially where outside supports are lacking.

The diverse and often conflicting bits of information about the individual's personality traits, behavior patterns, environmental demands, and so on must then be integrated into a consistent and meaningful picture. Some clinicians refer to this picture as a "dynamic formulation" because it not only describes the current situation but also includes hypotheses about what is driving the person to behave in maladaptive ways. At this point in the assessment, the clinician should have a plausible explanation for why a normally passive and mild-mannered man suddenly flew into a rage and started breaking up furniture, for example. The formulation should allow the clinician to develop hypotheses about the client's future behavior as well. What is the likelihood of improvement or deterioration if the person's problems are left untreated? Which behaviors should be the initial focus of change, and what treatment methods are likely to be most efficient in producing this change? How much change might be expected from a particular type of treatment?

Where feasible, decisions about treatment are made collaboratively with the consent and approval of the individual. In cases of severe disorder, however, they may have to be made without the client's participation or, in rare instances, even without consulting responsible family members. As has already been indicated, knowledge of the person's strengths and resources is important; in short, what qualities does the client bring to treatment that can enhance the chances of improvement? Because a wide range of factors can play important roles in causing and maintaining maladaptive behavior, assessment may involve the coordinated use of physical, psychological, and environmental assessment procedures. As we have indicated, however, the nature and comprehensiveness

Some patients with cognitive deterioration are difficult to evaluate and to provide health care for, often requiring special facilities.

of clinical assessments vary with the problem and the treatment agency's facilities. Assessment by phone in a suicide prevention center (Stolberg & Bongar, 2009), for example, is quite different from assessment aimed at developing a treatment plan for a person who has come to a clinic for help (Perry, 2009).

## Ensuring Culturally Sensitive Assessment Procedures

Increasingly, practitioners are being asked to conduct psychological evaluations with clients from diverse ethnic and language backgrounds. In both clinical and court settings, for example, a psychologist might be referred a client who has limited English language skills and low exposure to American mores, values, and laws. It is critical for the psychologist to be informed of the issues involved in multicultural assessment (often referred to as **cultural competence**) and to use testing procedures that have been adapted and validated for culturally diverse clients (Hays, 2008; Hunter et al., 2009).

Psychological assessment of clients from diverse ethnic backgrounds has increased greatly in recent years. The growing number of minorities requiring a clinical or forensic evaluation comes about, in part, from the influx of immigrants or refugees, many of whom encounter adjustment difficulties. The U.S. Census Bureau (2011) reports that the Hispanic population now makes up 16 percent of the U.S. population. People of Hispanic origin are now the largest ethnic minority group in the United States. African Americans now represent 12.9 percent of the population, Asians 4.5 percent, Native Americans 1.0 percent, and Native Hawaiians/Pacific Islanders less than 0.1 percent. Many immigrants, especially those of color, become members of ethnic minorities when they relocate to North America. They may thus experience racial discrimination or may be further viewed as inferior by the nonminority community due to their lack of political power or lack of adaptive skills arising from their difficulties in acculturation (Green, 2009; Hays, 2008).

In order to fairly and successfully treat such individuals, the ethics code of the American Psychological Association (APA, 2002) recommends that psychologists consider various test factors, test-taking abilities, and other characteristics of the person being assessed, such as situational, linguistic, and cultural differences, that might affect his or her judgments or reduce the accuracy of his or her interpretations. Thus, psychologists who use tests in a culturally competent manner must bear in mind a range of issues and factors involved with culturally and linguistically diverse clients. These issues involve the importance of ensuring that the characteristics of the test being employed are appropriate across cultures and that potential biasing factors do not interfere with critical thinking in the overall assessment process.

The challenges of understanding clients in multicultural assessment have been described (Butcher, Tsai, et al., 2006; Hays, 2008) and involve both test instrument characteristics and socio-cultural factors such as the relationships among culture, behavior, and psychopathology. Psychologists need to ensure that the test

procedures they employ are appropriate for the particular client. For example, the psychological equivalence of the test for use with the particular population should be determined. The meaning or cultural significance of test items should be similar across cultural groups (Butcher & Han, 1996), and the norms used to compare the client should be appropriate. In using Western-developed tests, users need to take into account the dominant language, socioeconomic status, ethnicity, and gender of their clients. For example, clients from non-English-speaking countries might have insufficient English language skills, which will influence their test performance. When using a translated version of a test, interpreters need to be aware of the possible differences that can be obtained using an adapted version. Thus, it is important for psychologists to be aware of the available research on the instrument's use with the target population in order to assess whether the adapted version measures the same variables in the new cultures. Finally, test users need to be concerned with the impact and fairness of the instruments they employ with clients from diverse groups—for example, whether there are any possible performance differences on the scales between groups.

The most widely used personality measure, the Minnesota Multiphasic Personality Inventory (MMPI-2) (to be discussed later in this chapter), has been widely evaluated both in international applications with translated versions (Butcher & Williams, 2009) and in diverse subcultural groups in the United States (Butcher et al., 2007). There are Spanish-language versions of the test. Recent research has provided support for the use of the MMPI-2 with minorities (Robin et al., 2003), and the analyses provided by Hall and colleagues (1999) support the use of the MMPI-2 with Hispanic clients.

## The Influence of Professional Orientation

How clinicians go about the assessment process often depends on their basic treatment orientations. For example, a biologically oriented clinician—typically a psychiatrist or other medical practitioner—is likely to focus on biological assessment methods aimed at determining any underlying organic malfunctioning that may be causing the maladaptive behavior. A psychodynamic or psychoanalytically oriented clinician may choose unstructured personality assessment techniques, such as the Rorschach inkblots or the Thematic Apperception Test (TAT), to be described later in the chapter, to identify intrapsychic conflicts or may simply proceed with therapy, expecting these conflicts to emerge naturally as part of the treatment process. A behaviorally oriented clinician, in an effort to determine the functional relationships between environmental events or reinforcements and the abnormal behavior, will rely on such techniques as behavioral observation and self-monitoring to identify learned maladaptive patterns; for a cognitively oriented behaviorist, the focus would shift to the dysfunctional thoughts supposedly mediating those patterns.

The preceding examples represent general trends and are in no way meant to imply that clinicians of a particular orientation

limit themselves to a particular assessment method or that each assessment technique is limited to a particular theoretical orientation. Such trends are instead a matter of emphasis and point to the fact that certain types of assessments are more conducive than others to uncovering particular causal factors or for eliciting information about symptomatic behavior central to understanding and treating a disorder within a given conceptual framework.

As you will see in what follows, both physical and psychosocial data can be extremely important to understanding the patient. In the sections that follow we will discuss several assessment instruments and examine in some detail an actual psychological study of a woman who experienced a traumatic situation in the workplace that resulted in severe emotional adjustment problems.

### Reliability, Validity, and Standardization

Three measurement concepts that are important in understanding clinical assessment and the utility of psychological tests are reliability, validity, and standardization. These concepts, illustrated throughout this chapter, will be briefly described. A psychological test or measurement construct needs to show reliability in order to be effective. **Reliability** is a term describing the degree to which an assessment measure produces the same result each time it is used to evaluate the same thing. If, for example, your scale showed a significantly different weight each time you stepped on it over a brief period of time, you would consider it a fairly unreliable measure of your body mass. In the context of assessment or classification, reliability is an index of the extent to which a measurement instrument can agree that a person's behavior fits a given diagnostic class. If the observations are different, it may mean that the classification criteria are not precise enough to determine whether the suspected disorder is present.

The psychological test or classification system must also be valid. **Validity** is the extent to which a measuring instrument actually measures what it is supposed to measure. In the context of testing or classification, validity is the degree to which a measure accurately conveys to us something clinically important about the person whose behavior fits the category, such as helping to predict the future course of the disorder. If, for example, a person is predicted to have or is diagnosed as having schizophrenia, we should be able to infer the presence of some fairly precise characteristics that differentiate the person from individuals who are considered normal or from those with other types of mental disorder. The classification or diagnosis of schizophrenia, for example, implies a disorder of unusually stubborn persistence, with recurrent episodes being common.

Normally, the validity of a mental health measure or classification presupposes reliability. If clinicians can't agree on the class to which a person with a disorder's behavior belongs, then the question of the validity of the diagnostic classifications under consideration becomes irrelevant. To put it another way, if we can't confidently pin down what the diagnosis is, then whatever useful information a given diagnosis might convey about the person being evaluated is lost. On the other hand, good reliability

does not in itself guarantee validity. For example, handedness (left, right, ambidextrous) can be assessed with a high degree of reliability, but handedness accurately predicts neither mental health status nor countless other behavioral qualities on which people vary; that is, it is not a valid index of these qualities (although it may be a valid index for success in certain situations involving the game of baseball, for example). In like manner, reliable assignment of a person's behavior to a given class of mental disorder will prove useful only to the extent that the validity of that class has been established through research.

**Standardization** is a process by which a psychological test is administered, scored, and interpreted in a consistent or "standard" manner. Standardized tests are considered to be more fair in that they are applied consistently and in the same manner to all persons taking them. Many psychological tests are standardized to allow the test user to compare a particular individual's score on the test with a reference population, often referred to as a normative sample. For example, comparing a particular individual's test score on a distribution of test scores from a large normative population can enable the user to evaluate whether the individual's score is low, average, or high along the distribution of scores (referred to as a **T score distribution**).

### Trust and Rapport Between the Clinician and the Client

In order for psychological assessment to proceed effectively and to provide a clear understanding of behavior and symptoms, the client being evaluated must feel comfortable with the clinician. In a clinical assessment situation, this means that a client must feel that the testing will help the practitioner gain a clear understanding of her or his problems and must understand how the tests will be used and how the psychologist will incorporate them into the clinical evaluation. The clinician should explain what will happen during assessment and how the information gathered will help provide a clearer picture of the problems the client is facing.

Clients need to be assured that the feelings, beliefs, attitudes, and personal history that they are disclosing will be used appropriately, will be kept in strict confidence, and will be made available only to therapists or others involved in the case. An important aspect of confidentiality is that the test results are released to a third party only if the client signs an appropriate release form. In cases in which the person is being tested for a third party such as the court system, the client in effect is the referring source—the judge ordering the evaluation—not the individual being tested. In these cases the testing relationship is likely to be strained and developing rapport is likely to be difficult. Of course, in a court-ordered evaluation, the person's test-taking behavior is likely to be very different from what it would be otherwise, and interpretation of the test needs to reflect this different motivational set created by the person's unwillingness to cooperate.

People being tested in a clinical situation are usually highly motivated to be evaluated and like to know the results of the

testing. They generally are eager for some definition of their discomfort. Moreover, providing test feedback in a clinical setting can be an important element in the treatment process (Harwood & Beutler, 2009). Interestingly, when patients are given appropriate feedback on test results, they tend to improve—just from gaining a perspective on their problems from the testing. The test feedback process itself can be a powerful clinical intervention (Finn & Kamphuis, 2006; Finn & Tonsager, 1997). When persons who were not provided psychological test feedback were compared with those who were provided with feedback, the latter group showed a significant decline in reported symptoms and an increase in measured self-esteem as a result of having a clearer understanding of their own resources.

### in review

- What is the difference between clinical diagnosis and psychological assessment? What components must be integrated into a dynamic formulation?
- Describe the important elements in a social or behavioral history.
- What does it mean to use culturally fair assessments?
- What is the impact of professional orientation on the structure and form of a psychological evaluation?
- Does providing test feedback to clients aid them in their adjustment?

## Assessment of the Physical Organism

In some situations and with certain psychological problems, a medical evaluation is necessary to rule out the possibility that physical abnormalities may be causing or contributing to the problem. The medical evaluation may include both a general physical examination and special examinations aimed at assessing the structural (anatomical) and functional (physiological) integrity of the brain as a behaviorally significant physical system (Fatemi & Clayton, 2008).

### The General Physical Examination

In cases in which physical symptoms are part of the presenting clinical picture, a referral for a medical evaluation is recommended. A physical examination consists of the kinds of procedures most of us have experienced when getting a “medical checkup.” Typically, a medical history is obtained, and the major systems of the body are checked (Fatemi & Clayton, 2008; LeBlond et al., 2004). This part of the assessment procedure is of obvious importance for disorders that entail physical problems, such as a psychologically based physical condition, addictive, and organic brain syndromes. In addition, a variety of organic conditions, including various hormonal irregularities, can produce behavioral symptoms that closely mimic those of mental disorders usually considered to have predominantly psychosocial origins. Although some long-lasting pain can be related to actual organic conditions, other such pain can result from strictly

emotional factors. A case in point is chronic back pain, in which psychological factors may sometimes play an important part. A diagnostic error in this type of situation could result in costly and ineffective surgery; hence, in equivocal cases, most clinicians insist on a medical clearance before initiating psychosocially based interventions.

### The Neurological Examination

Because brain pathology is sometimes involved in some mental disorders (e.g., unusual memory deficits or motor impairments), a specialized neurological examination can be administered in addition to the general medical examination. This may involve the client's getting an **electroencephalogram (EEG)** to assess brain wave patterns in awake and sleeping states. An EEG is a graphical record of the brain's electrical activity (O'Sullivan et al., 2006). It is obtained by placing electrodes on the scalp and amplifying the minute brain wave impulses from various brain areas; these amplified impulses drive oscillating pens whose deviations are traced on a strip of paper moving at a constant speed. Much is known about the normal pattern of brain impulses in waking and sleeping states and under various conditions of sensory stimulation. Significant divergences from the normal pattern can thus reflect abnormalities of brain function such as might be caused by a brain tumor or other lesion. When an EEG reveals a **dysrhythmia**, or irregular pattern, in the brain's electrical activity (for example, recent research has supported a link between resting frontal EEG asymmetry and depression, see Stewart et al., 2010; and anxiety, see Thibodeau et al., 2006), other specialized techniques may be used in an attempt to arrive at a more precise diagnosis of the problem.

**ANATOMICAL BRAIN SCANS** Radiological technology, such as a **computerized axial tomography (CAT) scan**, is one of these specialized techniques (Mishra & Singh, 2010). Through the use of X rays, a CAT scan reveals images of parts of the brain

An EEG is a graphical record of the brain's electrical activity. Electrodes are placed on the scalp, and brain wave impulses are amplified. The amplified impulses drive oscillating pens whose deviations are traced on a strip of paper moving at a constant speed. Significant differences from the normal pattern can reflect abnormalities of brain function.

that might be diseased. This procedure has aided neurological study in recent years by providing rapid access, without surgery, to accurate information about the localization and extent of anomalies in the brain's structural characteristics. The procedure involves the use of computer analysis applied to X-ray beams across sections of a patient's brain to produce images that a neurologist can then interpret.

CAT scans have been increasingly replaced by **magnetic resonance imaging (MRI)**. The images of the interior of the brain are frequently sharper with MRI because of its superior ability to differentiate subtle variations in soft tissue. In addition, the MRI procedure is normally far less complicated to administer, and it does not subject the patient to ionizing radiation.

Essentially, MRI involves the precise measurement of variations in magnetic fields that are caused by the varying amounts of water content of various organs and parts of organs. In this manner the anatomical structure of a cross section at any given plane through an organ such as the brain can be computed and graphically depicted with astonishing structural differentiation and clarity. MRI thus makes possible, by noninvasive means, visualization of all but the most minute abnormalities of brain structure. It has been particularly useful in confirming degenerative brain processes as shown, for example, in enlarged areas of the brain. Therefore, MRI studies have considerable potential to illuminate the contribution of brain anomalies to nonorganic psychoses such as schizophrenia, and some progress in this area has already been made (Mathalondolf et al., 2001).

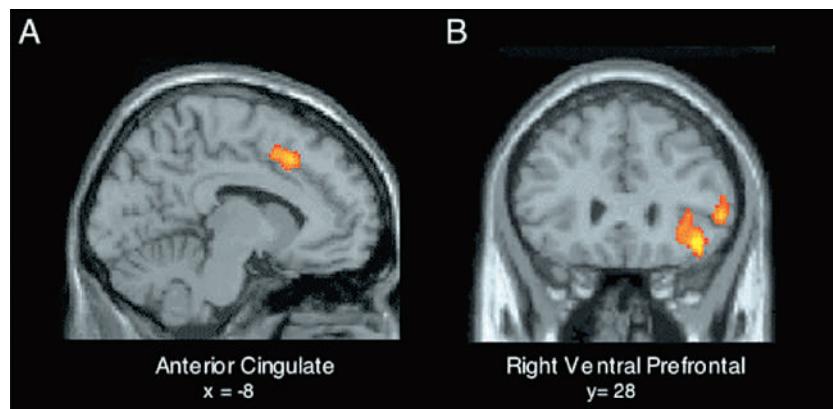

Still, the MRI can be problematic. For example, some patients have a claustrophobic reaction to being placed into the narrow cylinder of the MRI machine that is necessary to contain the magnetic field and block out external radio signals. In addition, a recent evaluation and critique of the MRI approach in medicine was published by Joyce (2008), who interviewed physicians and MRI technologists and also conducted ethnographic research at imaging sites and attended radiology conferences. In her critique, she demonstrated that current beliefs about MRI draw on cultural ideas about technology and are reinforced by health care policies and insurance reimbursement practices. However, her review raises questions about the work practices of many physicians and technologists and suggests that MRI scans do not reveal the truth about the body that many medical practices often hold. For example, she concludes that MRI studies do not always lead to better outcomes for patients.

**PET SCANS: A METABOLIC PORTRAIT** Another scanning technique is the **positron emission tomography (PET) scan**. Whereas a CAT scan is limited to distinguishing anatomical features such as the shape of a particular internal structure, a PET scan allows for an appraisal of how an organ is functioning (Kumano et al., 2007). The PET scan provides metabolic portraits by tracking natural compounds, such as glucose, as they are metabolized by the brain or other organs. By

revealing areas of differential metabolic activity, the PET scan enables a medical specialist to obtain more clear-cut diagnoses of brain pathology by, for example, pinpointing sites responsible for epileptic seizures, trauma from head injury or stroke, and brain tumors. Thus the PET scan may be able to reveal problems that are not immediately apparent anatomically. Moreover, the use of PET scans in research on brain pathology that occurs in abnormal conditions such as Alzheimer's disease may lead to important discoveries about the organic processes underlying these disorders and aid in the treatment of dementia (Saykin et al., 2006). PET scans have, however, been of somewhat limited value thus far because of the low-fidelity pictures obtained (Fletcher, 2004; Videbech et al., 2003) and their cost, since they require a very expensive instrument nearby to produce the short-lived radioactive atoms required for the procedure.

**THE FUNCTIONAL MRI** The technique known as **functional MRI (fMRI)** has been used in the study of psychopathology for a number of years. As originally developed and employed, the MRI could reveal brain structure but not brain activity. For the latter, clinicians and investigators remained dependent upon PET scans. Improving on these techniques, fMRI most often measures changes in local oxygenation (i.e., blood flow) of specific areas of brain tissue that in turn depend on neuronal activity in those specific regions (Bandettini, 2007). Ongoing psychological activity, such as sensations, images, and thoughts, can thus be "mapped," at least in principle, revealing the specific areas of the brain that appear to be involved in their neurophysiological processes. For example, one study (Wright & Jackson, 2007) examined the task of judgment of serve direction among tennis players and found that different patterns produce different responses in the brain.

Because the measurement of change in this context is critically time dependent, the emergence of fMRI required the development of high-speed devices for enhancing the recording process, as well as the computerized analysis of incoming data. (See photo below.) These improvements are now widely available and will likely lead to a marked increase in studying people

A pattern of increased activity in the anterior cingulate cortex (ACC) and the right ventral prefrontal cortex (RVPPC), shown here in persons who were excluded from participating in a game, are similar to cortical activity of persons experiencing physical pain.

with disorders using functional imaging. Optimism about the ultimate value of fMRI in mapping cognitive processes in mental disorders is still strong. The fMRI is thought by some to hold more promise for depicting brain abnormalities than currently used procedures such as the neuropsychological examination (see next section).

A number of published studies have provided support for this optimism (MacDonald & Jones, 2009). Research using fMRI has explored the cortical functioning that underlies various psychological processes; for example, one recent study showed that psychological factors or environmental events can affect brain processes as measured by fMRI. Eisenberger, Lieberman, and Williams (2003) found that participants who were excluded from social participation showed a similar pattern of brain activation (in the right ventral prefrontal cortex) as participants experiencing physical pain. (See photo on p. 106.) Longe and colleagues (2010) found that fMRI was effective at detecting neural correlates for self-critical thinking. Some researchers have pointed out that fMRI has a high potential for contributing to a treatment approach in mental health care (Schneider et al., 2009). Although some research has suggested that fMRI can be an effective procedure at detecting malingering or lying (Langleben et al., 2005), one court has recently ruled against the use of fMRI as a lie detector (Couzin-Frankel, 2010).

Other studies have addressed problems in abnormal behavior. One study showed that the impaired time estimation found in schizophrenics might result from dysfunction in specific areas of the brain, thalamus, and prefrontal cortex (Suzuki et al., 2004), while others addressed cortical functioning in auditory hallucinations in schizophrenia (Shergill et al., 2000); effects of neuroleptic medication with schizophrenics (Braus et al., 1999); and the neuroanatomy of anxiety (Paulesu et al. 2010) and depression (Brody et al., 2001). Finally, Whalley and colleagues (2004) found that fMRI technique has the potential of adding to our understanding of the early development of psychological disorder. One study of

treatment for **aphasia**, a disorder in which there is a loss of ability to communicate verbally (Meinzer et al., 2007), showed that changes in behavioral performance and the brain activation pattern were disclosed as affecting the brain's reorganization.

There are some clear methodological limitations that can influence fMRI results. For example, both MRI and fMRI are quite sensitive to instrument errors or inaccurate observations as a result of slight movements of the person being evaluated (Davidson et al., 2003). Additionally, the results of fMRI studies are often difficult to interpret. Even though group differences emerge between a cognitively impaired group and a control sample, the results usually do not provide much specific information about the processes studied. Fletcher (2004) provides a somewhat sobering analysis of the current status of fMRI in contemporary psychiatry, noting that many professionals who had hoped for intricate and unambiguous results might be disappointed with the overall lack of effective, pragmatic methodology in fMRI assessment of cognitive processes. At this point the fMRI is not considered to be a valid or useful diagnostic tool for mental disorders; however, investigators are optimistic that this procedure shows great promise for understanding brain functioning (MacDonald & Jones, 2009). The primary value of this procedure continues to be research into cortical activity and cognitive processes.

## The Neuropsychological Examination

The techniques described so far have shown success in identifying brain abnormalities that are very often accompanied by gross impairments in behavior and varied psychological deficits. However, behavioral and psychological impairments due to organic brain abnormalities may manifest before any organic brain lesion is detectable by scanning or other means. In these instances, reliable techniques are needed to measure any alteration in behavioral or psychological functioning that has occurred because of the organic brain pathology. This need is met by a growing cadre of psychologists specializing in **neuropsychological assessment**, which involves the use of various testing devices to measure a person's cognitive, perceptual, and motor performance as clues to the extent and location of brain damage (Snyder, Nussbaum, & Robins, 2006).

In many instances of known or suspected organic brain involvement, a clinical neuropsychologist administers a test battery to a patient. The person's performance on standardized tasks, particularly perceptual-motor tasks, can give valuable clues about any cognitive and intellectual impairment following brain damage (Cullum & Lacritz, 2009; Lezak, 1995; Horton, 2008; Reitan & Wolfson, 1985). Such testing can even provide clues to the probable location of the brain damage, although PET scans, MRIs, and other physical tests may be more effective in determining the exact location of the injury.

Many neuropsychologists prefer to administer a highly individualized array of tests, depending on a patient's case history and other available information. Others administer a standard

The functional MRI (fMRI), like the MRI, allows clinicians to "map" brain structure. The exciting breakthrough in fMRI technology gives clinicians the ability to measure brain activities underlying such things as sensations, images, and thoughts, revealing the specific areas of the brain involved.

set of tests that have been preselected to sample, in a systematic and comprehensive manner, a broad range of psychological competencies known to be adversely affected by various types of brain injury (Gass, 2009). The use of a constant set of tests has many research and clinical advantages, although it may compromise flexibility. Consider the components of one such standard procedure, the Halstead-Reitan neuropsychological test battery. The Halstead-Reitan battery is composed of several tests and variables from which an “index of impairment” can be computed (Horton, 2008; Reitan & Wolfson, 1985). In addition, it provides specific information about a subject’s functioning in several skill areas. The Halstead-Reitan battery for adults is made up of a group of tests such as the following:

1. **Halstead Category Test:** Measures a subject’s ability to learn and remember material and can provide clues as to his or her judgment and impulsivity. The subject is presented with a stimulus (on a screen) that suggests a number between 1 and 4. The subject presses a button indicating the number she or he believes was suggested. A correct choice is followed by the sound of a pleasant doorbell, an incorrect choice by a loud buzzer. The person is required to determine from the pattern of buzzers and bells what the underlying principle of the correct choice is.
2. **Tactual Performance Test:** Measures a subject’s motor speed, response to the unfamiliar, and ability to learn and use tactile and kinesthetic cues. The test surface is a board that has spaces for 10 blocks of varied shapes. The subject is blindfolded (never actually seeing the board) and asked to place the blocks into the correct grooves in the board. Later, the subject is asked to draw the blocks and the board from tactile memory.
3. **Rhythm Test:** Measures attention and sustained concentration through an auditory perception task. It includes 30 pairs of rhythmic beats that are presented on a tape recorder. The subject is asked whether the pairs are the same or different.
4. **Speech Sounds Perception Test:** Determines whether an individual can identify spoken words. Nonsense words are presented on a tape recorder, and the subject is asked to identify the presented word in a list of four printed words. This task measures the subject’s concentration, attention, and comprehension.
5. **Finger Oscillation Task:** Measures the speed at which an individual can depress a lever with the index finger. Several trials are given for each hand.

In summary, the medical and neuropsychological sciences are developing many new procedures to assess brain functioning and behavioral manifestations of organic disorder. Medical procedures to assess organic brain damage include EEGs and CAT, PET, and MRI scans. The new technology holds great promise for detecting and evaluating organic brain dysfunction and increasing our understanding of brain function. Neuropsychological testing provides a clinician with important behavioral information on how organic brain damage is affecting a person’s

present functioning. However, in cases where the psychological difficulty is thought to result from nonorganic causes, psychosocial assessment is used.

### in review

- Compare and contrast five important neurological procedures. What makes each one particularly valuable?
- What is the difference between a PET scan and an fMRI?
- Describe the use of neuropsychological tests in evaluating the behavioral effects of organic brain disorders.

## Psychosocial Assessment

Psychosocial assessment attempts to provide a realistic picture of an individual in interaction with his or her social environment. This picture includes relevant information about the individual’s personality makeup and present level of functioning, as well as information about the stressors and resources in her or his life situation. For example, early in the process, clinicians may act as puzzle solvers, absorbing as much information about the client as possible—present feelings, attitudes, memories, demographic facts—and trying to fit the pieces together into a meaningful pattern. Clinicians typically formulate hypotheses and discard or confirm them as they proceed. Starting with a global technique such as a clinical interview, clinicians may later select more specific assessment tasks or tests. The following are some of the psychosocial procedures that may be used.

### Assessment Interviews

An assessment interview, often considered the central element of the assessment process, usually involves a face-to-face interaction in which a clinician obtains information about various aspects of a client’s situation, behavior, and personality (Berthold & Ellinger, 2009; Craig, 2009; Meers, 2009). The interview may vary from a simple set of questions or prompts to a more extended and detailed format (Kici & Westhoff, 2004). It may be relatively open in character, with an interviewer making moment-to-moment decisions about his or her next question on the basis of responses to previous ones, or it may be more tightly controlled and structured so as to ensure that a particular set of questions is covered. In the latter case, the interviewer may choose from a number of highly structured, standardized interview formats whose reliability has been established in prior research.

**STRUCTURED AND UNSTRUCTURED INTERVIEWS** Although many clinicians prefer the freedom to explore as they feel responses merit, the research data show that the more controlled and **structured assessment interview** yields far more reliable results than the flexible format. There appears to be widespread overconfidence among clinicians in the accuracy of their own methods and judgments (Taylor & Meux, 1997). Every rule has exceptions, but in most instances, an assessor is wise to conduct an interview that

During an assessment interview, a clinician obtains information about various aspects of a patient's situation, behavior, and personality makeup. The interview is usually conducted face-to-face and may have a relatively open structure or be more tightly controlled, depending on the goals and style of the clinician.

is carefully structured in terms of goals, comprehensive symptom review, other content to be explored, and the type of relationship the interviewer attempts to establish with the person.

Structured interviews follow a predetermined set of questions throughout the interview. For example, "Have you ever had periods in which you could not sleep lately?" and "Have you experienced feeling very nervous about being in public?" The beginning statements or introduction to the interview follow set procedures. The themes and questions are predetermined to obtain particular responses for all items. The interviewer cannot deviate from the question lists and procedures. All questions are asked of each client in a preset way. Each question is structured in a manner so as to allow responses to be quantified or clearly determined. On the negative side, structured interviews typically take longer to administer than unstructured interviews and may include some seemingly tangential questions. Clients can sometimes be frustrated by the overly detailed questions in areas that are of no concern to them.

**Unstructured assessment interviews** are typically subjective and do not follow a predetermined set of questions. The beginning statements in the interview are usually general, and follow-up questions are tailored for each client. The content of the interview questions is influenced by the habits or theoretical views of the interviewer. The interviewer does not ask the same questions of all clients; rather, he or she subjectively decides what to ask based on the client's response to previous questions. Because the questions are asked in an unplanned way, important criteria needed for a *DSM-5* diagnosis might be skipped. Responses based on unstructured interviews are difficult to quantify or compare with responses of clients from other interviews. Thus, uses of unstructured interviews in mental health research are limited. On the positive side, unstructured interviews can be viewed by clients as being more sensitive to their needs or problems than more structured procedures. Moreover, the spontaneous follow-up questions that emerge in an unstructured interview can, at times, provide valuable information that would not emerge in a structured interview.

The reliability of the assessment interview may be enhanced by the use of **rating scales** that help focus inquiry and quantify the interview data. For example, the person may be rated on a 3-, 5-, or 7-point scale with respect to self-esteem, anxiety, and various other characteristics. Such a structured and preselected format is particularly effective in giving a comprehensive impression, or "profile," of the subject and her or his life situation and in revealing specific problems or crises—such as marital difficulties, drug dependence, or suicidal fantasies—that may require immediate therapeutic intervention.

Clinical interviews can be subject to error because they rely on human judgment to choose the questions and process the information. Evidence of this unreliability includes the fact that different clinicians have often arrived at different formal diagnoses on the basis of the interview data they elicited from a particular client. It is chiefly for this reason that recent versions of the *DSM* (that is, III, III-R, IV, and IV-TR) have emphasized an "operational" assessment approach, one that specifies observable criteria for diagnosis and provides specific guidelines for making diagnostic judgments. "Winging it" has limited use in this type of assessment process. The operational approach leads to more reliable psychiatric diagnoses, perhaps at some cost in reduced interviewer flexibility.

### The Clinical Observation of Behavior

One of the traditional and most useful assessment tools that a clinician has available is direct observation of a client's characteristic behavior (Hartmann et al., 2004). The main purpose of direct observation is to learn more about the person's psychological functioning by attending to his or her appearance and behavior in various contexts. Clinical observation is the clinician's objective description of the person's appearance and behavior—her or his personal hygiene and emotional responses and any depression, anxiety, aggression, hallucinations, or delusions she or he may manifest. Ideally, clinical observation takes place in a natural environment (such as observing a child's behavior in a classroom or at home), but it is more likely to take place upon admission to a clinic or hospital (Leichtman, 2009). For example, a brief description is usually made of a subject's behavior upon hospital admission, and more detailed observations are made periodically on the ward.

Some practitioners and researchers use a more controlled, rather than a naturalistic, behavioral setting for conducting observations in contrived situations. These *analogue situations*, which are designed to yield information about the person's adaptive strategies, might involve such tasks as staged **role-playing**, event reenactment, family interaction assignments, or think-aloud procedures (Haynes et al., 2009).

In addition to making their own observations, many clinicians enlist their clients' help by providing them instruction in **self-monitoring**: self-observation and objective reporting of behavior, thoughts, and feelings as they occur in various natural settings. This method can be a valuable aid in determining the kinds of situations in which maladaptive behavior is likely to be evoked, and numerous studies also show it to have therapeutic

benefits in its own right. Alternatively, a client may be asked to fill out a more or less formal self-report or a checklist concerning problematic reactions experienced in various situations. Many instruments have been published in the professional literature and are commercially available to clinicians. These approaches recognize that people are excellent sources of information about themselves. Assuming that the right questions are asked and that people are willing to disclose information about themselves, the results can have a crucial bearing on treatment planning.

**RATING SCALES** As in the case of interviews, the use of rating scales in clinical observation and in self-reports helps both to organize information and to encourage reliability and objectivity (Aiken, 1996; Garb, 2007). That is, the formal structure of a scale is likely to keep observer inferences to a minimum. The most useful rating scales are those that enable a rater to indicate not only the presence or absence of a trait or behavior but also its prominence or degree. The following item is an example from such a rating scale; the observer would check the most appropriate description.

#### Sexual Behavior

- \_\_\_ 1. Sexually assaultive: aggressively approaches males or females with sexual intent.
- \_\_\_ 2. Sexually soliciting: exposes genitals with sexual intent, makes overt sexual advances to other patients or staff, and masturbates openly.
- \_\_\_ 3. No overt sexual behavior: not preoccupied with discussion of sexual matters.
- \_\_\_ 4. Avoids sex topics: made uneasy by discussion of sex, becomes disturbed if approached sexually by others.
- \_\_\_ 5. Excessive prudishness about sex: considers sex filthy, condemns sexual behavior in others, becomes panic-stricken if approached sexually.

Ratings like these may be made not only as part of an initial evaluation but also to check on the course or outcome of treatment. One of the rating scales most widely used for recording observations in clinical practice and in psychiatric research is the **Brief Psychiatric Rating Scale (BPRS)** (Overall & Hollister, 1982; Serper et al., 2004). The BPRS provides a structured and quantifiable format for rating clinical symptoms such as over-concern with physical symptoms, anxiety, emotional withdrawal, guilt feelings, hostility, suspiciousness, and unusual thought patterns. It contains 24 scales that are scored from ratings made by a clinician following an interview with a patient. The distinct patterns of behavior reflected in the BPRS ratings enable clinicians to make a standardized comparison of their patients' symptoms with the behavior of other psychiatric patients. The BPRS has been found to be an extremely useful instrument in clinical research (e.g., see Davidson et al., 2004), especially for the purpose of assigning patients to treatment groups on the basis of similarity in symptoms. However, it is not widely used for making treatment

or diagnostic decisions in clinical practice. The Hamilton Rating Scale for Depression (HRSD), a similar but more specifically targeted instrument, is one of the most widely used procedures for selecting clinically depressed research subjects and also for assessing the response of such subjects to various treatments (see Beevers & Miller, 2004; Brown et al., 2007).

#### Psychological Tests

Interviews and behavioral observation are relatively direct attempts to determine a person's beliefs, attitudes, and problems. Psychological tests are a more indirect means of assessing psychological characteristics. Scientifically developed psychological tests (as opposed to the recreational ones sometimes appearing in magazines or on the Internet) are standardized sets of procedures or tasks for obtaining samples of behavior. A subject's responses to the standardized stimuli are compared with those of other people who have comparable demographic characteristics, usually through established test norms or test score distributions. From these comparisons, a clinician can then draw inferences about how much the person's psychological qualities differ from those of a reference group, typically a psychologically normal one. Among the characteristics that these tests can measure are coping patterns, motive patterns, personality characteristics, role behaviors, values, levels of depression or anxiety, and intellectual functioning. Impressive advances in the technology of test development

There are a wide variety of psychological tests that measure the intellectual abilities of children. The researcher in this photo is measuring this child's cognitive development by evaluating how she classifies and sorts the candy.

## The Automated Practice: Use of the Computer in Psychological Testing

Perhaps the most dramatic innovation in clinical assessment during the last 40 years has been the increasing use of computers in individual assessment. Computers are effectively used in assessment both to gather information directly from an individual and to assemble and evaluate all the information that has been gathered previously through interviews, tests, and other assessment procedures. By comparing the incoming information with data previously stored in its memory banks, a computer can perform a wide range of assessment tasks (Butcher et al., 2009; Butcher, 2009). It can supply a probable diagnosis, indicate the likelihood of certain kinds of behavior, suggest the most appropriate form of treatment, predict the outcome, and print out a summary report concerning the subject. In many of these functions, a computer is actually superior to a clinician because it is more efficient and accurate in recalling stored material (Epstein & Klinkenberg, 2001; Olson, 2001).

With the increased efficiency and reliability of the use of computers in clinical practice, one might expect a nearly unanimous welcoming of computers into the clinic. This is not always the case, however, and some practitioners we know even resist

using such "modern" techniques as e-mail, fax machines, and computerized billing in their practices (McMinn et al., 1999). Some clinicians are reluctant to use computer-based test interpretations in spite of their demonstrated utility and low cost. Even though many clinics and independent practitioners use microcomputers for record keeping and billing purposes, a smaller number incorporate computer-based clinical assessment procedures into their practice. Possible reasons for the underutilization of computer-based assessment procedures include the following: (1) Practitioners who were trained before the widespread use of computers may feel uncomfortable with them or may not have time to get acquainted with their use; (2) they may limit their practice to psychological treatment and do not use extensive pretreatment assessments in their practice; (3) they may have little interest in, or time for, the systematic evaluation of treatment efficacy that periodic formal assessments facilitate; or (4) they may feel that the impersonal and mechanized look of the booklets and answer sheets common to much computerized assessment is inconsistent with the image and style of warm and personal engagement they hope to convey to clients.

have made it possible to create instruments of acceptable reliability and validity to measure almost any conceivable psychological characteristic on which people may vary. Moreover, many procedures are available in a computer-administered and computer-interpreted format (see the Developments in Practice box).

Although psychological tests are more precise and often more reliable than interviews or some observational techniques, they are far from perfect tools. Their value often depends on the competence of the clinician who interprets them. In general, they are useful diagnostic tools for psychologists in much the same way that blood tests, X-ray films, and MRI scans are useful to physicians. In all these cases, pathology may be revealed in people who appear to be normal, or a general impression of "something wrong" can be checked against more precise information. Two general categories of psychological tests for use in clinical practice are intelligence tests and personality tests (projective and objective).

**INTELLIGENCE TESTS** A clinician can choose from a wide range of **intelligence tests**. The Wechsler Intelligence Scale for Children-Revised (WISC-IV) (see Weiss et al., 2006) and the current edition of the Stanford-Binet Intelligence Scale (Kamphaus & Kroncke, 2004) are widely used in clinical settings for measuring the intellectual abilities of children (Wasserman, 2003). Probably the most commonly used test for measuring adult intelligence is the Wechsler Adult Intelligence Scale-Revised (WAIS-IV) (Benson et al., 2010; Lichtenberger & Kaufman, 2009). It

includes both verbal and performance material and consists of 15 subtests. A brief description of two of the subtests will serve to illustrate the types of functions the WAIS-IV measures.

- **Vocabulary (verbal):** This subtest consists of a list of words to define that are presented orally to the individual. This task is designed to evaluate knowledge of vocabulary, which has been shown to be highly related to general intelligence.
- **Digit Span (performance):** In this test of short-term memory, a sequence of numbers is administered orally. The individual is asked to repeat the digits in the order administered. Another task in this subtest involves the individual's remembering the numbers, holding them in memory, and reversing the order sequence—that is, the individual is instructed to say them backward (Lichtenberger & Kaufman, 2009).

Individually administered intelligence tests—such as the WISC-IV, the WAIS-IV, and the Stanford-Binet—typically require 2 to 3 hours to administer, score, and interpret. In many clinical situations, there is not enough time or funding to use these tests. In cases where intellectual impairment or organic brain damage is thought to be central to a patient's problem, intelligence testing may be the most crucial diagnostic procedure in the test battery. Moreover, information about cognitive functioning or deterioration can provide valuable clues to a person's intellectual resources in dealing with problems (Kihlstrom, 2002). Yet in many clinical settings and for many clinical cases, gaining a thorough understanding of a client's problems and initiating a

David Wechsler (1896–1981) served in the military, testing army recruits during World War I. He came to believe that the ways in which psychologists viewed and measured “intelligence” was inadequate. In 1934 he began construction of the most widely used adult intelligence test battery, the Wechsler Adult Intelligence Scale (WAIS), which set the standard for practical measurement of intelligence.

treatment program do not require knowing the kind of detailed information about intellectual functioning that these instruments provide. In these cases, intelligence testing is not recommended.

**PROJECTIVE PERSONALITY TESTS** There are a great many tests designed to measure personal characteristics other than intellectual ability. It is customary to group these **personality tests** into projective and objective measures. **Projective personality tests** are unstructured in that they rely on various ambiguous stimuli such as inkblots or vague pictures rather than on explicit verbal questions, and in that the person’s responses are not limited to the “true,” “false,” or “cannot say” variety. Through their interpretations of these ambiguous materials, people reveal a good deal about their personal preoccupations, conflicts, motives, coping techniques, and other personality characteristics. An assumption underlying the use of projective techniques is that in trying to make sense out of vague, unstructured stimuli, individuals “project” their own problems, motives, and wishes into the situation. Such responses are akin to the childhood pastime of seeing objects or scenes in cloud formations, with the important exception that the stimuli are in this case fixed and largely the same for all subjects. It is the latter circumstance that permits determination of the normative range of responses to the test materials, which in turn can be used to identify objectively deviant responding. Thus projective tests are aimed at discovering the ways in which an individual’s past learning and personality structure may lead him or her to organize and perceive ambiguous information from the environment. Prominent among the several projective tests in common use are the Rorschach Inkblot Test, the Thematic Apperception Test (TAT), and sentence completion tests.

**The Rorschach** The **Rorschach Inkblot Test** is named after the Swiss psychiatrist Hermann Rorschach (1884–1922), who initiated the experimental use of inkblots in personality assessment in 1911. The test uses 10 inkblot pictures, to which

a subject responds in succession after being instructed as follows (Exner, 1993):

*People may see many different things in these inkblot pictures; now tell me what you see, what it makes you think of, what it means to you.*

The following excerpts are taken from a subject’s responses to one of the actual blots:

*This looks like two men with genital organs exposed. They have had a terrible fight and blood has splashed up against the wall. They have knives or sharp instruments in their hands and have just cut up a body. They have already taken out the lungs and other organs. The body is dismembered . . . nothing remains but a shell . . . the pelvic region. They were fighting as to who will complete the final dismemberment . . . like two vultures swooping down . . .*

The extremely violent content of this response was not common for this particular blot or for any other blot in the series. Although no responsible examiner would base conclusions on a single instance, such content was consistent with other data from this subject, who was diagnosed as an antisocial personality with strong hostility.

Use of the Rorschach in clinical assessment is complicated and requires considerable training (Exner & Erdberg, 2002; Weiner & Meyer, 2009). Methods of administering the test vary; some approaches can take several hours and hence must compete for time with other essential clinical services. Furthermore, the results of the Rorschach can be unreliable because of the subjective nature of test interpretations. For example, interpreters might disagree on the symbolic significance of the response “a house in flames.” One person might interpret this particular response as suggesting great feelings of anxiety, whereas another interpreter might see it as suggesting a desire on the part of the patient to set fires. One reason for the diminished use of the Rorschach in projective testing today comes from the fact that many clinical treatments used in today’s mental health facilities generally require specific behavioral descriptions rather than descriptions of deep-seated personality dynamics, such as those that typically result from interpretation of the Rorschach Test.

In the hands of a skilled interpreter, however, the Rorschach can be useful in uncovering certain psychodynamic issues, such as the impact of unconscious motivations on current perceptions of others (Weiner, 2013). Furthermore, there have been attempts to objectify Rorschach interpretations by clearly specifying test variables and empirically exploring their relationship to external criteria such as clinical diagnoses (Exner, 1995). The Rorschach, although generally considered an open-ended, subjective instrument, has been adapted for computer interpretation (Exner, 1987). In a study of the reliability of conclusions drawn from the computer interpretation system, Meyer and colleagues (2005) found that clinicians tended to draw the same conclusions from Rorschach responses as the computer system did.

Some researchers, however, have raised questions about the norms on which the Exner Rorschach Comprehensive System, a scoring and interpretation system, is based (Shaffer et al., 1999; Wood et al., 2001). The Rorschach was shown to “overpathologize” persons taking the test—that is, the test appears to show psychopathology even when the person is a “normal” person randomly drawn from the community. The extent to which the Rorschach provides valid information beyond what is available from other, more economical instruments has not been demonstrated. Although some researchers have rallied support for the Comprehensive System (Hibbard, 2003; Weiner & Meyer, 2009), the Rorschach test has also been widely criticized as an instrument with low or negligible validity (Garb et al., 1998; Hunsley & Bailey, 1999). The use of the test in clinical assessment has diminished somewhat (Piotrowski et al., 1998), in part because insurance companies do not pay for the considerable amount of time needed to administer, score, and interpret the test. However, the Rorschach remains one of the most frequently used instruments in personality assessment—even in some personnel assessment settings, as described by Del Guidice (2010)—and research today.

**The Thematic Apperception Test** The **Thematic Apperception Test (TAT)** was introduced in 1935 by its authors, C. D. Morgan and Henry Murray of the Harvard Psychological Clinic. It still is widely used in clinical practice (Rossini & Moretti, 1997) and personality research (Teglas, 2010). The TAT uses a series of simple pictures, some highly representational and others quite abstract, about which a subject is instructed to make up stories. The content of the pictures, much of them depicting people in various contexts, is highly ambiguous as to actions and motives, so subjects tend to project their own conflicts and worries onto it (see Morgan, 2002, for a historical description of the test stimuli).

Several scoring and interpretation systems have been developed to focus on different aspects of a subject’s stories such as expressions of needs (Atkinson, 1992), the person’s perception of reality (Arnold, 1962), and the person’s fantasies (Klinger, 1979). It is time-consuming to apply these systems, and there is little evidence that they make a clinically significant contribution. Hence, most often a clinician simply makes a qualitative and subjective determination of how the story content reflects the person’s underlying traits, motives, and preoccupations. Such interpretations often depend as much on “art” as on “science,” and there is much room for error in such an informal procedure.

An example of the way a subject’s problems may be reflected in TAT stories is shown in the following case, which is based on Card 1 (a picture of a boy staring at a violin on a table in front of him). The client, David, was a 15-year-old boy who had been referred to the clinic by his parents because of their concern about his withdrawal and poor work at school.

→ **David’s TAT Response** David was generally cooperative during the testing, although he remained rather unemotional and unenthusiastic throughout. When he was given Card

1 of the TAT, he paused for over a minute, carefully scrutinizing the card.

“I think this is a ... uh ... machine gun ... yeah, it’s a machine gun. The guy is staring at it. Maybe he got it for his birthday or stole it or something.” [Pause. The examiner reminded him that he was to make up a story about the picture.]

“OK. This boy, I’ll call him Karl, found this machine gun ... a Browning automatic rifle ... in his garage. He kept it in his room for protection. One day he decided to take it to school to quiet down the jocks that lord it over everyone. When he walked into the locker hall, he cut loose on the top jock, Amos, and wasted him. Nobody bothered him after that because they knew he kept the BAR in his locker.”

It was inferred from this story that David was experiencing a high level of frustration and anger in his life. The extent of this anger was reflected in his perception of the violin in the picture as a machine gun—an instrument of violence. The clinician concluded that David was feeling threatened not only by people at school but even in his own home, where he needed “protection.”

This example shows how stories based on TAT cards may provide a clinician with information about a person’s conflicts and worries as well as clues as to how the person is handling these problems.

The TAT has been criticized on several grounds (Lilienfeld et al., 2001). There is a “dated” quality to the test stimuli: The pictures, developed in the 1930s, appear quaint to many contemporary subjects, who have difficulty identifying with the characters in the pictures. Subjects often preface their stories with, “This is something from a movie I saw on the late-night movies.” Additionally, the TAT can require a great deal of time to administer and interpret. As with the Rorschach, interpretation of responses to the TAT is generally subjective, which limits the reliability and validity of the test.

A review (Rossini & Moretti, 1997) pointed out an interesting paradox: Even though the TAT remains popular among practicing clinicians, clinical training programs have reduced the amount of time devoted to teaching graduate students about the TAT, and relatively few contemporary training resources (such as books and manuals) exist. Again, we must note that some examiners, notably those who have long experience in the instrument’s use, are capable of making astonishingly accurate interpretations with TAT stories. Typically, however, they have difficulty teaching these skills to others. On reflection, such an observation should not be unduly surprising, but it does point to the essentially “artistic” element involved at this skill level.

**Sentence Completion Test** Another projective procedure that has proved useful in personality assessment is the **sentence completion test** (Fernald & Fernald, 2010). A number of such tests have been designed for children, adolescents, and adults.

Such tests consist of the beginnings of sentences that a person is asked to complete, as in these examples:

1. I wish \_\_\_\_\_
2. My mother \_\_\_\_\_
3. Sex \_\_\_\_\_
4. I hate \_\_\_\_\_
5. People \_\_\_\_\_

Sentence completion tests, which are related to the free-association method, a procedure in which the client is asked to respond freely, are somewhat more structured than the Rorschach and most other projective tests. They help examiners pinpoint important clues to an individual's problems, attitudes, and symptoms through the content of her or his responses.

Interpretation of the item responses, however, is generally subjective and unreliable. Despite the fact that the test stimuli (the sentence stems) are standard, interpretation is usually done in an ad hoc manner and without benefit of normative comparisons.

In sum, projective tests have an important place in many clinical settings, particularly those that attempt to obtain a comprehensive picture of a person's psychodynamic functioning and those that have the necessary trained staff to conduct extensive individual psychological evaluations. The great strengths of projective techniques—their unstructured nature and their focus

on the unique aspects of personality—are at the same time their weaknesses because they make interpretation subjective, unreliable, and difficult to validate. Moreover, projective tests typically require a great deal of time to administer and advanced skill to interpret—both scarce quantities in many clinical settings.

### OBJECTIVE PERSONALITY TESTS

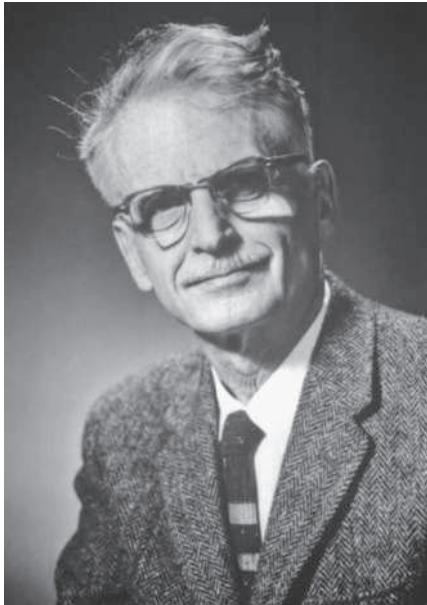

#### Objective personality tests

are structured—that is, they typically use questionnaires, self-report inventories, or rating scales in which questions or items are carefully phrased and alternative responses are specified as choices. They therefore involve a far more controlled format than projective devices and thus are more amenable to objectively based quantification. One virtue of such quantification is its precision, which in turn enhances the reliability of test outcomes.

There are a large number of available personality assessment measures for use in personality and clinical assessment. For example, the NEO-PI (Neuroticism-Extroversion-Openness Personality Inventory) provides information on the major dimensions in personality and is widely used in evaluating personality factors in normal-range populations (Costa & Widiger, 2002). There are also many objective assessment instruments developed to assess focused clinical problems. For example, the Millon Clinical Multiaxial Inventory (MCMI-III; see Choca, 2004) was developed to evaluate the underlying personality dimensions among clients in psychological treatment. In this chapter, we will focus primarily upon the most widely used personality assessment instrument, the MMPI-2.

**The MMPI** One of the major structured inventories for personality assessment is the **Minnesota Multiphasic Personality Inventory (MMPI)**, now called the MMPI-2 for adults after a revision in 1989 (Butcher, 2011; Greene, 2011). We focus on it here because in many ways it is the prototype and the standard of this class of instruments.

Several years in development, the MMPI was introduced for general use in 1943 by Starke Hathaway and J. C. McKinley; it is today the most widely used personality test for clinical and **forensic**—court related—assessment and in psychopathology research in the United States (Archer et al., 2006; Lally, 2003). It is also the assessment instrument most frequently taught in graduate clinical psychology programs (Piotrowski & Zalewski, 1993). Over 19,000 books and articles on the MMPI instruments have been published since the test was introduced. Moreover, translated versions of the inventory are widely used internationally (the original MMPI was translated over 150 times and used in over 46 countries; Butcher, 2010). International use of the revised inventory is increasing rapidly; over 32 translations have been made since it was published in 1989 (Butcher & Williams, 2009).

Starke R. Hathaway (1903–1984), clinical psychologist, was a pioneer in physiological psychology and personality assessment. In 1940, he and J. C. McKinley published the Minnesota Multiphasic Personality Inventory (MMPI) for evaluating symptoms and behavior of psychiatric and medical patients. The MMPI became the most widely used personality assessment instrument in use, and its revised version (MMPI-2) is the most frequently used personality measure today.

J. C. McKinley (1891–1950), a neuropsychiatrist at the University of Minnesota Hospital, coauthored the MMPI with Starke Hathaway and conducted research on the MMPI with both medical and psychiatric populations.

**The Validity and Clinical Scales of the MMPI** The original MMPI, a self-report questionnaire, consisted of 550 items covering topics ranging from physical condition and psychological states to moral and social attitudes. Typically, clients are encouraged to answer all of the items either “true” or “false.” The pool of items was originally administered to a large group of normal individuals (affectionately called the “Minnesota normals”) and several quite homogeneous groups of patients with particular psychiatric diagnoses. Answers to all the items were then item-analyzed to see which ones differentiated the various groups. On the basis of the findings, the 10 clinical scales were constructed, each consisting of the items that were answered by one of the patient groups in the direction opposite to the

predominant response of the normal group. This rather ingenious method of selecting scorable items, known as “empirical keying,” originated with the MMPI and doubtless accounts for much of the instrument’s power. Note that it involves no subjective pre-judgment about the “meaning” of a true or false answer to any item; that meaning resides entirely in whether the answer is the same as the answer deviantly given by patients of varying diagnoses. Should an examinee’s pattern of true and false responses closely approximate that of a particular pathological group, it is a reasonable inference that he or she shares other psychiatrically significant characteristics with that group—and may in fact “psychologically” be a member of that group. (See the MMPI-2 profile in Table 4.1.)

**TABLE 4.1**  
**The Scales of the MMPI-2**

<b>Validity Scales</b>	
Cannot say score (?)	Measures the total number of unanswered items
Infrequency scale (F)	Measures the tendency to falsely claim or exaggerate psychological problems in the first part of the booklet; alternatively, detects random responding
Infrequency scale (FB)	Measures the tendency to falsely claim or exaggerate psychological problems on items toward the end of the booklet
Infrequency scale (Fp)	Measures the tendency to exaggerate psychological problems among psychiatric inpatients
Lie scale (L)	Measures the tendency to claim excessive virtue or to try to present an overall favorable image
Defensiveness scale (K)	Measures the tendency to see oneself in an unrealistically positive way
Superlative Self-Presentation scale (S)	Measures the tendency for some people to present themselves in a highly positive manner or superlative manner. The S scale contains 5 subscales that address ways in which the person presents in an overpositive manner.
Response Inconsistency scale (VRIN)	Measures the tendency to endorse items in an inconsistent or random manner
Response Inconsistency scale (TRIN)	Measures the tendency to endorse items in an inconsistently true or false manner
<b>Clinical Scales</b>	
Scale 1 Hypochondriasis (Hs)	Measures excessive somatic concern and physical complaints
Scale 2 Depression (D)	Measures symptomatic depression
Scale 3 Hysteria (Hy)	Measures hysteroid personality features such as a “rose-colored glasses” view of the world and the tendency to develop physical problems under stress
Scale 4 Psychopathic deviate (Pd)	Measures antisocial tendencies
Scale 5 Masculinity-femininity (Mf)	Measures gender-role reversal
Scale 6 Paranoia (Pa)	Measures suspicious, paranoid ideation
Scale 7 Psychasthenia (Pt)	Measures anxiety and obsessive, worrying behavior
Scale 8 Schizophrenia (Sc)	Measures peculiarities in thinking, feeling, and social behavior
Scale 9 Hypomania (Ma)	Measures unrealistically elated mood state and tendencies to yield to impulses
Scale 0 Social introversion (Si)	Measures social anxiety, withdrawal, and overcontrol
<b>Special Scales</b>	
Scale APS Addiction Proneness scale	Assesses the extent to which the person matches personality features of people in substance-use treatment
Scale AAS Addiction Acknowledgment scale	Assesses the extent to which the person has acknowledged substance-abuse problems
Scale MAC-R MacAndrew Addiction scale	An empirical scale measuring proneness to become addicted to various substances
Scale MDS Marital Distress scale	Assesses perceived marital relationship problems
Hostility scale (Ho)	Addresses hostility or anger control problems
Posttraumatic Stress scale (Pk)	Assesses a number of symptoms and attitudes that are found among people who are experiencing posttraumatic stress problems

Each of these 10 clinical scales thus measures tendencies to respond in psychologically deviant ways. Raw scores on these scales are compared with the corresponding scores of the normal population, many of whom did (and do) answer a few items in the critical direction (suggesting psychological problems), and the results are plotted on the standard MMPI profile form. By drawing a line connecting the scores for the different scales, a clinician can construct a profile that shows how far from normal a patient's performance is on each of the scales. To reiterate the basic strategy with an example, the Schizophrenia scale is made up of the items that patients diagnosed with schizophrenia consistently answered in a way that differentiated them from normal individuals. People who score high (relative to norms) on this scale, though not necessarily schizophrenic, often show characteristics typical of that clinical population. For instance, high scorers on this scale may be socially inept, may be withdrawn, and may have peculiar thought processes; they may have diminished contact with reality and, in severe cases, may have delusions and hallucinations.

The MMPI also includes a number of validity scales to detect whether a patient has answered the questions in a straightforward, honest manner. For example, there is one scale that detects lying by one's claiming of extreme virtue and several scales that detect possible malingering or faking of symptoms. Extreme endorsement of the items on any of these scales may invalidate the test, whereas lesser endorsements frequently contribute important interpretive insights. In addition to the validity scales and the 10 clinical scales, a number of additional scales have been devised—for example, to detect substance abuse, marital distress, and posttraumatic stress disorder.

Clinically, the MMPI is used in several ways to evaluate a patient's personality characteristics and clinical problems. Perhaps the most typical use of the MMPI is as a diagnostic standard. As we have seen, the individual's profile pattern is compared with profiles of known patient groups. If the profile matches a group, information about patients in this group can suggest a broad descriptive diagnosis for the patient under study.

**Revision of the Original MMPI** The original MMPI, in spite of being the most widely used personality measure, has not been without its critics. Some psychodynamically oriented clinicians felt that the MMPI (like other structured, objective tests) was superficial and did not adequately reflect the complexities of an individual taking the test. Some behaviorally oriented critics, on the other hand, criticized the MMPI (and in fact, the entire genre of personality tests) as being too oriented toward measuring unobservable "mentalistic" constructs such as traits. A more specific criticism was leveled at the datedness of the MMPI.

In response to these criticisms, the publisher of the MMPI sponsored a revision of the instrument. The scales listed on the standard original MMPI-2 profile form are described in Table 4.1. This revised MMPI, designated "MMPI-2" for adults, became available for general professional use in mid-1989

(Butcher, 2011; Butcher, Graham, et al., 2001), and the MMPI-A for adolescents (see Williams & Butcher, 2011) was published in 1992. The original 10 clinical scales were kept on the revised version. The revised versions of the MMPI have been validated in many clinical studies (Butcher et al., 2000; Graham, Ben-Porath, & McNulty, 1999; Greene, 2011).

Research has provided strong support for the revised versions of the MMPI (Greene et al., 2003). The clinical scales, which, apart from minimal item deletion or rewording, have been retained in their original form, seem to measure the same properties of personality organization and functioning as they always have. A comparable stability of meaning is observed for the standard validity scales (also essentially unchanged), which have been reinforced with three additional scales to detect tendencies to respond untruthfully to some items.

### Advantages and Limitations of Objective Personality Tests

**Tests** Self-report inventories such as the MMPI have a number of advantages over other types of personality tests. They are cost effective, highly reliable, and objective; they also can be scored and interpreted (and, if desired, even administered) by computer. A number of general criticisms, however, have been leveled against the use of self-report inventories. As we have seen, some clinicians consider them too mechanistic to portray the complexity of human beings and their problems accurately. Also, because these tests require the subject to read, comprehend, and answer verbal material, patients who are illiterate or confused cannot take the tests. Furthermore, the individual's cooperation is required in self-report inventories, and it is possible that the person might distort his or her answers to create a particular impression. The validity scales of the MMPI-2 are a direct attempt to deal with this last criticism.

Because of their scoring formats and emphasis on test validation, scientifically constructed objective personality inventories lend themselves particularly well to automated interpretation. The earliest practical applications of computer technology to test scoring and interpretation involved the MMPI. Over 50 years ago, psychologists at the Mayo Clinic programmed a computer to score and interpret clinical profiles. Computerized personality assessment has evolved substantially over the past few years, and other highly sophisticated MMPI and MMPI-2 interpretation systems have been developed (Butcher et al., 2004). Computer-based MMPI interpretation systems typically employ powerful **actuarial procedures** (Grove et al., 2000). In such systems, descriptions of the actual behavior or other established characteristics of many subjects with particular patterns of test scores have been stored in the computer. Whenever a person has one of these test score patterns, the appropriate description is printed out in the computer's evaluation. Such descriptions have been written and stored for a number of different test score patterns, most of them based on MMPI-2 scores.

The accumulation of precise actuarial data for an instrument like the MMPI-2 is difficult, time consuming, and expensive.

This is in part because of the complexity of the instrument itself; the potential number of significantly different MMPI-2 profile patterns is legion. The profiles of many subjects therefore do not “fit” the profile types for which actuarial data are available. Problems of actuarial data acquisition also arise at the other end: the behaviors or problems that are to be detected or predicted by the instrument. Many conditions that are of vital clinical importance are relatively rare (for example, suicide) or are psychologically complex (for example, possible psychogenic components in a patient’s physical illness). Thus it is difficult to accumulate enough cases to serve as an adequate actuarial database. In these situations, the interpretive program writer is forced to fall back on general clinical lore and wisdom to formulate clinical descriptions appropriate to the types of profiles actually obtained.

Sometimes the different paragraphs generated by the computer have inconsistencies resulting from the fact that different parts of a subject’s test pattern call up different paragraphs from the computer. The computer simply prints out blindly what has been found to be typical for people making similar scores on the various clinical scales and cannot integrate the descriptions it picks up. At this point the human element comes in: In the clinical use of computers, it is always essential that a trained professional further interpret and monitor the assessment data (Atlis et al., 2006).

Computerized personality assessment is no longer a novelty but an important, dependable adjunct to clinical assessment. Computerized psychological evaluations are a quick and efficient means of providing a clinician with needed information early in the decision-making process. Examples of computer-generated descriptions for the case of Andrea C., presented in the next section, appear in the evaluations reprinted in the Developments in Practice box starting on page 118.

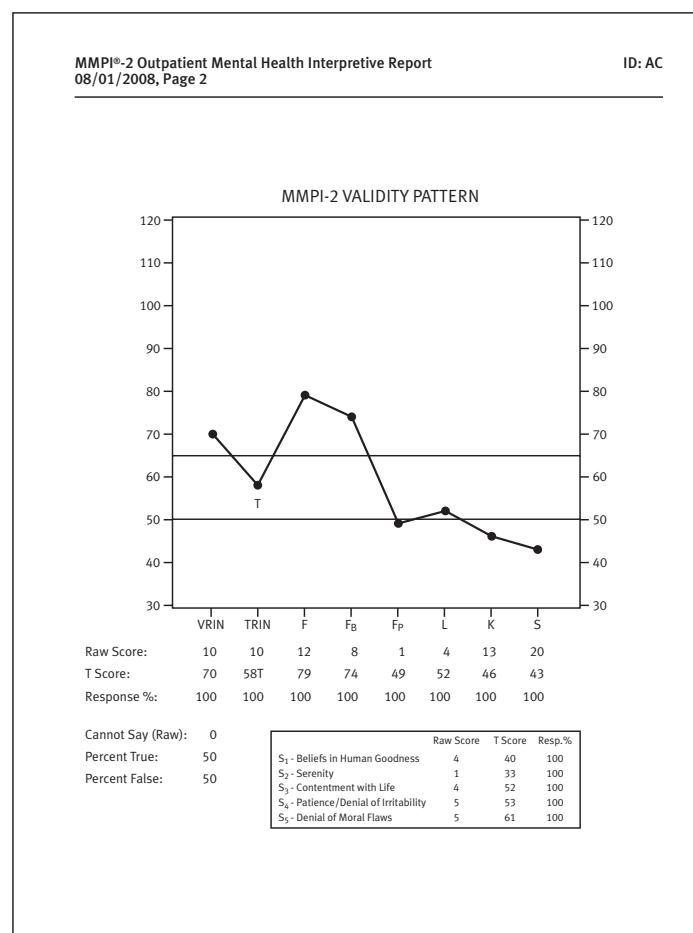

## The Case of Andrea C.: Experiencing Violence in the Workplace

Andrea C., a 49-year-old divorced woman, was employed as a manager in a firm whose office was located in a somewhat isolated section of the community. Her responsibilities included opening the office building at 6:00 a.m. and preparing the office activities for the day. She felt somewhat unsafe in opening up the office alone and had complained to upper management about the lack of security in the building. One morning, as she was opening the door to the building, she was accosted by a stranger who hit her on the head, knocking her unconscious, breaking her nose, and cutting her face and neck. The assailant stabbed her several times in her leg and attempted to sexually assault her but ran away with her purse as car lights came on the street.

Andrea suffered a number of physical injuries and recurring symptoms from the assault and was hospitalized for 8 days following the attack. Her symptoms included a fractured skull, fractured nose, multiple stab wounds on her body, facial injuries, dizziness, impaired balance, wrist pain, residual cognitive

symptoms from being unconscious, poor memory, intense anxiety, and symptoms of posttraumatic stress. After recovery from the physical injuries she was fearful to return to work, and she applied for disability as a result of her injuries. The company for which she worked rejected her request, and she filed a lawsuit for personal injury disability.

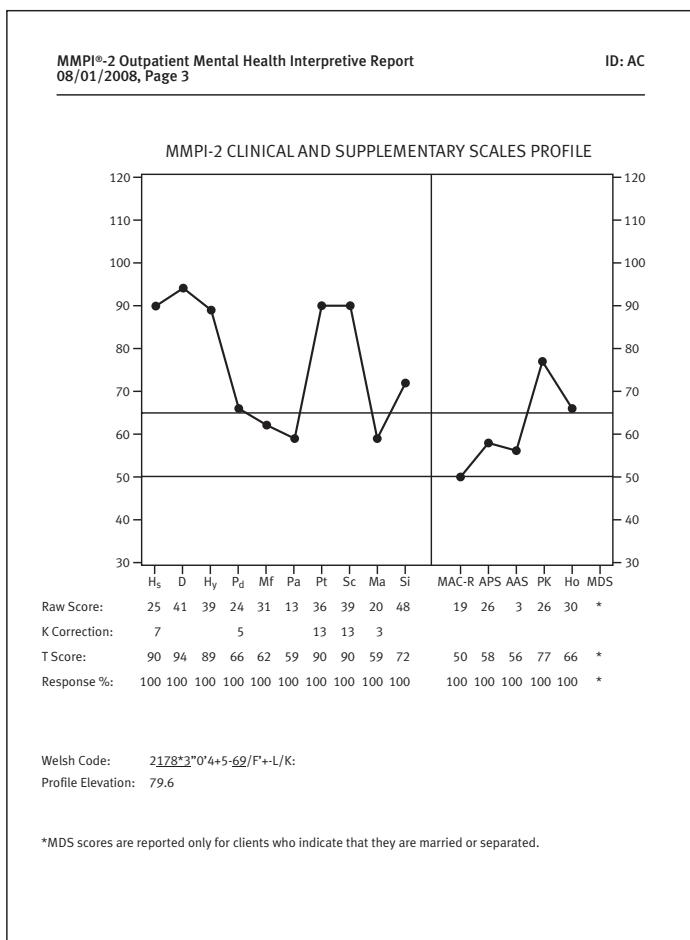

A psychological evaluation was requested by the company’s insurer to determine the legitimacy of Andrea’s disability claim. As a central part of the evaluation, the MMPI-2 was administered by the psychologist hired by the defense to appraise Andrea’s personality and symptoms (see the validity, clinical, and supplementary profiles shown in Figures 4.1 and 4.2). The MMPI-2 clinical scale pattern shows clear mental health problems. Her clinical scale pattern with the high scores on the D (Depression) scale, the Hs (Hypochondriasis), and Pt (Anxiety) scales, along with the high score obtained on the PTSD scale, indicate that she is experiencing mental health symptoms related to stressful life events. A full description of this symptom picture is presented in the computer-based interpretive report shown in the Developments in Practice box.

## developments in PRACTICE

### Computer-Based MMPI-2 Report for Andrea C.

#### PROFILE VALIDITY

This client endorsed a number of psychological problems, suggesting that she is experiencing a high degree of stress. Although the MMPI-2 clinical scale profile is probably valid, it may show some exaggeration of symptoms. In addition, please note that the client's approach to the MMPI-2 items was somewhat inconsistent. She endorsed items in a pattern that suggests some carelessness or inattention to content.

#### SYMPOMATIC PATTERNS

Her profile configuration, which incorporates correlates of Hs and D, is not as clearly defined as those of many other clients from this clinical setting. In interpreting the profile, the practitioner should also consider any prominent clinical scale elevations that are close in elevation to the prototype. This client's profile presents a broad and mixed picture in which physical complaints

Interestingly, the insurance company psychological expert recommended against Andrea's receiving compensation based on his interpretation of a controversial psychological scale (referred to as the Fake Bad Scale, or FBS) that was designed to assess "malingering." After an initial hearing to examine the validity and acceptability of the FBS, the judge in the case prohibited the use of the scale as a measure of effort, malingering, or over-reporting of symptoms to bolster his opinion.

The case went to trial, and Andrea's attorneys relied upon the medical evidence and results of the MMPI-2 to support her claim of physical damages and posttraumatic adjustment problems. The jury awarded Andrea substantial damages as a result of the injuries and the trauma that she experienced from the assault.

#### EVALUATING ANDREA'S COMPUTER-GENERATED MMPI-2 REPORT

The narrative report of the computer-based MMPI-2 interpretation contains technical test information to assist the assessment psychologist in interpreting the test results. The report is considered a professional-to-professional consultation and is not recommended for release to patients. The computer report for Andrea contains detailed data about the relative frequency of the test pattern's occurrence in relevant clinical settings and in the normative or standardized population. For example, the report provides information as to how Andrea's elevated clinical scale scores compare with persons being evaluated in an outpatient clinical setting as well as the frequency of the score in the MMPI-2 general normative sample of women. Her test results indicated that her highest score, the Depression scale score, typically occurs in 18.7 percent of the outpatient women. Moreover, only 4.4 percent of women in the normative sample obtain this high elevation

and depressed affect are likely to be salient features. The client is exhibiting much somatic distress and may be experiencing a problem with her psychological adjustment. Her physical complaints are probably extreme, possibly reflecting a general lack of effectiveness in life. There are likely to be long-standing personality problems predisposing her to develop physical symptoms under stress. She is probably feeling quite tense and nervous, and she may be feeling that she cannot get by without help for her physical problems. She is likely to be reporting a great deal of pain, and she feels that others do not understand how sick she is feeling. She may be quite irritable and may become hostile if her symptoms are not given "proper" attention.

Many individuals with this profile have a history of psychophysiological disorders. They tend to overreact to minor problems with physical symptoms. Ulcers and gastrointestinal distress are common. The possibility of actual organic problems, therefore, should be carefully evaluated. Individuals with this profile report

(Continued)

a great deal of tension and a depressed mood. They tend to be pessimistic and gloomy in their outlook.

In addition, the following description is suggested by the client's scores on the content scales. She endorsed a number of items suggesting that she is experiencing low morale and a depressed mood. She reports a preoccupation with feeling guilty and unworthy. She feels that she deserves to be punished for wrongs she has committed. She feels regretful and unhappy about life, and she seems plagued by anxiety and worry about the future. She feels hopeless at times and feels that she is a condemned person. She has difficulty managing routine affairs, and the items she endorsed suggest a poor memory, concentration problems, and an inability to make decisions. She appears to be immobilized and withdrawn and has no energy for life. She views her physical health as failing and reports numerous somatic concerns. She feels that life is no longer worthwhile and that she is losing control of her thought processes.

According to her response content, there is a strong possibility that she has seriously contemplated suicide. She feels somewhat self-alienated and expresses some personal misgivings or a vague sense of remorse about past acts. She feels that life is unrewarding and dull, and she finds it hard to settle down. The client's response content suggests that she feels intensely fearful about a large number of objects and activities. This hypersensitivity and fearfulness appear to be generalized at this point and may be debilitating to her in social and work situations.

Long-term personality factors identified by other scale elevations may help provide a clinical context for the symptoms she is presently experiencing. She apparently holds some unusual beliefs that appear to be disconnected from reality. Her high score on one MMPI-2 scale, the PSYC (Psychoticism) scale, suggests that she often feels alienated from others and might experience unusual symptoms such as delusional beliefs, circumstantial and tangential thinking, and loose associations. She also shows a meager capacity to experience pleasure in life. Persons with high scores on another MMPI-2 scale, the INTR (Introversion/Low Positive Emotionality), tend to be pessimistic.

### PROFILE FREQUENCY

Profile interpretation can be greatly facilitated by examining the relative frequency of clinical scale patterns in various settings. The client's high-point clinical scale score (D) occurred in 7.0 percent of the MMPI-2 normative sample of women. However, only 4.4 percent of the women had D scale peak scores at or above a T score of 65, and only 2.1 percent had well-defined D spikes. Her elevated MMPI-2 profile configuration (1-2/2-1) is rare in samples of normals, occurring in 1.0 percent of the MMPI-2 normative sample of women.

This high-point MMPI-2 score is the most frequent clinical scale score in various samples of outpatient women. In the Pearson outpatient sample, the high-point clinical scale score on D occurred in 18.7 percent of the women. Moreover, 17.1 percent of the outpatient women had the D scale spike at or above a T score of 65, and 9.0 percent had well-defined D spikes.

Her elevated MMPI-2 profile configuration (1-2/2-1) occurred in 2.9 percent of the women in the Pearson outpatient sample.

### PROFILE STABILITY

The relative elevation of her clinical scale scores suggests that her profile is not as well defined as many other profiles. There was no difference between the profile type used to develop the present report (involving Hs and D) and the next highest scale in the profile code. Therefore, behavioral elements related to elevations on Pt should be considered as well. For example, intensification of anxiety, negative self-image, and unproductive rumination could be important in her symptom pattern.

### INTERPERSONAL RELATIONS

She appears to be somewhat passive-dependent in relationships. She may manipulate others through her physical symptoms, and she may become hostile if sufficient attention is not paid to her complaints.

She is a very introverted person who has difficulty meeting and interacting with other people. She is shy and emotionally distant. She tends to be very uneasy, rigid, and overcontrolled in social situations. Her shyness is probably symptomatic of a broader pattern of social withdrawal. Personality characteristics related to social introversion tend to be stable over time. Her generally reclusive behavior, introverted lifestyle, and tendency toward interpersonal avoidance may be prominent in any future test results.

The client's scores on the content scales suggest the following additional information concerning her interpersonal relations. She appears to be an individual who has rather cynical views about life. Any efforts to initiate new behaviors may be colored by her negativism. She may view relationships with others as threatening and harmful.

### DIAGNOSTIC CONSIDERATIONS

Individuals with this profile type are often seen as neurotic and may receive a diagnosis of somatoform disorder. Actual organic problems such as ulcers or hypertension might be part of the clinical picture. Some individuals with this profile have problems with abuse of pain medication or other prescription drugs.

### TREATMENT CONSIDERATIONS

Her view of herself as physically disabled needs to be considered in any treatment planning. She tends to somatize her difficulties and to seek medical solutions rather than deal with them psychologically. She seems to tolerate a high level of psychological conflict and may not be motivated to deal with her problems directly. She is probably not a strong candidate for psychotherapy treatment approaches that require self-scrutiny, insight development, and high motivation for change. Psychological treatment may progress more rapidly if her symptoms are dealt with through behavior modification techniques. However, with her generally pessimistic attitude and low energy resources, she seems to have little hope of getting better.

(Continued)

The client's scores on the content scales seem to indicate low potential for change. She may feel that her problems are not addressable through therapy and that she is not likely to benefit much from psychological treatment at this time. Her apparently negative treatment attitudes may need to be explored early in therapy if treatment is to be successful.

She harbors many negative work attitudes that could limit her adaptability in the workplace. Her low morale and lack of interest in work could impair future adjustment to employment, a factor that should be taken into consideration in treatment.

Source: Excerpted from *The Minnesota Report™: Adult Clinical System-Revised*, 4th Edition by James N. Butcher.

on the Depression scale. Thus, this high Depression scale elevation is considered to be a relatively common symptom among women seeking outpatient mental health services.

The reader should also note that there are some scales mentioned in the computer narrative report for Andrea that are not listed in Table 4.1. There are a number of other MMPI-2 scales in the literature and in common use with the MMPI-2 that are not listed due to space restrictions in this book. For example, there are 15 MMPI-2 content-based scales, that is, scales that are comprised of homogeneous content themes (such as Negative Work Attitudes, Family Problems, and Type-A Behavior). These scales address specific problem themes in mental health patients. In addition, there are five scales, referred to as the Psychopathology Five (PSY-5) scales that address the personality disorder content domains that are referred to as the "Big 5" personality dimensions. These personality dimensions include Aggressiveness, Psychoticism, Disconstraint, Negative Emotionality/Neuroticism, and Introversion/Low Positive Emotionality.

- What advantages do objective personality tests offer over less structured tests?
- What is the Minnesota Multiphasic Personality Inventory (MMPI-2)? Describe how the scales work.

## The Integration of Assessment Data

As assessment data are collected, their significance must be interpreted so that they can be integrated into a coherent working model for use in planning. Clinicians in individual private practice normally assume this complicated task on their own. In a clinic or hospital setting, assessment data are often evaluated in a staff conference attended by members of an interdisciplinary team (perhaps consisting of a clinical psychologist, a psychiatrist, a social worker, and other mental health personnel) who are concerned with the decisions to be made regarding treatment. By putting together all the information they have gathered, they can see whether the findings complement each other and form a definitive clinical picture or whether gaps or discrepancies exist that necessitate further investigation.

In a clinic or hospital setting, assessment data are usually evaluated in a staff conference attended by members of an interdisciplinary team—including, for example, a clinical psychologist, a psychiatrist, a social worker, and a psychiatric nurse. A staff decision may determine whether a severely depressed person will be hospitalized or remain with his or her family or whether an accused person will be declared competent to stand trial. Because these decisions can have such great impact on the lives of the clients, it is critical that clinicians be well aware of the limitations of assessment.

This integration of all the data gathered at the time of an original assessment may lead to agreement on a tentative diagnostic classification for a patient. In any case, the findings of each member of the team, as well as the recommendations for treatment, are entered into the case record so that it will always be possible to check back and see why a certain course of therapy was undertaken, how accurate the clinical assessment was, and how valid the treatment decision turned out to be.

New assessment data collected during the course of therapy provide feedback on its effectiveness and serve as a basis for making needed modifications in an ongoing treatment program. As we have noted, clinical assessment data are also commonly used in evaluating the final outcome of therapy and in comparing the effectiveness of different therapeutic and preventive approaches.

### Ethical Issues in Assessment

The decisions made on the basis of assessment data may have far-reaching implications for the people involved. A staff decision may determine whether a severely depressed person will be hospitalized or remain with her or his family, or whether an accused person will be declared competent to stand trial. Thus a

valid decision, based on accurate assessment data, is of far more than theoretical importance. Because of the impact that assessment can have on the lives of others, it is important that those involved keep several factors in mind in evaluating test results:

#### 1. Potential Cultural Bias of the Instrument or the Clinician:

**Clinician:** There is the possibility that some psychological tests may not elicit valid information for a patient from a minority group (Gray-Little, 2009; Wen-Shing & Strelitz, 2008). A clinician from one sociocultural background may have trouble assessing objectively the behavior of someone from another background. It is important to ensure—as Greene, Robin, Albaugh, Caldwell, and Goldman (2003) and Hall, Bansal, and Lopez (1999) have shown with the MMPI-2—that the instrument can be confidently used with persons from minority groups.

**2. Theoretical Orientation of the Clinician:** Assessment is inevitably influenced by a clinician's assumptions, perceptions, and theoretical orientation. For example, a psychoanalyst and a behaviorist might assess the same behaviors quite differently. The psychoanalytically oriented professional is likely to view behaviors as reflecting underlying motives, whereas the behavioral clinician is likely to view the behaviors in the context of the immediate or preceding stimulus situations. Different treatment recommendations are likely to result.

**3. Underemphasis on the External Situation:** Many clinicians overemphasize personality traits as the cause of patients' problems without paying enough attention to the possible role of stressors and other circumstances in the patients' life situations. An undue focus on a patient's personality, which some assessment techniques encourage, can divert attention from potentially critical environmental factors.

**4. Insufficient Validation:** Some psychological assessment procedures in use today have not been sufficiently validated. For example, unlike many of the personality scales, widely used procedures for behavioral observation and behavioral self-report and the projective techniques have not been subjected to strict psychometric validation.

**5. Inaccurate Data or Premature Evaluation:** There is always the possibility that some assessment data—and any diagnostic label or treatment based on them—may be inaccurate or that the team leader (usually a psychiatrist) might choose to ignore test data in favor of other information. Some risk is always involved in making predictions for an individual on the basis of group data or averages. Inaccurate data or premature conclusions may not only lead to a misunderstanding of a patient's problem but also close off attempts to get further information, with possibly grave consequences for the patient.

- Are there concerns over cultural biases in some psychological tests?
- What is test validity?

## Classifying Abnormal Behavior

Classification is important in any science, whether we are studying chemical elements, plants, planets, or people. With an agreed-upon classification system we can be confident that we are communicating clearly. If someone says to you, "I saw a dog running down the street," you can probably produce a mental image broadly approximating the appearance of that dog—not from seeing it but rather from your knowledge of animal classifications. There are of course many breeds of dogs, which vary widely in size, color, muzzle length, and so on, and yet we have little difficulty in recognizing the essential features of "dogness." "Dogness" is an example of what psychologists refer to as a "cognitive prototype" or "pattern."

In abnormal psychology, classification involves the attempt to delineate meaningful subvarieties of maladaptive behavior. Like defining abnormal behavior, classification of some kind is a necessary first step toward introducing order into our discussion of the nature, causes, and treatment of such behavior. Classification makes it possible to communicate about particular clusters of abnormal behavior in agreed-upon and relatively precise ways. For example, we cannot conduct research on what might cause eating disorders unless we begin with a more or less clear definition of the behavior under examination; otherwise, we would be unable to select, for intensive study, persons whose behavior displays the aberrant eating patterns we hope to understand. There are other reasons for diagnostic classifications, too, such as gathering statistics on how common the various types of disorders are and meeting the needs of medical insurance companies (which insist on having formal diagnoses before they will authorize payment of claims).

Keep in mind that, just as with the process of defining abnormality itself, all classification is the product of human invention—it is, in essence, a matter of making generalizations based on what has been observed. Even when observations are precise and carefully made, the generalizations we arrive at go beyond those observations and enable us to make inferences about underlying similarities and differences. For example, it is common for people experiencing episodes of panic to feel they are about to die. When "panic" is carefully delineated, we find that it is not in fact associated with any enhanced risk of death but, rather, that the people experiencing such episodes tend to share certain other characteristics, such as recent exposure to highly stressful events.

It is not unusual for a classification system to be an ongoing work in progress as new knowledge demonstrates an earlier generalization to be incomplete or flawed. It is important to bear in mind, too, that formal classification is successfully accomplished only through precise techniques of psychological, or clinical, assessment—techniques that have been increasingly refined over the years.

### in review

- What are some ethical issues that clinicians should be aware of when evaluating a patient's test results?

## Differing Models of Classification

There are currently three basic approaches to classifying abnormal behavior: the categorical, the dimensional, and the prototypal (Widiger & Boyd, 2009). The categorical approach, like the diagnostic system of general medical diseases, assumes (1) that all human behavior can be divided into the categories of “healthy” and “disordered,” and (2) that within the latter there exist discrete, nonoverlapping classes or types of disorder that have a high degree of within-class homogeneity in both symptoms displayed and the underlying organization of the disorder identified.

**THE DIMENSIONAL APPROACH** The dimensional and prototypal approaches differ fundamentally in the assumptions they make, particularly with respect to the requirement of discrete and internally homogeneous classes of behavior. In the dimensional approach, it is assumed that a person’s typical behavior is the product of differing strengths or intensities of behavior along several definable dimensions such as mood, emotional stability, aggressiveness, gender identity, anxiousness, interpersonal trust, clarity of thinking and communication, social introversion, and so on. The important dimensions, once established, are the same for everyone. People are assumed to differ from one another in their configuration or profile of these dimensional traits (each ranging from very low to very high), not in terms of behavioral indications of a corresponding “dysfunctional” entity presumed to underlie and give rise to the disordered pattern of behavior (Miller, Reynolds, & Pilkonis, 2004; Widiger et al., 2006). “Normal” is discriminated from “abnormal,” then, in terms of precise statistical criteria derived from dimensional intensities among unselected people in general, most of whom may be presumed to be close to average, or mentally “normal.” We could decide, for example, that anything above the 97th normative percentile on aggressiveness and anything below the 3rd normative percentile on sociability would be considered “abnormal” findings.

Dimensionally based diagnosis has the incidental benefit of directly addressing treatment options. Because the patient’s profile of psychological characteristics will normally consist of deviantly high and low points, therapies can be designed to moderate those of excessive intensity (e.g., anxiety) and to enhance those that constitute deficit status (e.g., inhibited self-assertiveness).

Of course, in taking a dimensional approach, it would be possible (perhaps even probable) to discover that such profiles tend to cluster together in types—and even that some of these types are correlated, though imperfectly, with recognizable sorts of gross behavioral malfunctions such as anxiety disorders or depression. It is highly unlikely, however, that any individual’s profile will exactly fit a narrowly defined type or that the types identified will not have some overlapping features. This brings us to the prototypal approach.

**THE PROTOTYPAL APPROACH** A prototype (as the term is used here) is a conceptual entity (e.g., personality disorder) depicting an idealized combination of characteristics that more or

less regularly occur together in a less-than-perfect or standard way at the level of actual observation. Westen, Shedler, and Bradley (2006), for example, suggest that the *DSM* should provide a narrative description of a prototypic case of each personality disorder rather than having a listing of diagnostic criteria as it now has. The diagnostician could indicate on a 5-point scale the extent to which a patient matches this description. The clinician would simply rate the overall similarity or “match” between a patient and the prototype.

As we shall see, the official diagnostic criteria defining the various recognized classes of mental disorder, although explicitly intended to create categorical entities, more often than not result in prototypal ones. The central features of the various identified disorders are often somewhat vague, as are the boundaries purporting to separate one disorder from another. Much evidence suggests that a strict categorical approach to identifying differences among types of human behavior, whether normal or abnormal, may well be an unattainable goal. Bearing this in mind as we proceed may help you avoid some confusion. For example, we commonly find that two or more identified disorders regularly occur together in the same individual—a situation known as **comorbidity**. Does this really mean that such a person has two or more entirely separate and distinct disorders? In the typical instance, probably not.

## Formal Diagnostic Classification of Mental Disorders

Today, there are two major psychiatric classification systems in use: the *International Classification of Disease* (ICD-10) system, published by the World Health Organization, and the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM*), published by the American Psychiatric Association. The ICD-10 system is widely used in Europe and many other countries, whereas the *DSM* system is the standard guide for the United States. Both systems are similar in many respects, such as in using symptoms as the focus of classification and in dividing problems into different facets (to be described in the section that follows).

Certain differences in the way symptoms are grouped in these two systems can sometimes result in a different classification on the *DSM* than on the ICD-10. We will focus on the *DSM* system in our discussion of what is to be considered a mental disorder. This manual specifies what subtypes of mental disorders are currently officially recognized and provides, for each, a set of defining criteria in the United States and some other countries. As already noted, the system purports to be a categorical one with sharp boundaries separating the various disorders from one another, but it is in fact a prototypal one with much fuzziness of boundaries and considerable interpenetration, or overlap, of the various “categories” of disorder it identifies.

The criteria that define the recognized categories of disorder consist for the most part of symptoms and signs. The term **symptoms** generally refers to the patient’s subjective description,

the complaints she or he presents about what is wrong. **Signs**, on the other hand, are objective observations that the diagnostician may make either directly (such as the patient's inability to look another person in the eye) or indirectly (such as the results of pertinent tests administered by a psychological examiner). To make any given diagnosis, the diagnostician must observe the particular criteria—the symptoms and signs that the *DSM* indicates must be met.

**THE EVOLUTION OF THE DSM** The *DSM* is currently in its fifth edition (*DSM-5*), published in 2013 after considerable debate and controversy. This system is the product of more than a six-decade evolution involving increasing refinement and precision in the identification and description of mental disorders. The first edition of the manual (*DSM-I*) appeared in 1952 and was largely an outgrowth of attempts to standardize diagnostic practices in use among military personnel in World War II. The 1968 *DSM-II* reflected the additional insights gleaned from a markedly expanded postwar research effort in mental health sponsored by the federal government. Over time, practitioners recognized a defect in both these early efforts: The various types of disorders identified were described in narrative and jargon-laden terms that proved too vague for mental health professionals to agree on their meaning. The result was a serious limitation of diagnostic reliability; that is, two professionals examining the same patient might very well come up with completely different

impressions of what disorder(s) the patient had. *DSM-III* (1980) and *DSM-IV-TR* (2000) provided further modification and elaboration of disorders with efforts to make the diagnostic classification clearer. *DSM-5*, published in 2013, incorporated more theoretical shifts in diagnostic thinking for many years and has been the most controversial alteration to diagnostic thinking to date.

To address this clinical and scientific impasse, the *DSM-III* of 1980 introduced a radically different approach, one intended to remove, as much as possible, the element of subjective judgment from the diagnostic process. It did so by adopting an “operational” method of defining the various disorders that would officially be recognized. This innovation meant that the *DSM* system would now specify the exact observations that must be made for a given diagnostic label to be applied. In a typical case, a specific number of signs or symptoms from a designated list must be present before a diagnosis can properly be assigned. The new approach, continued in the *DSM-III-R* and in the 1994 *DSM-IV*, clearly enhanced diagnostic reliability and made efforts to incorporate cultural and ethnic considerations. As an example of the operational approach to diagnosis in *DSM-5*, the diagnostic criteria for Persistent Depressive Disorder (Dysthymia) (see Chapter 7) are reproduced in the box below. Note that the revised diagnostic system combines diagnostic criteria from two diagnoses from *DSM-IV*: Chronic Major Depression and Dysthymic Disorder.

## criteria for Persistent Depressive Disorder (Dysthymia)

This disorder represents a consolidation of *DSM-IV*-defined chronic major depressive disorder and dysthymic disorder.

- A. Depressed mood for most of the day, for more days than not, as indicated by either subjective account or observation by others, for at least 2 years.  
**Note:** In children and adolescents, mood can be irritable and duration must be at least 1 year.
- B. Presence, while depressed, of two (or more) of the following:
  1. Poor appetite or overeating.
  2. Insomnia or hypersomnia.
  3. Low energy or fatigue.
  4. Low self-esteem.
  5. Poor concentration or difficulty making decisions.
  6. Feelings of hopelessness.
- C. During the 2-year period (1 year for children or adolescents) of the disturbance, the individual has never been without the symptoms in Criteria A and B for more than 2 months at a time.
- D. Criteria for a major depressive disorder may be continuously present for 2 years.
- E. There has never been a manic episode or a hypomanic episode, and criteria have never been met for cyclothymic disorder.

**DSM-5**

F. The disturbance is not better explained by a persistent schizoaffective disorder, schizophrenia, delusional disorder, or other specified or unspecified schizophrenia spectrum and other psychotic disorder.

G. The symptoms are not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or another medical condition (e.g. hypothyroidism).

H. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

**Note:** Because the criteria for a major depressive episode include four symptoms that are absent from the symptom list for persistent depressive disorder (dysthymia), a very limited number of individuals will have depressive symptoms that have persisted longer than 2 years but will not meet criteria for persistent depressive disorder. If full criteria for a major depressive episode have been met at some point during the current episode of illness, they should be given a diagnosis of major depressive disorder. Otherwise, a diagnosis of other specified depressive disorder or unspecified depressive disorder is warranted.

Source: Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, (Copyright 2013). American Psychiatric Association.

The number of recognized mental disorders has increased enormously from *DSM-I* to *DSM-5* due both to the addition of new diagnoses and to the elaborate subdivision of older ones. Because it is unlikely that the nature of the American psyche has changed much in the interim period, it seems more reasonable to assume that mental health professionals view their field in a different light than they did 50 years ago. The *DSM* system is now both more comprehensive and more finely differentiated into subsets of disorders. Most diagnostic categories in *DSM-5* contain a listing of Subtypes and Specifiers that allow the diagnostician to further refine the diagnosis in order to provide more specific subgroupings of patients.

**GENDER DIFFERENCES IN DIAGNOSIS.** In the origin and manifestation of mental health symptoms, gender differences have long been noted for some disorders. Some disorders show a higher prevalence rate for male patients (such as antisocial personality) than females; other disorders (such as anorexia) are more prominently found in females. Moreover, males and females who are diagnosed with the same disorder (such as conduct disorder) often show different symptom patterns. Males have a higher rate of fighting and aggression and females have a greater tendency to lie, being truant from school and tend to run away from home. The *DSM-5* allows for gender related differences to be incorporated into the diagnosis.

**APPRAISAL OF CULTURAL BACKGROUND IN DSM-5.** The United States is a highly diverse society that is comprised of people from multiple language and cultural backgrounds. Increasingly today, mental health practitioners find themselves engaged in a diagnostic evaluation of a client from a diverse background and with marginal or limited English language skill. The client's ethnicity and cultural background, level of English language comprehension, religious background and the extent of their acculturation to the United States can result in incorrect appraisal of mental health symptoms. People who have not been acculturated to the environment in which they live can appear more psychologically disturbed on tests and interviews than they actually are (Okazaki, Okazaki, & Sue, 2009). It is extremely important for the clinician to carefully appraise the client's background, including the values and attitudes they might bring to the interview, in order to reduce negative impact on the decision process.

The *DSM-5* provides a structured interview that focuses upon the patient's approach to problems. The Cultural Formulation Interview (CFI) contains sixteen questions that the practitioner can use to obtain information during a mental health assessment about the potential impact the client's culture can have on mental health care. The interview questions inquire about the patient's perspectives on their present problems, how they perceive the influence of others in influencing their problems, and ways in which their cultural background can influence their adjustment. Moreover, the interview inquires into what the patient's experiences have been in seeking treatment for their

problems. The interview questions attempt to obtain the client's perspective without typecasting their problems.

**THE PROBLEM OF LABELING** The psychiatric diagnoses of the sort typified by the *DSM* system are not uniformly revered among mental health professionals (e.g., MacCulloch, 2010; Sarbin, 1997). One important criticism is that a psychiatric diagnosis is little more than a label applied to a defined category of socially disapproved or otherwise problematic behavior.

The diagnostic label describes neither a person nor any underlying pathological condition ("dysfunction") the person necessarily harbors but, rather, some behavioral pattern associated with that person's current level of functioning. Yet once a label has been assigned, it may close off further inquiry. It is all too easy—even for professionals—to accept a label as an accurate and complete description of an individual rather than of that person's current behavior. When a person is labeled "depressed" or "schizophrenic," others are more likely to make certain assumptions about that person that may or may not be accurate. In fact, a diagnostic label can make it hard to look at the person's behavior objectively, without preconceptions about how he or she will act. These expectations can influence even clinically important interactions and treatment choices. For example, arrival at the diagnosis "persistent depressive disorder" may cut off any further inquiry about the patient's life situation and lead abruptly to a prescription for antidepressant medication (Tucker, 1998), or the application of a label such as "borderline personality" might cause the mental health treatment staff to be less optimistic about the patient's prognosis (Markham, 2003).

Once an individual is labeled, he or she may accept a redefined identity and play out the expectations of that role. ("I'm nothing but a substance abuser. I might as well do drugs—everyone expects me to anyway. Also, this is a condition deemed out of my control, so it is pointless for me to be an active participant in my treatment.") This acquisition of a new social identity can be harmful for a variety of reasons. The pejorative and stigmatizing implications of many psychiatric labels can mark people as second-class citizens with severe limitations that are often presumed to be permanent (Link, 2001; Slovenco, 2001). They can also have devastating effects on a person's morale, self-esteem, and relationships with others. The person so labeled may decide that he or she "is" the diagnosis and may thus adopt it as a life "career."

Clearly, it is in the person with the disorder's best interests for mental health professionals to be circumspect in the diagnostic process, in their use of labels, and in ensuring confidentiality with respect to both. A related change has developed over the past 50 years: For years the traditional term for a person who goes to see a mental health professional was patient, a term that is closely associated with medical sickness and a passive stance, waiting (patiently) for the doctor's cure. Today many mental health professionals, especially those trained in nonmedical settings, prefer the term client because it implies greater participation on the part of an individual and more responsibility for

bringing about his or her own recovery. We shall be using these terms interchangeably in this text.

**LIMITED USEFULNESS OF DIAGNOSIS** It should be kept in mind that a *DSM* diagnosis per se may be of limited usefulness. Arriving at a diagnosis is usually required, at least in the form of a “diagnostic impression,” before the commencement of clinical services. This is necessitated, perhaps unwisely, by medical insurance requirements and long-standing clinical administrative tradition. The additional information required for adequate clinical assessment may be extensive and extremely difficult to

unearth. For the most part, in keeping with psychiatric tradition, that process is interview based. That is, the examiner engages the patient (or perhaps a family member of the patient) in a conversation designed to elicit the information necessary to place the patient in one or more *DSM* diagnostic categories. The interviewer introduces various questions and probes, typically becoming increasingly specific as she or he develops diagnostic hypotheses and checks them out with additional probes related to the criteria for particular *DSM* diagnoses. Physicians in general medical practice do something similar in the course of an examination.

## THINKING CRITICALLY about *DSM-5*

### Completion does not assure acceptance

DSM-5

The development of *DSM-5* was an arduous task, initiated in 2007 by the American Psychiatric Association. The revision program involved obtaining substantial input from numerous mental health professionals, both practitioners and researchers, before it was completed. Although many aspects of the *DSM-IV-TR* were continued in the *DSM-5* because of their clarity and broad acceptance, some categories were modified, moved to different locations in the system, or even dropped. Moreover, a number of new diagnostic criteria were added.

Prior to the May 2013 release of *DSM-5*, numerous articles and books were published detailing problems with the new system (e.g., Alarcón et al., 2009; Batstra & Frances; Frances, 2010a, 2010b; Jones, 2012; Greenberg, 2013; Insel, 2013; Kirk, et al., 2013; Kornstein, 2010). A number of *DSM-5* critics have complained, for example, that the American Psychiatric Association (APA) was overly secretive in the development process and failed to obtain and use critical viewpoints of diagnostic experts in their process of modifying the *DSM-IV*. In his recent publication entitled “The Book of Woe,” Greenberg (2013) details the backstage working of the APA, the *DSM-5* committee, and their critics in the *DSM* revision process. Greenberg is highly critical of the APA’s management of the revision process and presents a very skeptical view of psychiatry’s lack of understanding for diagnosing and curing mental health problems, pointing out that psychiatry does not understand the differences between sickness and health. He provides a lengthy description of the contrary views of the *DSM-5* and the views of many critics about the resulting diagnostic manual. For example, he expresses concerns of over-diagnosis of some disorders such as bipolar disorder, expansion of ADHD into adulthood that would likely increase substance abuse problems, and the inclusion of normal behavior such as a natural grief after the death of a loved one in the diagnosis of depression.

The National Institute of Mental Health (NIMH), has rejected the use of *DSM-5* in its research studies on mental illness and has re-oriented its diagnostic focus away from using *DSM* categories in

future research studies (Insel, 2013.) In order to obtain a clearer grouping of underlying causal physical factors in mental illness, the NIMH has undertaken a different approach to categorizing mental health patients in federally sponsored research in lieu of *DSM* categories—the Research Domain Criteria (RDoC). This approach to categorizing patients in research studies attempts to use, instead of interview/history based symptoms that are employed in *DSM*, objective data from genetics, imaging and cognitive science as a basis for the new classification system. Over the past two years, NIMH, through a series of workshops, has attempted to define several major categories for a new classification system for mental health disorders that are biologically based conditions. The RDoC is a system of categories that allow for the collection of genetic, imaging, physiologic, and cognitive data to determine how these variables are related to mental health treatment effects. The RDoC is not recommended for use in clinical assessment but for federally funded research programs.

The diagnostic criteria for mental disorders in the *DSM* are not viewed by most mental health professionals as fixed-component systems but as workable criteria that evolve and develop to accommodate new research and practical developments. The periodic remaking of *DSM* is never a smooth transition, but the resulting system can be, nevertheless, a valuable conceptual guide that provides an agreed-upon language that students, practitioners, and researchers can employ to enable clear communication about mental disorders. Even critics of *DSM-5*, Frances and Widiger (2012), pointed out that the *DSM* system is “imperfect, but it is indispensable.”

In this book, our goal is not to condemn or to champion the revised diagnostic manual but to provide a comprehensive review and evaluation of research and clinical information about mental health problems. We do include in the following chapters a number of *DSM-5* category descriptions and the recommended diagnostic criteria in order to illustrate current thinking about the diagnoses underlying mental health conditions.

**UNSTRUCTURED DIAGNOSTIC INTERVIEWS** Like the assessment interviews described earlier, diagnostic interviews are of two general types: unstructured and structured. In the unstructured interview, the examiner follows no preexisting plan with respect to content and sequence of the probes introduced. Unstructured interviews, as their name implies, are somewhat freewheeling. The therapist/clinician asks questions as they occur to him or her, in part on the basis of the responses to previous questions. For example, if the patient/client mentions a father who traveled a lot when he or she was a child, the clinician is free to ask, “Did you miss your father?” or (pursuing a different tack), “How did your mother handle that?” rather than being required to ask the next question in a predetermined list. Many clinical examiners prefer this unfettered approach because it enables them to follow perhaps idiosyncratic “leads.” In the above example, the clinician might have chosen to ask about the mother’s reaction on the basis of a developing suspicion that the mother may have been depressed during the client’s childhood years. There is one serious drawback to the freewheeling style, however: The information that an interview yields is limited to the content of that interview. Should another clinician conduct another unstructured interview of the same patient, he or she might come up with a different clinical picture.

**STRUCTURED DIAGNOSTIC INTERVIEWS** The structured interview probes the client in a manner that is highly controlled (Daniel & Gurczynski, 2010). Guided by a sort of master plan (sometimes to the extent of specifying the examiner’s exact

wording), the clinician using a structured interview typically seeks to discover whether the person’s symptoms and signs “fit” diagnostic criteria that are more precise and “operational” than in the past. The use of more precise criteria and of highly structured diagnostic interviewing has substantially improved diagnostic reliability, but the structured interview format is still used only sporadically in routine clinical work. Nevertheless, the precision of clinical research, including epidemiological research to be discussed later, has profited enormously from these developments.

There are a number of structured diagnostic interviews that may be used in various contexts. In clinical and research situations, a popular instrument has been the Structured Clinical Interview for *DSM* Diagnosis (SCID), which yields, almost automatically, diagnoses carefully attuned to the *DSM* diagnostic criteria. Another structured diagnostic instrument, the Schedules for Clinical Assessment in Neuropsychiatry (SCAN), published by the World Health Organization (1994), enables the diagnostician to arrive at either an ICD-10 or a *DSM-5* diagnosis.

### in review

- Why is a classification system needed in abnormal psychology?
- What is the meaning of reliability and validity in the context of such a classification system?
- What is the difference between dimensional and prototypal classification strategies?
- Describe the differences between structured and unstructured diagnostic interviews.

#### 4.1 What are the basic elements in assessment?

- Clinical assessment is one of the most important and complex responsibilities of mental health professionals. The extent to which a person’s problems are understood and appropriately treated depends largely on the adequacy of the psychological assessment.
- The goals of psychological assessment include identifying and describing the individual’s symptoms; determining the chronicity and severity of the problems; evaluating the potential causal factors in the person’s background; and exploring the individual’s personal resources that might be an asset in his or her treatment program.

#### 4.2 What is involved in the assessment of the physical organism?

- Because many psychological problems have physical components, either as underlying causal factors or as symptom patterns, it is often important to include a medical examination in the psychological assessment.
- In cases where organic brain damage is suspected, it is important to have neurological tests—such as an EEG; a CAT, PET, or MRI scan; or an fMRI—to help determine the site and extent of organic brain disorder.
- For someone with suspected organic brain damage, a battery of neuropsychological tests might be recommended to determine whether or in what manner the underlying brain disorder is affecting her or his mental and behavioral capabilities.

#### 4.3 What is psychosocial assessment?

- Psychosocial assessment methods are techniques for gathering psychological information relevant to clinical decisions about patients.

- The most widely used and most flexible psychosocial assessment methods are the clinical interview and behavior observation. These methods provide a wealth of clinical information.
- Psychological tests include standardized stimuli for collecting behavior samples that can be compared with other individuals' behavior via test norms. Examples include intelligence and personality tests.
- Two different personality-testing approaches have evolved: (1) projective tests, such as the Rorschach or the TAT, in which unstructured stimuli are presented to a subject, who then "projects" meaning or structure onto the stimulus, thereby revealing "hidden" motives, feelings, and so on; and (2) objective tests, or personality inventories, in which a subject is required to read and respond to itemized statements or questions.
- Objectively scored personality tests, such as the MMPI-2 and MMPI-A, provide a cost-effective means of collecting a great deal of personality information rapidly.

#### **4.4 How do practitioners integrate assessment data?**

- Possibly the most valuable recent innovation in clinical assessment involves the widespread use of computers in the administration,

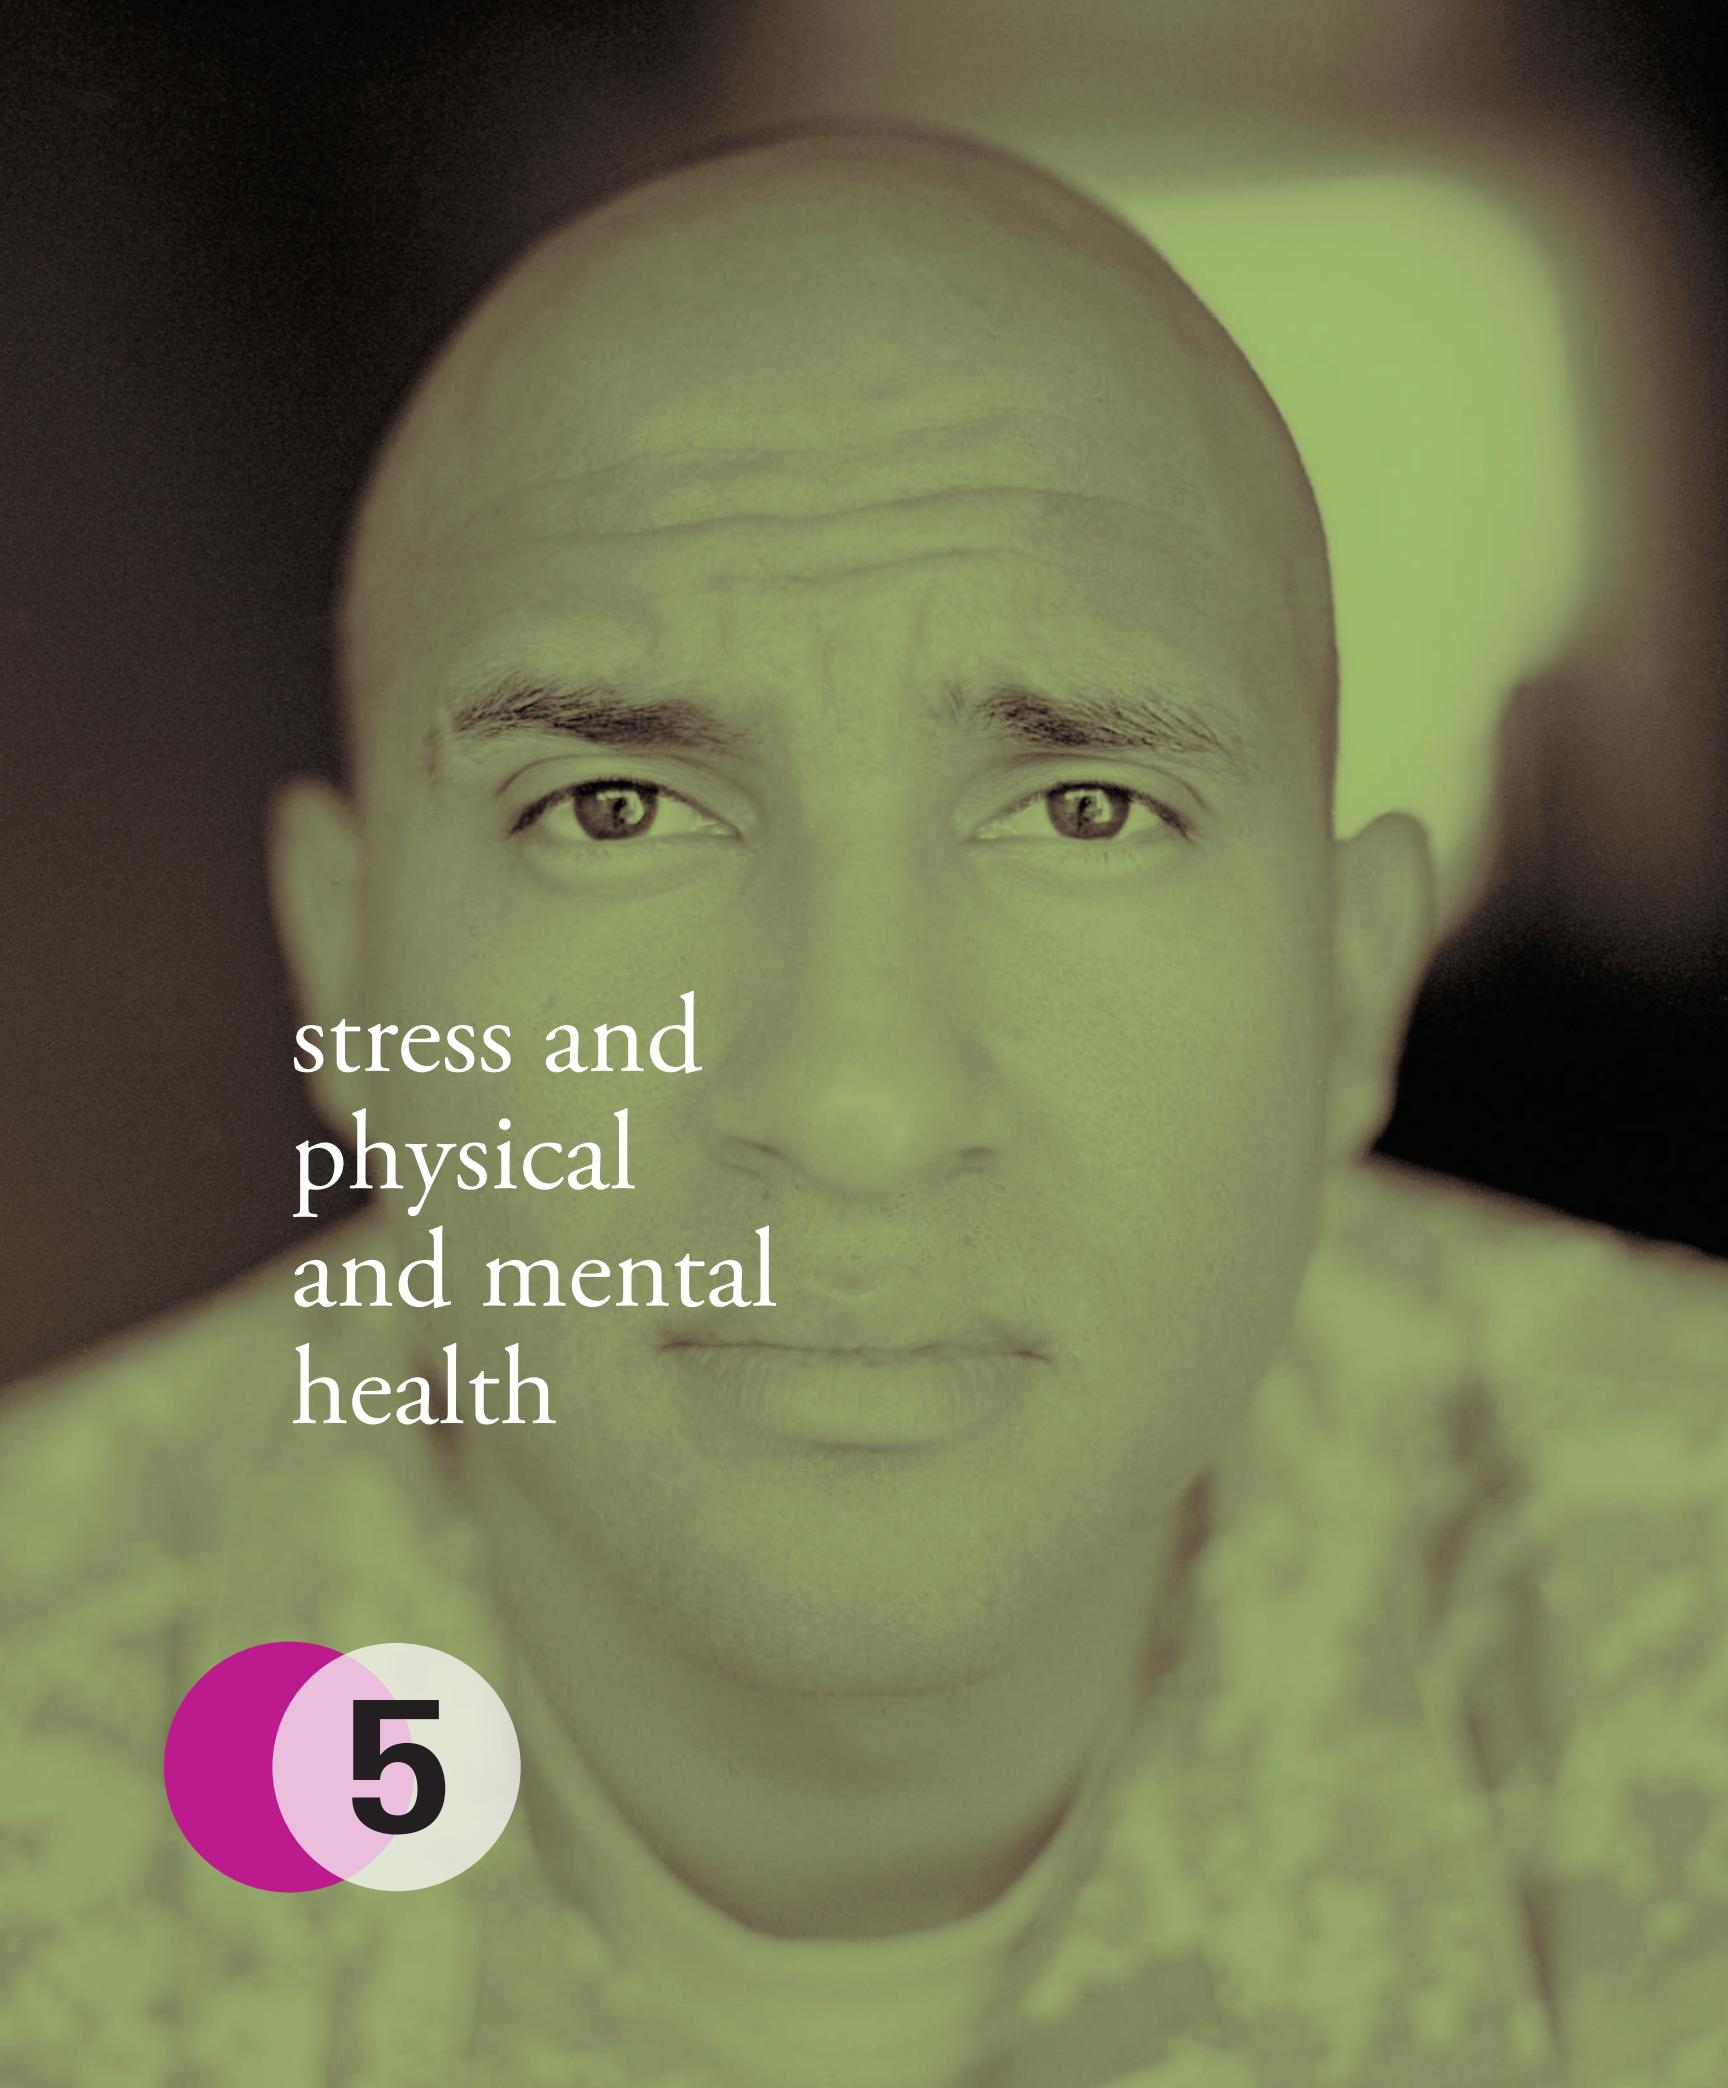

scoring, and interpretation of psychological tests. It is now possible to obtain immediate interpretation of psychological test results, either through a direct computer interactive approach or through an Internet hookup.

#### **4.5 What is the process for classifying abnormal behavior?**

- The formal definition of mental disorder, as offered in the fifth edition of the Diagnostic and Statistical Manual of Mental Disorders (*DSM-5*), has certain problems that limit its clarity and results in controversy.
- There are problems with the category type of classification system adopted in *DSM-5*. Notably, the categories do not always result in within-class homogeneity or between-class discrimination. This can lead to high levels of comorbidity among disorders.
- The changes in the diagnostic system has prompted extensive criticism.
- For all of its problems, however, knowledge of the *DSM-5* is essential to serious study in the field of abnormal behavior.

## learning objectives

### 5.1

What is stress?

### 5.2

How does the body respond to stress?

### 5.3

What role does our emotional state play in our physical health?

### 5.4

What mental disorders are explicitly recognized as being triggered by stress?

### 5.5

What are the clinical features of posttraumatic stress disorder?

### 5.6

What are the risk factors for PTSD?

### 5.7

What treatment approaches are used for PTSD?

With its deadlines, interpersonal tensions, financial pressures, and everyday hassles, daily life places many demands on us. We are all exposed to stress, and this exposure affects our physical and our psychological well-being. Sometimes even leisure activities can be stressful. For example, a loss in the Superbowl is followed by an increase in heart attacks and death over the following two weeks in the losing team's city (Kloner et al., 2011). And watching a stressful soccer match more than doubles the risk of having acute cardiovascular problems (Wilbert-Lampen et al., 2008). How are you affected by stress? Does it make you anxious? Does it give you migraines?

The field of **health psychology** is concerned with the effects of stress and other psychological factors in the development and maintenance of physical problems. Health psychology is a subspecialty within **behavioral medicine**. A behavioral medicine approach to physical illness is concerned with psychological factors that may predispose an individual to medical problems. These may include such factors as stressful life events, certain personality traits, particular coping styles, and lack of social support. Within behavioral medicine there is also a focus on the effects of stress on the body, including the immune, endocrine, gastrointestinal, and cardiovascular systems.

But stress affects the mind as well as the body. As we discussed in Chapter 3, the role that stress can play in triggering

the onset of mental disorders in vulnerable people is explicitly acknowledged in the diathesis-stress model. Moreover, exposure to extreme and traumatic stress may overwhelm the coping resources of otherwise apparently healthy people, leading to mental disorders such as **posttraumatic stress disorder (PTSD)**, as in the following example.

### → Posttraumatic Stress in a Military Nurse

Jennifer developed PTSD after she served as a nurse in Iraq. During her deployment she worked 12- to 14-hour shifts in 120-degree temperatures. Sleep was hard to come by and disaster was routine. Day in and day out there was a never-ending flow of mangled bodies of young soldiers. Jennifer recalled one especially traumatic event:

I was working one evening. We received information that a vehicle, on a routine convoy mission, had been hit by an improvised explosive device (IED). Three wounded men and one dead soldier were on their way to our hospital. Two medics in the back room were processing the dead soldier for Mortuary Affairs. The dead soldier was lying on a cot. The air was strong with the smell of burned flesh. I was staring at the body and trying to grasp what was different about this particular body. After a while I realized. The upper chest and head of the dead soldier was completely missing. We received his head about an hour later. (Based on Feczer & Bjorklund, 2009).

In this chapter we consider the role that stress plays in the development of physical and mental disorders. We discuss both physical and mental problems because the mind and the body are powerfully connected and because stress takes its toll on both. Although the problems that are linked to stress are many, we limit our discussion to the most severe stress-related physical and mental disorders. In the physical realm, we focus on heart disease. For mental disorders, we concern ourselves primarily with PTSD.

After a Superbowl loss, heart attacks and death increase in the losing team's city.

## What Is Stress?

Life would be very simple if all of our needs were automatically satisfied. In reality, however, many obstacles, both personal and environmental, get in the way. A promising athletic career may be brought to an end by injury; we may have less money than we need; we may be rejected by the person we love. The demands of life require that we adjust. When we experience or perceive challenges to our physical or emotional well-being that exceed our coping resources and abilities, the psychological condition that results is typically referred to as stress (see Shalev, 2009). To avoid confusion, we will refer to external demands as **stressors**, to the effects they create within the organism as **stress**, and to efforts to deal with stress as **coping strategies**. It is also important to note that stress is fundamentally an interactive and dynamic construct because it reflects the interaction between the organism and the environment over time (Monroe, 2008).

All situations that require adjustment can be regarded as potentially stressful. Prior to the influential work of Canadian physician and endocrinologist Hans Selye (1956, 1976), *stress* was a term used by engineers. Selye took the word and used it to describe the difficulties and strains experienced by living organisms as they struggled to cope with and adapt to changing environmental conditions. His work provided the foundation for current stress research. Selye also noted that stress could occur not only in negative situations (such as taking an examination) but also in positive situations (such as a wedding). Both kinds of stress can tax a person's resources and coping skills, although bad stress (**distress**) typically has the potential to do more damage. Stress can also occur in more

than one form—not just as a simple catastrophe but also as a continuous force that exceeds the person's capability of managing it.

### Stress and the DSM

The relationship between stress and psychopathology is considered so important that the role of stress is recognized in diagnostic formulations. Nowhere is this more apparent than in the diagnosis of PTSD—a severe disorder that we will discuss later. PTSD was classified as an anxiety disorder in DSM-IV. However, DSM-5 introduced a new diagnostic category called trauma- and stressor related disorders. PTSD is now included there. Other disorders in this new category are adjustment disorder and acute stress disorder. These disorders involve patterns of psychological and behavioral disturbances that occur in response to identifiable stressors. The key differences among them lie not only in the severity of the disturbances but also in the nature of the stressors and the time frame during which the disorders occur (Cardeña et al., 2003).

### Factors Predisposing a Person to Stress

Everyone faces a unique pattern of demands to which he or she must adjust. This is because people perceive and interpret similar situations differently and also because, objectively, no two people are faced with exactly the same pattern of stressors. Some individuals are also more likely to develop long-term problems under stress than others. This may be linked, in part, to coping skills and the presence of particular resources. Children, for example, are particularly vulnerable to severe stressors such as war and terrorism (Petrovic, 2004). Research also suggests that adolescents

Stress can result from both negative and positive events. Both types of stress can tax a person's resources and coping skills, although distress (negative stress) typically has the potential to do more damage.

with depressed parents are more sensitive to stressful events; these adolescents are also more likely to have problems with depression themselves after experiencing stressful life events than those who do not have depressed parents (Bouma et al., 2008).

Individual characteristics that have been identified as improving a person's ability to handle life stress include higher levels of optimism, greater psychological control or mastery, increased self-esteem, and better social support (Declercq et al., 2007; Taylor & Stanton, 2007). These stable factors are linked to reduced levels of distress in the face of life events as well as more favorable health outcomes. There is also some evidence from twin studies that differences in coping styles may be linked to underlying genetic differences (Jang et al., 2007).

A major development in stress research was the discovery that a particular form of a particular gene (the 5HTTLPR gene) was linked to how likely it was that people would become depressed in the face of life stress. Caspi and colleagues (2003) found that people who had two "short" forms of this gene (the s/s genotype) were more likely to develop depression when they experienced four or more stressful life events than were people who had two "long" forms of this gene (the l/l genotype). Although this specific finding was controversial for a while a recent meta-analysis has provided clear support for the original finding (Karg et al., 2011). More generally, it is now widely accepted that our genetic makeup can render us more or less "stress-sensitive." Researchers are exploring genes that may play a role in determining how reactive to stress we are (Alexander et al., 2009; Armbruster et al., 2012).

The amount of stress we experience early in life may also make us more sensitive to stress later on (Gillespie & Nemeroff, 2007; Lupien et al., 2009). The effects of stress may be cumulative, with each stressful experience serving to make the system more reactive. Evidence from animal studies shows that being exposed to a single stressful experience can enhance responsiveness to stressful events that occur later (Johnson, O'Connor et al., 2002). Rats that were exposed to stressful tail shocks produced more of the stress hormone cortisol when they were later exposed to another stressful experience (being placed on a platform). Other biological changes associated with stress were also more pronounced in these rats. These results suggest that prior stressful experiences may sensitize us biologically, making us more reactive to later stressful experiences. The term **stress tolerance** refers to a person's ability to withstand stress without becoming seriously impaired.

Stressful experiences may also create a self-perpetuating cycle by changing how we think about, or appraise, the things that happen to us. Studies have shown that stressful situations may be related to or intensified by a person's cognitions (Nixon & Bryant, 2005). This may explain why people with a history of depression tend to experience negative events as more stressful than other people do (Havermans et al., 2007). For example, if you're feeling depressed or anxious already, you may perceive a friend's canceling a movie date as an indication that she doesn't want to spend time with you. Even though the reality may be that a demand in her own life has kept her from keeping your date, when you feel bad you will be much more inclined to come to a negative conclusion

about what just happened rather than see the situation in a more balanced or more optimistic way. Can you think of an example in your own life when something like this has happened to you?

## Characteristics of Stressors

Why is misplacing our keys so much less stressful than being in an unhappy marriage or being fired from a job? At some level we all intuitively understand what makes one stressor more serious than another. The key factors involve (1) the severity of the stressor, (2) its chronicity (i.e., how long it lasts), (3) its timing, (4) how closely it affects our own lives, (5) how expected it is, and (6) how controllable it is.

Stressors that involve the more important aspects of a person's life—such as the death of a loved one, a divorce, a job loss, a serious illness, or negative social exchanges—tend to be highly stressful for most people (Aldwin, 2007; Newsom et al., 2008). Furthermore, the longer a stressor operates, the more severe its effects. A person may be frustrated in a boring and unrewarding job from which there is seemingly no escape, suffer for years in an unhappy and conflict-filled marriage, or be severely frustrated by a physical limitation or a long-term health problem. As we have already noted, stressors also often have cumulative effects (Miller, 2007). A married couple may endure a long series of difficulties and frustrations, only to divorce after experiencing what might seem to be a minor precipitating stressor. Encountering a number of stressors at the same time also makes a difference. If a man loses his job, learns that his wife is seriously ill, and receives news that his son has been arrested for selling drugs, all at the same time, the resulting stress will be more severe than if these events occurred separately and over an extended period. Symptoms of stress also intensify when a person is more closely involved in an immediately traumatic situation. Learning that the uncle of a close friend was injured in a car accident is not as stressful as being in an accident oneself.

Extensive research has shown that events that are unpredictable and unanticipated (and for which no previously developed coping strategies are available) are likely to place a person under severe stress. A devastating house fire and the damage it brings

A devastating house fire is not an event we can anticipate. It is almost impossible to be psychologically prepared to experience a stressor such as this.

Unpredictable and uncontrollable events cause the greatest stress. These people are reacting to the collapse of the World Trade Center towers.

are not occurrences with which anyone has learned to cope. Likewise, recovery from the stress created by major surgery can be improved when a patient is given realistic expectations beforehand; knowing what to expect adds predictability to the situation. In one study, patients who were about to undergo hip replacement surgery watched a 12-minute film the evening before they had the operation. The film described the entire procedure from the patient's perspective. Compared to controls who did not see the film, patients who saw the video were less anxious on the morning of the surgery, were less anxious after the surgery, and needed less pain medication (Doering et al., 2000).

Finally, with an uncontrollable stressor, there is no way to reduce its impact, such as by escape or avoidance. In general, both people and animals are more stressed by unpredictable and uncontrollable stressors than by stressors that are of equal physical magnitude but are either predictable or controllable or both (e.g., Evans & Stecker, 2004; Maier & Watkins, 1998).

**THE EXPERIENCE OF CRISIS** Most of us experience occasional periods of especially acute (sudden and intense) stress. The term **crisis** is used to refer to times when a stressful situation threatens to exceed or exceeds the adaptive capacities of a person or a group. Crises are often especially stressful, because the stressors are so potent that the coping techniques we typically use do not work. Stress can be distinguished from crisis in this way: A traumatic situation or crisis overwhelms a person's ability to cope, whereas stress does not necessarily overwhelm the person.

## Measuring Life Stress

Life changes, even positive ones such as being promoted or getting married, place new demands on us and may therefore be stressful. The stress from life changes can trigger problems, even in disorders, such as bipolar disorder, that have strong biological underpinnings (see Johnson & Miller, 1997). The faster life changes occur, the greater the stress that is experienced.

A major focus of research on life changes has concerned the measurement of life stress. Years ago, Holmes and Rahe (1967) developed the Social Readjustment Rating Scale. This is a self-report checklist of fairly common, stressful life experiences (see also Chung et al., 2010; Cooper & Dewe, 2007). Although easy to use, limitations of the checklist method later led to the development of interview-based approaches such as the Life Events and Difficulties Schedule (LEDS; Brown & Harris, 1978). One advantage of the LEDS is that it includes an extensive manual that provides rules for rating both acute and chronic forms of stress. The LEDS system also allows raters to consider a person's unique circumstances when rating each life event. For example, if a woman who is happily married and in good financial circumstances learns that she is going to have a baby, she may experience this news in a way that is quite different from that of an unmarried teenager who is faced with the prospect of having to tell her parents that she is pregnant. Although interview-based approaches are more time consuming and costly to administer, they are considered more reliable and are preferred for research in this area (see Monroe, 2008).

## Resilience

After experiencing a potentially traumatic event, some people function well and experience very few symptoms in the following weeks and months. This kind of healthy psychological and physical functioning after a potentially traumatic event is called **resilience**. You might be surprised to learn that resilience is not rare. In fact, resilience is the most common reaction following loss or trauma (Bonnano et al., 2011; Quale & Schanke, 2010).

But why are some people more resilient than others? Research suggests that there is no single factor that predicts resilience. Rather, resilience is linked to a variety of different characteristics and resources. Factors that increase resilience include being male, being older, and being well educated. Having more economic resources is also beneficial. Some earlier studies suggested that, after the 9/11 attacks in New York, African Americans and members of some Latino groups fared more poorly and showed lower levels of resilience compared to whites. However, race and ethnicity are often confounded with social class. Importantly, when social class is controlled for, statistics show that race and ethnicity are no longer predictive of reduced resiliency.

It also helps to be a positive person. Research shows that people who can still show genuine positive emotions when talking about their recent loss also tend to adjust better after bereavement (see Bonnano et al., 2011). In contrast, having more negative affect, being more inclined to ruminate, and trying to find meaning in what has happened is associated with people doing less well after a traumatic event.

The importance of positive and negative emotions is nicely illustrated in a study of 80 people who were being treated in a specialized rehabilitation hospital (Quale & Schanke, 2010). All had multiple traumatic injuries or severe spinal cord injuries, usually caused by accidents. The people who showed most resilience in

Resilience is the most common response to a potentially traumatic event. Optimism, positive emotions, and having more economic resources are all predictive of resilience.

the months after their injuries were those who, when interviewed shortly after arriving in the hospital, reported that they generally had an optimistic approach to life. In addition to optimism, being generally high on positive affect and low on negative affect also predicted having a more resilient trajectory (as opposed to a distress trajectory) over the period of rehabilitation treatment.

Finally, it is interesting to note that people who are very self-confident and who view themselves in an overly positive light also tend to cope remarkably well in the face of trauma. Although people with this kind of self-enhancing style are sometimes unpleasant to interact with, such a style may serve them well in times of crisis. For example, in a recent prospective study, Gupta and Bonanno (2010) showed that college students with this self-enhancing style coped much better over a four-year period than people who did not.

### in review

- What is resilience? Describe three factors that increase resilience and three factors that are associated with reduced resilience.

## Stress and the Stress Response

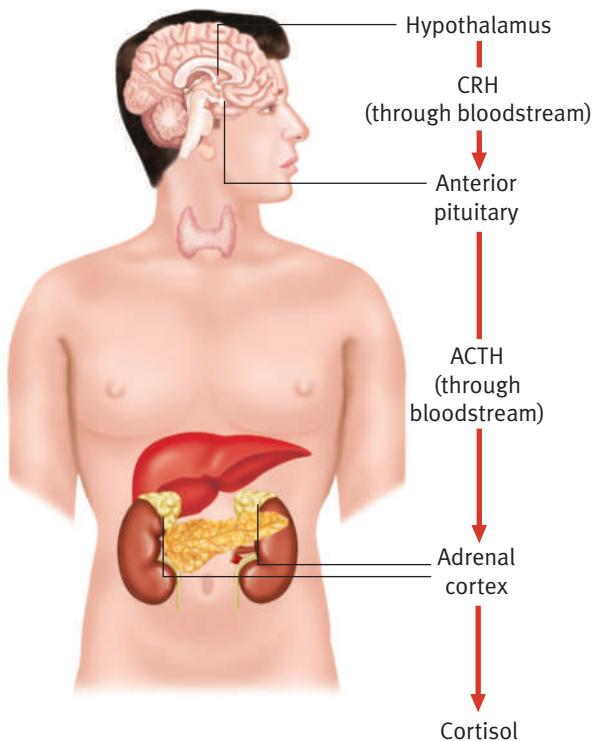

To understand why stress can lead to physical and psychological problems, we need to know what happens to our bodies when we experience stress. Faced with the threat of a perceived stressor, the body undergoes a cascade of biological changes. Two distinct systems are involved here. The **sympathetic-adrenomedullary (SAM) system** (see Gunnar & Quevedo, 2007) is designed to mobilize resources and prepare for a fight-or-flight response. The stress response begins in the hypothalamus, which stimulates the sympathetic nervous system (SNS). This, in turn, causes the inner portion of the adrenal glands (the adrenal medulla) to secrete adrenaline (epinephrine) and noradrenaline

(norepinephrine). As these circulate through the blood, they cause an increase in heart rate (familiar to all of us). They also get the body to metabolize glucose more rapidly.

The second system involved in the stress response is called the **hypothalamus-pituitary-adrenal (HPA) system** (which we introduced in Chapter 3; also see Figure 5.1). In addition to stimulating the SNS, the hypothalamus releases a hormone called "corticotrophin-releasing hormone" (or CRH). Traveling in the blood, this hormone stimulates the pituitary gland. The pituitary then secretes adrenocorticotropic hormone (ACTH). This induces the adrenal cortex (the outer portion of the adrenal gland) to produce the stress hormones called glucocorticoids. In humans, the stress glucocorticoid that is produced is called **cortisol**. Figure 5.1 illustrates this sequence of events.

Cortisol is a good hormone to have around in an emergency. It prepares the body for fight or flight. It also inhibits the innate immune response. This means that if an injury does occur, the body's inflammatory response to it is delayed. In other words, escape has priority over healing, and tissue repair is secondary to staying alive. This obviously has survival value if you need to run away from a lion that has just mauled you. It also explains why cortisone injections are sometimes used to reduce inflammation in damaged joints.

But there is also a downside to cortisol. If the cortisol response is not shut off, cortisol can damage brain cells,

**FIGURE 5.1**

**The Hypothalamic-Pituitary-Adrenal (HPA) Axis.** Prolonged stress leads to secretion of the adrenal hormone cortisol, which elevates blood sugar and increases metabolism. These changes help the body sustain prolonged activity but at the expense of decreased immune system activity.

[Explore the simulation LivePsych! Stress and Immune System on MyPsychLab.](#)

especially in the hippocampus (see Sapolsky, 2000). At a very fundamental level, stress is bad for your brain. It may even stunt growth (babies who are stressed don't gain weight in the normal way and "fail to thrive"). Accordingly, the brain has receptors to detect cortisol. When these are activated, they send a feedback message that is designed to dampen the activity of the glands involved in the stress response. But if the stressor remains, the HPA axis stays active and cortisol release continues. Although short-term cortisol production is highly adaptive, a chronically overactive HPA axis, with high levels of circulating cortisol, may be problematic.

### Biological Costs of Stress

The biological cost of adapting to stress is called the **allostatic load** (McEwan, 1998). When we are relaxed and not experiencing stress, our allostatic load is low. When we are stressed and feeling pressured, our allostatic load will be higher. Although efforts to relate specific stressors to specific medical problems have not generally been successful, stress is becoming a key underlying theme in our understanding of the development and course of virtually all physical illness. Moreover, the focus now is not just on major stressors such as job loss or the death of a loved one, but also on daily stressors such as commuting, unexpected work deadlines, or even computer problems (Almeida, 2005). For example, a person with allergies may find his or her resistance further lowered by emotional tension. Similarly, when a virus has already entered a person's body—as is thought to be the case in multiple sclerosis—emotional stress may interfere with the body's normal defensive forces or immune system. In like manner, any stress may tend to aggravate and maintain certain disorders, such as migraine headaches (Levor et al., 1986) and rheumatoid arthritis (Affleck et al., 1994; Keefe et al., 2002).

### The Mind–Body Connection

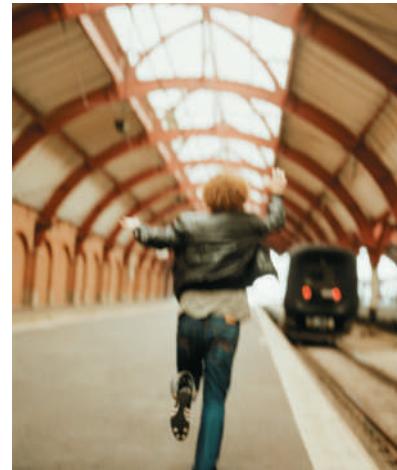

The link between stress and physical illness involves diseases (like colds) that are not directly related to nervous system activity. This suggests that stress may cause an overall vulnerability to disease by compromising immune functioning.

**Psychoneuroimmunology** is the study of the interaction between the nervous system and the immune system. Although it was once thought that the immune system was essentially "closed" and responsive only to challenges from foreign substances, we now realize that this is not the case. The nervous system and the immune system communicate in ways that we are now beginning to understand.

Evidence continues to grow that the brain influences the immune system and that the immune system influences the

When we are relaxed and calm, our allostatic load is low.

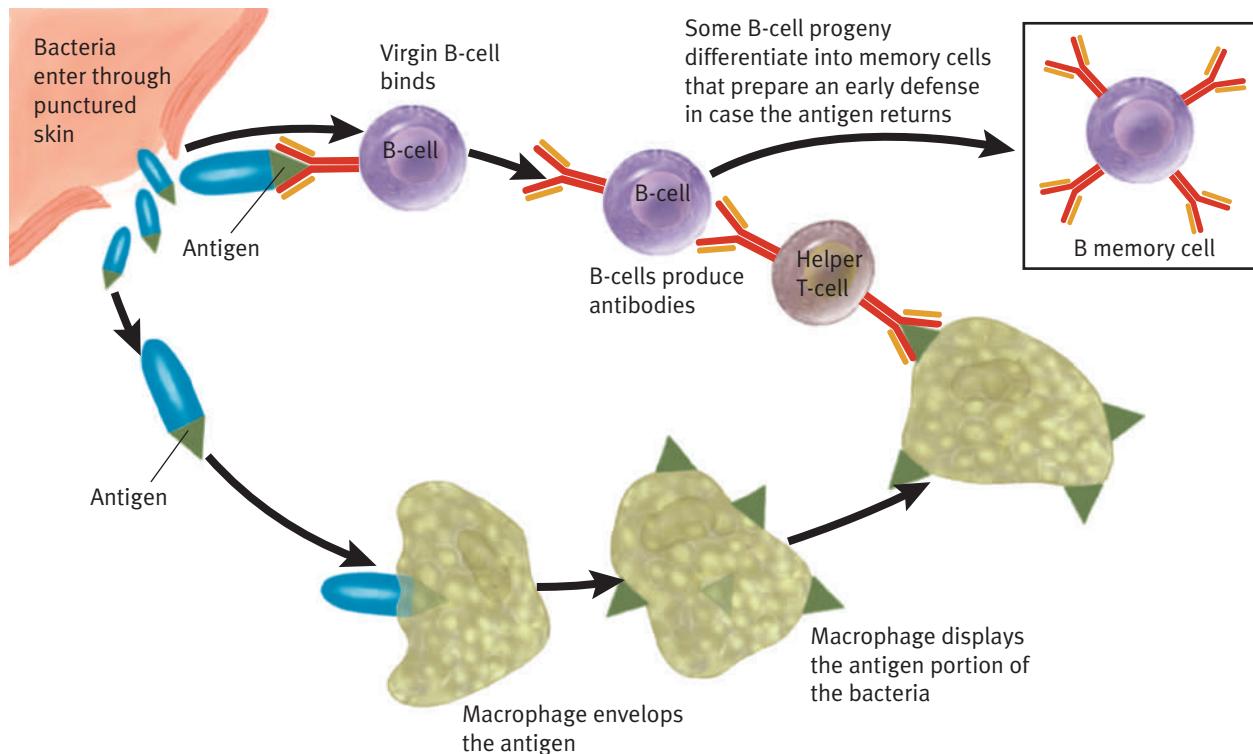

When our allostatic load is high, we experience the biological signs of stress including high heart rate and increased levels of cortisol.

brain. In other words, a person's behavior and psychological states do indeed affect immune functioning, but the status of the immune system also influences current mental states and behavioral dispositions by affecting the blood levels of circulating neurochemicals; these, in turn, modify brain states. For example, we have already seen that glucocorticoids can cause stress-induced **immunosuppression**. In the short term, this can be adaptive (escape first, heal later). However, it makes sense that longer-term stress might create problems for the immune system. To appreciate why this might be, we need to describe briefly the basics of immune functioning.

### Understanding the Immune System

The word *immune* comes from the Latin *immunis*, which means "exempt." The **immune system** protects the body from such things as viruses and bacteria. It has been likened to a police force (Kalat, 2001). If it is too weak, it cannot function effectively, and the body succumbs to damage from invading viruses and bacteria. Conversely, if the immune system is too strong and unselective, it can turn on the body's own healthy cells. This is what may happen in the case of autoimmune diseases such as rheumatoid arthritis and lupus.

The front line of defense in the immune system is the white blood cells. These **leukocytes** (or **lymphocytes**) are produced in the bone marrow and then stored in various places throughout the body, such as the spleen and the lymph nodes. There are two important types of leukocytes. One type, called a **B-cell** (because it matures in the bone marrow) produces specific antibodies that are designed to respond to specific antigens. **Antigens** (the word is a contraction of *antibody generator*) are foreign bodies such as viruses and bacteria, as well as internal invaders such as tumors and cancer cells. The second important type of leukocyte is the **T-cell** (so named because it matures in the thymus, which is an important endocrine gland). When the immune system is stimulated, B-cells and

**FIGURE 5.2**

**Immune System Responses to a Bacterial Infection.**

Source: J. W. Kalat. 2001. *Biological Psychology*, 7th ed. Belmont, CA: Wadsworth.

T-cells become activated and multiply rapidly, mounting various forms of counterattack (see Figure 5.2).

T-cells circulate through the blood and lymph systems in an inactive form. Each T-cell has receptors on its surface that recognize one specific type of antigen. However, the T-cells are unable to recognize antigens by themselves. They become activated when immune cells called *macrophages* (the word means “big eater”) detect antigens and start to engulf and digest them. To activate the T-cells, the macrophages release a chemical known as *interleukin-1*. With the help of the macrophages, the T-cells become activated and are able to begin to destroy antigens (Maier et al., 1994).

B-cells are different in structure from T-cells. When a B-cell recognizes an antigen, it begins to divide and to produce antibodies that circulate in the blood. This process is facilitated by cytokines that are released by the T-cells. Production of antibodies takes 5 days or more (Maier et al., 1994). However, the response of the immune system will be much more rapid if the antigen ever appears in the future because the immune system has a “memory” of the invader.

The protective activity of the B- and T-cells is supported and reinforced by other specialized components of the system, most notably natural killer cells, macrophages (which we have already mentioned), and granulocytes. The immune system’s response to antigen invasion is intricately orchestrated, requiring the intact functioning of numerous components.

An important component of the immune system response involves **cytokines**. Cytokines are small protein molecules that serve as chemical messengers and allow immune cells to communicate with each other. Interleukin-1, which we have just discussed, is a cytokine. Another cytokine that you may have heard about is interferon, which is given to patients with cancer, multiple sclerosis, and hepatitis C.

Cytokines play an important role in mediating the inflammatory and immune response (see Kronfol & Remick, 2000, for a review). They can be divided into two main categories: proinflammatory cytokines and anti-inflammatory cytokines. Proinflammatory cytokines such as interleukin-1 (IL-1), IL-6, or tumor necrosis factor help us deal with challenges to our immune system by augmenting the immune response. In contrast, anti-inflammatory cytokines such as IL-4, IL-10, and IL-13 decrease or dampen the response that the immune system makes. Sometimes they accomplish this by blocking the synthesis of other cytokines.

What makes cytokines especially interesting is that in addition to communicating with the immune system, they also send signals to the brain. Because the brain and the immune system can communicate via the cytokines, we can regard the immune system almost as another sensory organ. Far from being a self-contained system, the immune system can monitor our internal state and send the brain information about infection and injury. The brain can then respond. What this means is that the brain

is capable of influencing immune processes. With this in mind, some of the findings discussed in this chapter (the link between depression and heart disease, for example, and the health benefits of optimism and social support) make much more sense. In a very tangible way, what is going on at the level of the brain can affect what is going on with the body, and vice versa.

We also know that IL-1 and other cytokines can stimulate the HPA axis (refer back to Figure 5.1). The resulting increase in cortisol sets off a negative feedback loop that is designed to prevent an excessive or exaggerated immune or inflammatory response. However, if this feedback system fails and is either too sensitive or not sensitive enough, serious disorders such as cancer, infection, or autoimmune diseases can develop. Because the brain is also involved in this feedback loop, emotional factors and psychosocial stresses may tilt the balance in the feedback loop in either a helpful or a detrimental way.

One implication of developments in cytokine research is that disorders of the brain could potentially have “downstream” effects on the immune system. In the opposite direction, problems with the immune system may also lead to some behavioral changes or even to psychiatric problems. For example, when you are ill you sleep more, have a diminished appetite, and have little sexual interest. This is classic sickness behavior. It may also result, at least in part, from the effects of specific cytokines on the brain. When cytokines such as IL-1 or interferon are injected, subjects become lethargic, lose their appetites, and have trouble concentrating, among other problems (Reichenberg et al., 2001). In other words, they have some of the symptoms of depression. And when cancer patients are treated with cytokines such as interferon, they experience both flu-like symptoms and depression, the latter of which is typically treated with paroxetine (Paxil), an antidepressant (Musselman et al., 2001). In short, cytokines may have great potential for helping us understand the links between physical and mental well-being that are at the heart of behavioral medicine.

### Stress, Depression, and the Immune System

Did you know that stress slows the healing of wounds by as much as 24 to 40 percent (Kiecolt-Glaser et al., 2002)? This is because stress is linked to suppression of the immune system (Segerstrom & Miller, 2004). The list of stressors that have been linked to immunosuppression is varied and includes sleep deprivation, marathon running, space flight, being the caregiver for a patient with dementia, and death of a spouse (Cacioppo et al., 1998; Schleifer et al., 1985; Schleifer et al., 1989; Vasiljeva et al., 1989). On the positive side, there is evidence that laughter is associated with enhanced immune functioning (Berk et al., 1988; Lefcourt, 2002).

Although short-term stress (such as occurs when we take an examination) compromises the immune system (Glaser et al., 1985; Glaser et al., 1987), it is the more enduring stressors such as unemployment or loss of a spouse that are associated with the most global immunosuppression. This is of particular concern in today’s

Stress causes our immune system to function less efficiently.

difficult economic times. People who are unemployed have lower levels of immune functioning than people who are employed. The good news, however, is that immune functioning returns to normal again once people find another job (Cohen et al., 2007).

Depression is also associated with compromised immune function (Kiecolt-Glaser et al., 2002). Moreover, the relationship between depression and suppression of the immune system is at least partially independent of specific situations or events that may have provoked depressed feelings. In other words, the state of being depressed adds something beyond any negative effects of the stressors precipitating the depressed mood.

Although there is a great deal of evidence linking stress to suppression of the immune system, researchers are becoming aware that both chronic stress and depression may also *enhance* certain immune system responses, although not in a good way (Robles et al., 2005). Chronic stress and depression may trigger the production of proinflammatory cytokines such as interleukin-6 (IL-6). One **correlational research** study showed that women who were caring for a family member with Alzheimer’s disease had higher levels of IL-6 than women who were either anticipating the stress of relocation or who were experiencing neither of these stressors (Lutgendorf et al., 1999). This difference was found even though the women who were caregivers were 6 to 9 years younger than the women in the other two groups and even though IL-6 levels are known to increase with age. Major depression has also been linked to enhanced production of proinflammatory cytokines, including

### research CLOSE-UP

#### Correlational Research

In contrast to experimental research (which involves manipulating variables in some way and seeing what happens), in correlational research the researcher observes or assesses the characteristics of different groups, learning much about them without manipulating the conditions to which they are exposed.

IL-6, but treatment with antidepressant medications can reduce this elevation (Kenis & Maes, 2002).

These findings are especially interesting in light of research showing a relationship between IL-6 and aging, as well as to chronic diseases including certain cancers and cardiovascular disease (Papanicolaou et al., 1998). Further evidence that higher levels of IL-6 are bad for health is suggested by their association with being overweight, smoking, and having a sedentary lifestyle (Ferrucci et al., 1999).

One group of investigators has reported that older adults (average age 71 years) who regularly attended church had lower levels of IL-6 and were less likely to die during the course of a 12-year follow-up than those who did not go to church regularly (Lutgendorf et al., 2004). These findings also held when other potential confounding variables such as age, social support, being overweight, having medical problems, and being depressed were also considered. Given all of the findings, it is not hard to see why researchers are becoming excited about the possibility that proinflammatory cytokines like IL-6 could be key mediators in the link between psychosocial factors and disease. Overall, what the research findings suggest is that chronic stress and depression can result in the immune system going out of balance in ways that may compromise health (see Robles et al., 2005). In short, the potential for psychological factors to influence our health and for our health to affect our psychological well-being is becoming ever more apparent.

- What is meant by the term allostatic load?
- Describe the relationship between stress and the immune system.

## STRESS AND PHYSICAL HEALTH

This chapter concerns the role of stress in physical and mental disorders. In this section we concern ourselves with medical conditions that are linked to stress. Because the brain influences the immune system, psychological factors are of great importance to our health and well-being. How you view problems and cope with challenges, and even your temperament, may directly affect your underlying physical health.

Negative emotions such as depression, anxiety, and anger may be especially important to avoid because they are associated with poor health (Kiecolt-Glaser et al., 2002). On the other hand, an optimistic outlook on life, as well as an absence of negative emotions, may have some beneficial health consequences (see Rasmussen et al., 2009). Indeed, there is now a growing interest in **positive psychology** (Snyder & Lopez, 2002). This school of psychology focuses on human traits and resources such as humor, gratitude, and compassion that might have direct implications for our physical and mental well-being.

An illustration of this comes from a study by Witvliet and colleagues (2001). These researchers asked college students to select

Forgiving those who have wronged us may lower our stress levels and enhance overall well-being.

a real-life interpersonal offense (such rejection, betrayals of trust, and personal insults) that they had experienced in the past. The researchers then collected self-reports as well as heart rate, blood pressure, and facial muscle tension data from the students while they were imagining responding to the real-life transgression in a way that was either forgiving or unforgiving. In the forgiving condition, the students were asked to think about granting forgiveness or developing feelings of empathy for the perpetrator. In the unforgiving condition, they were asked to stay in the victim role, to go over the hurt in their minds, and to nurse a grudge.

The findings showed that when they were asked to be forgiving, participants did indeed report more feelings of empathy and forgiveness. And, when asked to ruminate and be unforgiving, participants reported that they felt more negative, angry, sad, aroused, and out of control. They also showed greater tension in their brows. Importantly, their heart rates went up, their blood pressures increased, and their skin conductance (a measure of SNS arousal) revealed more arousal. Even more striking was the finding that even after the grudge-harboring imagery was over and the subjects were told to relax, they were unable to do so. In other words, the high state of physiological arousal that had been triggered by dwelling on the past hurt could not easily be turned off.

What are the implications of these findings? Although fleeting feelings of anger probably do us no real harm, people who have a tendency to brood about the wrongs that other people have done to them may be doing themselves a major disservice. To the extent that perpetuating feelings of anger and increasing

cardiovascular reactivity have consequences for heart disease and immune system functioning, harboring grudges may be hazardous to our health. Although it is not always easy, forgiving those who have offended us may lower our stress levels and enhance our well-being.

## Cardiovascular Disease

Because cardiovascular disease is the leading cause of death in the United States (American Heart Association, 2001), and because the impact of stress on the heart has been well researched, we use this disease to illustrate the many links between psychological factors and physical disease. Some of these are illustrated in the following case study. As you read the case of Dr. M., consider the role that negative emotions play. Also consider Dr. M's personality. Do you consider him an optimist or a pessimist?

**The Angry Physician** Dr. M was a 44-year-old physician. The middle son of parents who had emigrated from Italy, he was ambitious and determined to make a successful life for himself and his family. He worked long hours helping patients with cancer, and he was caring and compassionate. His patients loved him. But his job was also very stressful. Added to the many demands of maintaining a busy medical practice was the great sadness that he felt when (inevitably) many of his terminally ill patients died.

At home Dr. M was a loyal husband and devoted father to his three children. But he was not an easy person to live with. He found it hard to relax, and he had a very volatile disposition. He was frequently angry and would shout at everyone whenever he had had a bad day. Often his moods were caused by his feeling that he was not fully appreciated by the other doctors with whom he worked. Although his wife realized that he "just needed to vent," his moods took a toll on the family. His children distanced themselves from him much of the time, and his wife became less and less happy in the marriage.

One day at work, Dr. M started to feel unwell. He began to sweat and experienced a heavy pressure in his chest. It was difficult for him to breathe. Dr. M recognized the severity of his symptoms and called out for medical help. He had a sudden and severe heart attack and survived only because he was working in a hospital at the time of the attack. If he had not received prompt medical attention, he almost certainly would have died.

After his heart attack Dr. M became very depressed. It was almost as though he could not accept that he, a physician, had a severe medical problem. Although he lived in fear of having another heart attack, his efforts to lose weight (which his doctor had told him to do) were sabotaged by his unwillingness to

follow any diet. He would try and then give up, coming back from the Italian bakery with bags of pastries. Making the problem worse was the fact that because he was a doctor, his own doctors were somewhat reticent about telling him what he had to do to manage his illness. He went back to work, and his family walked on eggshells, afraid to do or say anything that might stress him. His wife tried to encourage him to follow the doctors' recommendations. However, Dr. M's attitude was that if he was going to die anyway, he might as well enjoy himself until he did.

## Hypertension

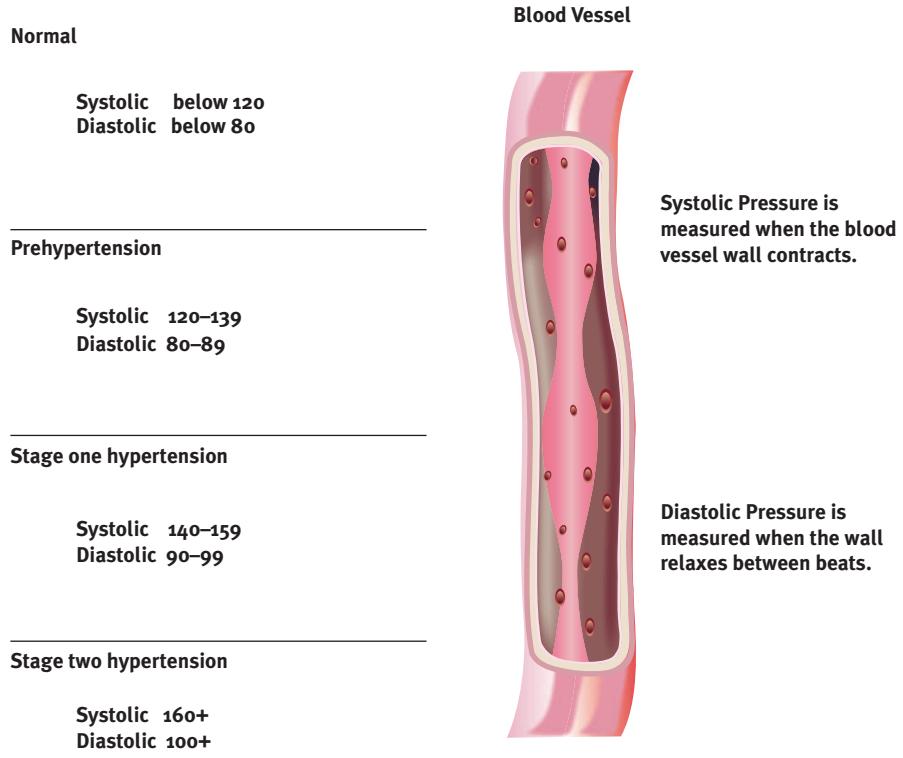

When we are stressed the blood vessels supplying our internal organs constrict (become more narrow) and blood flows in greater quantity to the muscles of the trunk and limbs. When this happens the heart must work harder. As it beats faster and with greater force, our pulse quickens and blood pressure increases. When the period of stress is over, blood pressure returns to normal. If the emotional strain is more enduring, however, high blood pressure may become a chronic problem.

Ideally, blood pressure should be below 120/80. (By convention, the first number given is the systolic pressure when the heart contracts; the second is the diastolic or between-beat pressure; see Figure 5.3 on p. 139.) The unit of measurement is millimeters of mercury (Hg). The definition of **hypertension** is having a persisting systolic blood pressure of 140 or more and a diastolic blood pressure of 90 or higher. Blood pressure is simple and painless to measure by means of the familiar inflated arm cuff.

In general, blood pressure increases as we age. In younger adults, more men than women suffer from high blood pressure. After about age 50, however, the prevalence of hypertension is greater in women (Burt et al., 1995), probably because menopause amplifies the stiffness in the arteries that naturally occurs with increasing age (Takahashi et al., 2005). Current estimates suggest that sustained hypertension afflicts around 28 percent of Americans (Friedewald et al., 2010).

A small percentage of cases of hypertension are caused by distinct medical problems. However, in the majority of cases there is no specific physical cause. This is referred to as **essential hypertension**. Hypertension is an insidious and dangerous disorder. The person who has it may have no symptoms until its consequences show up as medical complications. Hypertension increases the risk of coronary heart disease and stroke. It is also often a causal factor in occlusive (blocking) disease of the peripheral arteries, congestive heart failure (due to the heart's inability to overcome the resistance of constricted arteries), kidney failure, blindness, and a number of other serious physical ailments.

Many clinicians and investigators think that hypertension begins when a person has a biological tendency toward high cardiovascular reactivity to stress (e.g., Tuomisto, 1997; Turner, 1994). This might be considered to represent a diathesis, or vulnerability factor. Over time, and in the face of chronic and difficult life circumstances, which create stress, the vulnerable person

**FIGURE 5.3**

**Defining Hypertension.** Blood pressure levels once thought normal are now considered high enough to signal prehypertension.

will go from having borderline hypertension to having a serious clinical problem. Not being able to express anger in a constructive way (e.g., by expressing why one feels angry and trying to reach an understanding by engaging in open communication with the person one is angry with) may also increase a person's risk for hypertension (Davidson et al., 2000).

**HYPERTENSION AND AFRICAN AMERICANS** African Americans have much higher rates of hypertension than European Americans (40% versus 27%; see Fox et al., 2011). Their death rate from hypertension is also three times higher. Interestingly, the higher prevalence of hypertension in African Americans is not just found in the United States but seems to be the case for blacks worldwide. Rates of hypertension in young people are also alarmingly high. Ten percent of African American men aged 18 to 21 have hypertension compared with prevalence rates of 1 to 2 percent in other groups (see Friedewald et al., 2010).

Higher levels of stress from such factors as inner-city living, economic disadvantage, exposure to violence, and race-based discrimination may play a key role in this (Din-Dzietham et al., 2004; Wilson et al., 2004). Lifestyle may also be a factor. African American women in particular are more likely to be overweight than Caucasian women (see Whitfield et al., 2002). African Americans are also less likely to exercise than Caucasians are (Bassett et al., 2002; Whitfield et al., 2002), perhaps because many live in places where health clubs are scarce and it is not safe to walk outside.

Biological factors likely also play a role. Like most Americans, African Americans consume a lot of fast food, which is loaded with salt. There is evidence that, as a group, African Americans are more likely to retain sodium, which results in fluid retention and endocrine changes that in turn elevate blood pressure (Anderson & McNeilly, 1993). Renin, an enzyme produced by the kidneys that is linked to blood pressure, is also processed differently by African Americans. Finally, studies suggest that nitric oxide (a dissolved gas that is crucial for the proper functioning of blood vessels and blood cells) is produced in lower levels in the blood vessels of African Americans and may also be destroyed more quickly too. All of these biological differences, as well as the presence of some specific genes (see Fox et al., 2011), may increase the risk that African Americans have of developing hypertension.

### Coronary Heart Disease

The heart is a pump, made of muscle. Coronary heart disease (CHD) is a potentially lethal blockage of the arteries that supply blood to the heart muscle, or myocardium. If the muscles of the heart are not getting enough oxygenated blood, the person may experience severe chest pain (angina pectoris). This is a signal that the delivery of oxygenated blood to the affected area of the heart is insufficient for its current workload. An even more severe problem is myocardial infarction. This results from a blockage in a section of the coronary arterial system. Because the heart muscle is being deprived of oxygen, tissue may die, permanently damaging the heart. If the myocardial infarction is extensive

enough the person may not survive. Many instances of sudden cardiac death, in which victims have no prior history of CHD symptoms, are attributed to silent CHD. This often occurs when a piece of the atherosclerotic material adhering to the arterial walls (a “plaque”) breaks loose and lodges in a smaller vessel, blocking it. Every year, more than 900,000 people in the United States experience a myocardial infarction (Schwartz et al., 2010).

## Risk and Causal Factors in Cardiovascular Disease

**CHRONIC AND ACUTE STRESS** Stress increases the risk of having a heart attack. Several researchers have documented that deaths from CHD rise in the days and weeks following a severe earthquake (see Leor et al., 1996). As Figure 5.4 shows, after the Northridge earthquake in Los Angeles in 1994, the number of sudden deaths due to CHD rose from an average of 4.6 (in the days preceding the earthquake) to 24 on the day of the earthquake (Kloner et al., 1997). There was also an increase in sudden death from cardiac events after the Hanshin-Awaji earthquake in Japan (Kario & Ohashi, 1997).

Everyday forms of stress can also elevate risk for CHD and death (Matthews & Gump, 2002; Smith & Ruiz, 2002). A good example is work-related stress. Here the key factors appear to be having a highly demanding job and having little control over decision making. Both of these types of job stress increase risk for future CHD. Moreover, this association still holds when other negative health behaviors (such as smoking) are controlled (see Peter & Siegrist, 2000). It is also interesting to note that, in people who work, most heart attacks occur on a Monday. The stress of returning to work after the weekend is thought to play a role in this (Kloner et al., 2006).

Finally, simply being asked to give a 5-minute speech about an assigned topic to a small (but evaluative) audience was

## research CLOSE-UP

### Risk Factor

A risk factor is a variable that increases the likelihood of a specific (and usually negative) outcome occurring at a later time. For example, obesity is a risk factor for heart disease; perfectionism is a risk factor for eating disorders.

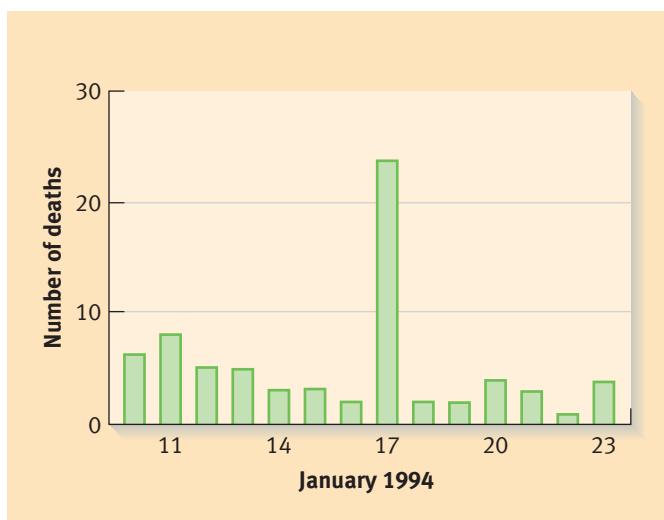

enough to produce detectable changes in cardiac function in about 20 percent of patients with existing coronary artery disease (see Sheps et al., 2002). Furthermore, those patients who were most reactive to this form of mental stress were almost three times more likely (compared to the less reactive patients) to die in the next 5 to 6 years. Mental stress is known to raise systolic blood pressure and also to cause an elevation in epinephrine. Mental stress may also reduce the oxygen supply to the heart muscle (Yeung et al., 1991). What the results of the Sheps study illustrate, however, is that stress does not have to be extreme or severe to be associated with lethal consequences later.

**PERSONALITY** Attempts to explore the psychological contribution to the development of CHD date back to the identification of the **Type A behavior pattern** (Friedman & Rosenman, 1959). Type A behavior is characterized by excessive competitive drive, extreme commitment to work, impatience or time urgency, and hostility. Many of us know people who are like this, and the term *Type A* is now quite commonly used in everyday language.

Interest in Type A behavior escalated after the results of the Western Collaborative Group Study began to be published. This investigation involved some 3,150 healthy men between the ages of 35 and 59 who, on entry, were typed as A or B status. (Type B personalities do not have Type A traits and tend to be more relaxed, more laid-back, and less time-pressured people.) All the men were then carefully followed for eight and a half years. Compared to Type B personality, Type A personality was associated with a twofold increase in coronary artery disease and an eightfold increased risk of recurrent myocardial infarction over the course of the follow-up (Rosenman et al., 1975).

The second major study of Type A behavior and CHD was the Framingham Heart Study. This began in 1948 and involved the long-term follow-up of a large sample of men and women from Framingham, Massachusetts (see Kannel et al., 1987). Approximately 1,700 CHD-free subjects were typed as A or B in the mid-1960s. Analysis of the data for CHD occurrence during an 8-year follow-up period not only confirmed the major findings of the earlier Western Collaborative Group Study but extended them to women as well.

Not all studies reported positive associations between Type A behavior and risk of coronary artery disease, however (Case et al., 1985; Shekelle et al., 1985). Moreover, as research

**FIGURE 5.4**

**Cardiac Deaths and Earthquakes.** On the day of the Northridge earthquake in California (January 17, 1994), cardiac deaths showed a sharp increase.

Source: Leor et al., 1996. *The New England Journal of Medicine*, 334(7), February 15, 1996, p. 415.

with the construct has continued, it has become clear that it is the hostility component of the Type A construct (including anger, contempt, scorn, cynicism, and mistrust) that is most closely correlated with coronary artery deterioration (see Rozanski et al., 1999, for a summary of studies).

A more recent development is the identification of the “distressed” or **Type D personality** type (Denollet et al., 2000). People with Type D personality have a tendency to experience negative emotions and also to feel insecure and anxious. Men with CHD who scored high on measures of chronic emotional distress were more likely to have fatal and nonfatal heart attacks over the 5-year follow-up period than were men who did not have these Type D personality traits (Denollet et al., 2000). People with higher scores on the negative affectivity component of Type D personality (see Figure 5.5) are also at increased risk of

### TEST: ARE YOU A TYPE D?

The social and emotional problems associated with Type D personality can increase your chances of developing heart disease. Read each statement and circle the appropriate number to indicate your answer. There are no right or wrong answers: your own impression is the only thing that matters.

#### 1 TAKE THE TEST Circle your answers:

	False	Less false	Neutral	Less true	True
1. I make contact easily when I meet people	4	3	2	1	0
2. I often make a fuss about unimportant things	0	1	2	3	4
3. I often talk to strangers	4	3	2	1	0
4. I often feel unhappy	0	1	2	3	4
5. I am often irritated	0	1	2	3	4
6. I often feel inhibited in social interactions	0	1	2	3	4
7. I take a gloomy view of things	0	1	2	3	4
8. I find it hard to start a conversation	0	1	2	3	4
9. I am often in a bad mood	0	1	2	3	4
10. I am a closed kind of person	0	1	2	3	4
11. I would rather keep people at a distance	0	1	2	3	4
12. I often find myself worrying about something	0	1	2	3	4
13. I am often down in the dumps	0	1	2	3	4
14. When socializing, I don't find the right things to talk about	0	1	2	3	4

#### 2 ADD YOUR ANSWERS

##### Negative Affectivity:

Add scores for questions 2, 4, 5, 7, 9, 12 and 13

##### Social Inhibition:

Add scores for questions 1, 3, 6, 8, 10, 11, and 14

#### 3 SCORE THE RESULTS

You qualify as a Type D personality if your Negative Affectivity is 10 or higher and your Social Inhibition is 10 or higher.

**FIGURE 5.5**

#### Characteristics of the Type D Personality.

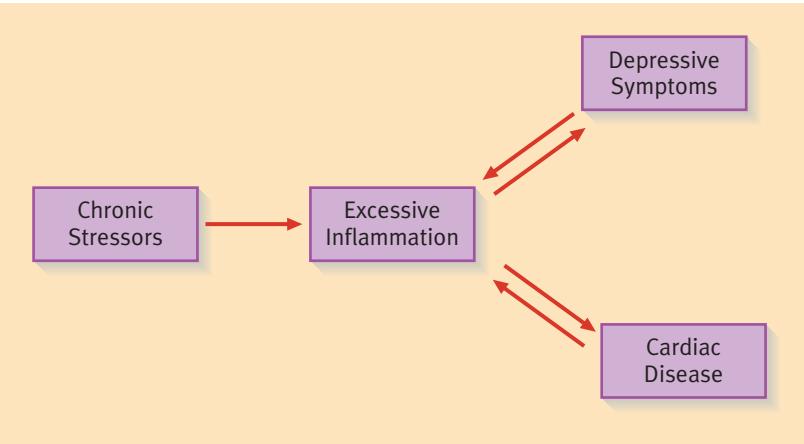

Source: Based on Johan Denollet. 1998 Personality and coronary heart disease: The type-D Scale-16 (DS16). *Annals of Behavioral Medicine*, 20 (3) 209–215, and N. Kupper and J. Denollet (2007). Type D Personality as a prognostic factor in heart disease: Assessment and mediating mechanisms. *Journal of Personality Assessment*, 89 (3) 265–276.

having more problems after cardiac surgery (Tully et al., 2011). Overall, the Type D personality construct also provides a way to tie in some of the other findings linking negative emotions and CHD, which we discuss more below.

**DEPRESSION** People with heart disease are approximately three times more likely than healthy people to be depressed (Chesney, 1996; Shapiro, 1996). This may not strike you as especially surprising. If you had heart disease, perhaps you would be depressed too. However, depression is much more commonly found in people who have heart disease than it is in people who have other serious medical problems, like cancer (Miller & Blackwell, 2006). Furthermore, heart attack patients with high levels of depressive symptoms after having a heart attack are three times more likely to die over the next 5 years than patients who do not show high levels of depression (Glassman, 2007; Lesperance et al., 2002). The most recent research in this area suggests that anhedonia (which is a symptom of depression characterized by profound loss of interest or pleasure) may be especially predictive of increased mortality after a heart attack (Davidson et al., 2010).

Depression also appears to be a risk factor for the *development* of CHD. Pratt and her colleagues (1996), for 14 years, followed over 1,500 men and women with no prior history of heart disease. They found that 8 percent of those who had experienced major depression at some point and 6 percent of those who had experienced mild depression at some point had a heart attack during the 14-year follow-up interval. By contrast, only 3 percent of those without a history of depression suffered heart attacks. When medical history and other variables were taken into account, those who had experienced major depression were found to be four times more likely to have had a heart attack. Similar findings have also been reported in other studies (Ferketich et al., 2000; Ford et al., 1998).

Why are depression and heart disease so closely linked? Current thinking is that this is another example of the mind–body connection. Stress is thought to activate the immune system, triggering the production of proinflammatory cytokines such as IL-1, IL-6, and tumor necrosis factor by the white blood cells. Long-term exposure to these proinflammatory cytokines is thought to lead to changes in the brain that manifest themselves as symptoms of depression. Proinflammatory cytokines also trigger the growth of plaques in the blood vessels as well as making it more likely that those plaques will rupture and cause a heart attack. In other words, as illustrated in Figure 5.6, the link between heart disease and depression is due to inflammation and the presence of inflammatory cytokines (see Miller & Blackwell, 2006; Robles et al., 2005). This is why doctors now test for the presence of C-reactive protein (CRP)—a molecule produced by the liver in response to IL-6—when they want to assess a person’s risk for heart disease. New research is also linking discrimination to elevated levels of CRP in African Americans (see The World Around Us box on p. 142).

**FIGURE 5.6**

Model of how inflammatory processes mediate the relations among chronic stressors, depressive symptoms, and cardiac disease. Stressors activate the immune system in a way that leads to persistent inflammation. With long-term exposure to the molecular products of inflammation, people are expected to develop symptoms of depression and experience progression of cardiac disease.

Source: Miller & Blackwell. 2006, Dec. Turning Up the Heat: Inflammation as a Mechanism Linking Chronic Stress, Depression and Heart Disease. *Current Directions in Psychological Science*, 15, (6): 269–272(4). Copyright © 2006. Reproduced with permission of Blackwell Publishing Ltd.

**ANXIETY** Depression is not the only form of negative affect that is linked to CHD. Research has also demonstrated a relationship between phobic anxiety and increased risk for sudden cardiac death. In a classic early study, Kawachi, Colditz, and colleagues (1994) studied nearly 34,000 male professionals who had been assessed for panic disorder, agoraphobia, and generalized anxiety. Over the course of the 2-year follow-up study, sudden cardiac death was six times higher in the men with the highest levels of anxiety. The findings were replicated in a second study of nearly 2,300 men who were participating in a normative aging study

(Kawachi, Sparrow, et al., 1994, 1995). Prospective studies of women (who were free of cardiac disease at the start of the study) have also linked phobic anxiety with a higher risk of sudden cardiac death (Albert et al., 2005).

**SOCIAL ISOLATION AND LACK OF SOCIAL SUPPORT** Studies point to the strong link between social factors and the development of CHD. Monkeys housed alone have four times more atherosclerosis (fatty deposits in blood vessels that eventually create a blockage) than monkeys housed in social groups (Shively

## the WORLD around us

### Racial Discrimination and Cardiovascular Health in African Americans

**E**xperiences of discrimination have been linked to a number of bad health outcomes, including increased blood pressure and signs of cardiovascular disease. But how might this association arise? New research suggests that an important mediator in this relationship could be C-reactive protein, or CRP.

CRP is a protein synthesized in the liver. High levels of CRP signal widespread inflammation in the body. In an interesting study, Lewis and colleagues (2010) measured levels of CRP in blood samples taken from 296 older African Americans, whose average age was 73. These research participants also completed a questionnaire that asked about their experiences of everyday discrimination. Items on the questionnaire included being treated with disrespect, getting poorer service in restaurants or stores, as well as experiences of being insulted or harassed.

The findings revealed a significant correlation between everyday discrimination and CRP, where more experiences of discrimination were associated with higher levels of CRP. The association also remained even after factors such as smoking, high blood pressure, depression, and other health problems

were considered. Although much more remains to be learned, these preliminary findings are very exciting. They provide a clue about a potential pathway through which experiences of racial bias might ultimately play a role in the poor cardiovascular health of older African Americans.

et al., 1989). Similarly, people who have a relatively small social network or who consider themselves to have little emotional support are more likely to develop CHD over time (see Rozanski et al., 1999, for a review).

For people who already have CHD, there is a similar association. In one study of people who had already suffered a heart attack, those who reported that they had low levels of emotional support were almost three times more likely to experience another cardiac event (Berkman et al., 1992). In another study, death in CHD patients was three times more likely over the next 5 years if they were unmarried or had no one that they could confide in (Williams et al., 1992). Echoing these findings, Coyne and colleagues (2001) have shown that the quality of the marital relationship predicts 4-year survival rates in patients with congestive heart failure. Although uncertain at this time, it may be that the stress that comes from marital tension or from a lack of social support triggers an inflammatory response in the immune system, causing depression and heart problems as a result. It may also be that depression, which is linked to relationship problems, could trigger an inflammatory response in its own right.

**THE IMPORTANCE OF EMOTION REGULATION** If hostility, depression, and anxiety are all predictive of developing coronary heart disease, is it beneficial to be able to regulate one's emotions? New research suggests that it is. In one study of men and women without a history of heart disease, it was found that it was the people who were *least* able to control their anger who developed more heart problems over the next 10 to 15 years (Haukkala et al., 2010). In another study of 1,122 men who were followed for an average of 13 years, it was again those with the best emotion regulation skills who were the least likely to develop cardiac disease (Kubzansky et al., 2011). Taken together these findings suggest that self-regulation skills may be very important—not only for our psychological well being but for our physical health as well.

## Treatment of Stress-Related Physical Disorders

As you have learned, environmental stressors are often closely linked to the development of a physical illness. Unfortunately, once an illness has developed and physical changes

have taken place, removal of the stressor may not be enough to bring about recovery and restore health. This emphasizes the value of prevention and highlights the importance of stress management.

### Biological Interventions

People who have serious physical diseases obviously require medical treatment for their problems. For patients with CHD, such treatments might include surgical procedures as well as medications to lower cholesterol or reduce the risk of blood clots. However, in light of the strong associations between depression and risk for CHD, treating depression is also of the utmost importance. Unfortunately, most people with clinical depression go untreated, resulting in an unnecessary added risk for CHD. Moreover, even though there is no medical risk factor that is more important in predicting mortality for patients who have already had a heart attack (Welin et al., 2000), physicians often fail to treat depression in their cardiac patients. Instead, they dismiss it as an understandable consequence of having had a life-threatening medical scare (Glassman, 2005). Of those with major depression at the time of a heart attack, approximately one-half of those who have gone without treatment remain depressed or else have relapsed again 1 year later (Hance et al., 1996). However, research shows that thousands of lives can be saved each year by giving antidepressant medications to patients who have suffered a myocardial infarction and who are depressed. In one study, patients treated with selective serotonin reuptake inhibitors (SSRIs) were much less likely to die or have another heart attack than patients who were not taking antidepressant medications (Taylor et al., 2005). It is also worth noting that, in this study, treatment with cognitive-behavior therapy (CBT; see Chapter 16 for more about this approach) was not associated with reduced mortality in the patients, although CBT treatment did help alleviate depression (see Berkman et al., 2003; Glassman, 2005).

### Psychological Interventions

How can we help ourselves stay healthy in the face of stress? As we have already mentioned, developing effective emotion regulation skills is probably beneficial. Evidence suggests that the following approaches are also helpful.

**EMOTIONAL DISCLOSURE** “Opening up” and writing expressively about life problems in a systematic way does seem to be an effective therapy for many people with illnesses (Pennebaker, 1997). In the first study of emotional disclosure in people with rheumatoid arthritis, Kelley, Lumley, and Leisen (1997) found that people who had written about their emotions had significantly less physical dysfunction than those assigned to a control condition. In another study, people with either rheumatoid arthritis or asthma were asked to write about either

their most traumatically stressful life experience or (in the case of the control group) their plans for the day. Subjects wrote for 20 minutes for 3 consecutive days. When they were assessed 4 months later, the participants with rheumatoid arthritis who were assigned to the emotional disclosure condition were doing significantly better than the participants with rheumatoid arthritis assigned to the control group.

In studies that involve emotional disclosure, patients often experience initial increases in emotional distress during the writing phase but then show improvement in their medical status over follow-up. Why emotional disclosure provides clinical benefits for patients is still not clear, however. One reason could be that patients are given an opportunity for emotional catharsis, or “blowing off steam.” Another possibility is that writing gives people an opportunity to rethink their problems. Given what we know about the link between emotional and physical well-being, it is not unreasonable to speculate that both emotional catharsis and rethinking problems could help improve immune function or perhaps decrease levels of circulating stress hormones.

**BIOFEEDBACK** Biofeedback procedures aim to make patients more aware of such things as their heart rate, level of muscle tension, or blood pressure. This is done by connecting the patient to monitoring equipment and then providing a cue (for example, an audible tone) to the patient when he or she is successful at making a desired response (e.g., lowering blood pressure or decreasing tension in a facial muscle). Over time, patients become more consciously aware of their internal responses and able to modify them when necessary.

Biofeedback seems to be helpful in treating some conditions, such as headaches (Nestoriuc et al., 2008). After an average of 11 sessions, patients report improvement in their symptoms and a decrease in the frequency of their headaches. Moreover, these treatment effects tend to be stable over time. Although it is especially helpful for children and adolescents, adults who have experienced headaches for a long time are also helped by biofeedback.

**RELAXATION AND MEDITATION** Researchers have examined the effects of various behavioral relaxation techniques on selected stress-related illnesses. The results have been variable, though generally encouraging. For example, there is evidence that relaxation techniques can help patients with essential hypertension (see Blumenthal et al., 2002). Relaxation training can also help patients who suffer from tension headaches (Holroyd, 2002). However, in general, headache sufferers treated with biofeedback appear to do better than those treated only with relaxation, and the best clinical results occur when these two treatments are combined (Nestoriuc et al., 2008).

A growing topic of interest is meditation. Schneider and colleagues (2005) have shown that the daily practice of

Making an effort to slow down and relax may provide many health benefits.

Transcendental Meditation may be helpful in reducing blood pressure. In this study, 194 African American patients with chronic hypertension were randomly assigned to receive training in either Transcendental Meditation or progressive muscle relaxation (which involves tensing and relaxing various muscle groups in a systematic way) or else to receive general information about lifestyle changes that would be helpful to them. Patients who practiced Transcendental Meditation for 20 minutes twice a day reduced their diastolic blood pressure significantly more than did patients who practiced muscle relaxation or who received sound health care advice.

**COGNITIVE-BEHAVIOR THERAPY** CBT has been shown to be an effective intervention for headache (Martin, Forsyth et al., 2007) as well as for other types of pain. CBT-oriented family therapy was markedly more successful than routine pediatric care in alleviating children’s complaints of recurrent abdominal pain (Robins et al., 2005). Some CBT techniques have also been used for patients suffering from rheumatoid arthritis. Compared to those receiving standard medical care, patients who received CBT showed better physical, social, and psychological functioning (Evers et al., 2002).

Finally, we note that making a conscious effort to slow down and enjoy life seems to be a prescription for better health. Meyer Friedman, who was the codiscoverer of the link between Type A behavior and heart disease, had a heart attack at age 55. A self-described Type-A personality, he made a conscious choice to change his ways in accordance with his own discoveries. To get more in touch with his slow, patient, and creative side, he read Proust’s languid seven-volume opus *Remembrance of Things Past* three times. In short, he trained himself to relax and to enjoy life. He had the last laugh at stress by living to the ripe old age of 90 (Wargo, 2007).

- What clinical approaches have been used to help people?

## STRESS AND MENTAL HEALTH

Our focus thus far has been to describe the nature of stress, highlighting the role it plays in physical disorders. But, as we have noted repeatedly throughout this chapter, when we experience stress, we pay a price not only in our bodies but also in our minds. In the sections below, we discuss the psychological consequences of experiencing the kind of stress that overwhelms our abilities to adjust and to cope. More specifically, we focus on two *DSM* disorders, **adjustment disorder** and PTSD. Both of these are triggered by exposure to stress. There is an important difference between them, however. In adjustment disorder, the stressor is something that is commonly experienced, and the nature of the psychological reaction is much less severe. In the case of PTSD, there is exposure to a traumatic stressor that is accompanied by fear, helplessness, or horror. Not surprisingly, the stress disorder that results from this can be intense and debilitating.

### Adjustment Disorder

An adjustment disorder is a psychological response to a common stressor (e.g., divorce, death of a loved one, loss of a job) that results in clinically significant behavioral or emotional symptoms. The stressor can be a single event, such as going away to college, or involve multiple stressors, such as a business failure and marital problems. People undergoing severe stress that exceeds their coping resources may warrant the diagnosis of adjustment disorder (Strain & Newcorn, 2007). For the diagnosis to be given, symptoms must begin within 3 months of the onset of the stressor. In addition, the person must experience more distress than would be expected given the circumstances or be unable to function as usual.

In adjustment disorder, the person's symptoms lessen or disappear when the stressor ends or when the person learns to adapt to the stressor. In cases where the symptoms continue beyond 6 months, the diagnosis is usually changed to some other mental disorder. Adjustment disorder is probably the least stigmatizing and mildest diagnosis a therapist can assign to a client. Next we discuss two situations that frequently lead to adjustment disorder.

### Adjustment Disorder Caused by Unemployment

Work-related problems can produce great stress in employees (Lennon & Limonic, 2010). But being unemployed can be even more stressful. As a result of the recent recession millions of Americans have been coping with chronic unemployment. Tony is one of them.

→ **Maybe Today Will Be the Day** Tony wakes up at 5:30 every morning and makes coffee. He arranges his laptop, phone,

and notepad on the kitchen table. And then he waits for the phone to ring. Unemployed for the last 16 months after losing his job as a transportation sales manager, Tony spends the day sending out resumes and cover letters. But most days nothing happens. "The worst moment is at the end of the day when it's 4:30 and you did everything you could, and the phone hasn't rung, the emails haven't come through," says Tony. He asks himself what he is doing wrong. Tony misses his old routine of getting dressed in the morning and going out to work. But he tries to stay optimistic. "You always have to hope that that morning when you get up, it's going to be the day." (Based on Kwok, 2010)

Unemployment reached a peak of 10.6 percent of the labor force in January 2010. It is now around 7.6 percent (Bureau of Labor Statistics, 2013). In almost every community, one can find workers who have been laid off from jobs they had held for many years and who are facing the end of their unemployment compensation. Unemployment is an especially severe problem for young minority males, many of whom live in a permanent economic depression with few job prospects. Rates of unemployment for blacks are twice as high as they are for whites (Bureau of Labor Statistics, 2013).

Managing the stress associated with unemployment requires great coping strength, especially for people who have previously earned an adequate living. Some people (like Tony in the case example above) find ways to stay focused and motivated, even though this can be very difficult at times. For others, however, unemployment can have serious long-term effects. One of the most disturbing findings is that unemployment, especially if it is prolonged, increases the risk of suicide (Borges et al, 2010; Classen & Dunn, 2011). Unemployment also takes its toll on other family members, especially children. When children live in families where a parent has lost a job, they are 15 percent more likely to have to repeat a grade at school (Stevens & Schaller, 2009).

## in review

- What is an adjustment disorder?
- What kinds of stressors are potential triggers for the development of an adjustment disorder?

## Posttraumatic Stress Disorder

In *DSM-5* post-traumatic stress disorder is now grouped with other disorders in a new diagnostic category called trauma- and stressor-related disorders. Adjustment disorder, which we have just discussed, and acute stress disorder (see next section) are also part of this new diagnostic category. This is because the experience of major stress is central to the development of all of these conditions.

→ **Watch the Video Bonnie: Posttraumatic Stress Disorder** on [MyPsychLab](#)

**Note:** The following criteria apply to adults, adolescents, and children older than 6 years.

**A.** Exposure to actual or threatened death, serious injury, or sexual violence in one (or more) of the following ways:

1. Directly experiencing the traumatic event(s).
2. Witnessing, in person, the event(s) as it occurred to others.
3. Learning that the traumatic event(s) occurred to a close family member or close friend. In cases of actual or threatened death of a family member or friend, the event(s) must have been violent or accidental.
4. Experiencing repeated or extreme exposure to aversive details of the traumatic event(s) (e.g., first responders collecting human remains; police officers repeatedly exposed to details of child abuse).

**Note:** Criterion A4 does not apply to exposure through electronic media, television, movies, or pictures, unless this exposure is work related.

**B.** Presence of one (or more) of the following intrusion symptoms associated with the traumatic event(s), beginning after the traumatic event(s) occurred:

1. Recurrent, involuntary, and intrusive distressing memories of the traumatic event(s).

**Note:** In children older than 6 years, repetitive play may occur in which themes or aspects of the traumatic event(s) are expressed.

2. Recurrent distressing dreams in which the content and/or affect of the dream are related to the traumatic event(s).

**Note:** In children, there may be frightening dreams without recognizable content.

3. Dissociative reactions (e.g., flashbacks) in which the individual feels or acts as if the traumatic event(s) were recurring. (Such reactions may occur on a continuum, with the most extreme expression being a complete loss of awareness of present surroundings.)

**Note:** In children, trauma-specific reenactment may occur in play.

4. Intense or prolonged psychological distress at exposure to internal or external cues that symbolize or resemble an aspect of the traumatic event(s).

5. Marked physiological reactions to internal or external cues that symbolize or resemble an aspect of the traumatic event(s).

**C.** Persistent avoidance of stimuli associated with the traumatic event(s), beginning after the traumatic event(s) occurred, as evidenced by one or both of the following:

1. Avoidance of or efforts to avoid distressing memories, thoughts, or feelings about or closely associated with the traumatic event(s).

**2.** Avoidance of or efforts to avoid external reminders (people, places, conversations, activities, objects, situations) that arouse distressing memories, thoughts, or feelings about or closely associated with the traumatic event(s).

**D.** Negative alterations in cognitions and mood associated with the traumatic event(s), beginning or worsening after the traumatic event(s) occurred, as evidenced by two (or more) of the following:

1. Inability to remember an important aspect of the traumatic event(s) (typically due to dissociative amnesia and not to other factors such as head injury, alcohol, or drugs).

2. Persistent and exaggerated negative beliefs or expectations about oneself, others, or the world (e.g., "I am bad," "No one can be trusted," "The world is completely dangerous," "My whole nervous system is permanently ruined").

3. Persistent, distorted cognitions about the cause or consequences of the traumatic event(s) that lead the individual to blame himself/herself or others.

4. Persistent negative emotional state (e.g., fear, horror, anger, guilt, or shame).

5. Markedly diminished interest or participation in significant activities.

6. Feelings of detachment or estrangement from others.

7. Persistent inability to experience positive emotions (e.g., inability to experience happiness, satisfaction, or loving feelings).

**E.** Marked alterations in arousal and reactivity associated with the traumatic event(s), beginning or worsening after the traumatic event(s) occurred, as evidenced by two (or more) of the following:

1. Irritable behavior and angry outbursts (with little or no provocation) typically expressed as verbal or physical aggression toward people or objects.

2. Reckless or self-destructive behavior.

3. Hypervigilance.

4. Exaggerated startle response.

5. Problems with concentration.

6. Sleep disturbance (e.g., difficulty falling or staying asleep or restless sleep).

**F.** Duration of the disturbance (Criteria B, C, D, and E) is more than 1 month.

**G.** The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

**H.** The disturbance is not attributable to the physiological effects of a substance (e.g., medication, alcohol) or another medical condition.

**Source:** Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, (Copyright 2013). American Psychiatric Association.

The diagnosis of PTSD first entered the *DSM* in 1980 (see the *DSM* table for current clinical criteria). At this time, psychiatry began to realize that many veterans were emotionally scarred and unable to return to normal civilian life after their military service in Vietnam. The proposal to include PTSD in the diagnostic system was initially opposed, not least because including a disorder that had a clear and explicit cause (trauma) was inconsistent with the atheoretical nature of the *DSM*. Nonetheless, a consensus emerged that any extreme, terrifying, and stressful event that was life-threatening and outside the ordinary bounds of everyday experience could lead to psychological symptoms similar to those experienced by the Vietnam veterans. In other words, at the time of its entry into the *DSM* (which is after all a manual of mental disorders), PTSD was viewed as a *normal* response to an *abnormal* stressor (see McNally, 2008). In the Thinking Critically About *DSM-5* below

we describe how changes to the diagnostic criteria for PTSD have changed over time.

However, in keeping with the diathesis-stress model, research over the past two decades has made it clear that certain preexisting vulnerabilities also play an important role. Traumatic stressors include combat, rape, being confined in a concentration camp, and experiencing a natural disaster such as a tsunami, earthquake, or tornado.

Stress symptoms are very common in the immediate aftermath of a traumatic event. However, for most people, these symptoms decrease with time. Rothbaum and Foa (1993) reported that 95 percent of women who had been raped met the symptom criteria for PTSD within 2 weeks of the assault. One month after the rape, this figure had declined to 63.3 percent of women, and after 3 months, 45.9 percent of the women were diagnosed with the PTSD. Natural recovery with time is therefore a common pattern.

## THINKING CRITICALLY about *DSM-5*

### Changes to the Diagnostic Criteria for PTSD

**DSM-5**

When PTSD was first introduced into the *DSM*, the diagnostic criteria required exposure to a traumatic event that was "outside the range of usual human experience" and that would cause "significant symptoms of distress in almost anyone." The exemplars provided included rape, earthquakes, torture, and military combat. In other words, the emphasis was on the nature of the stressor itself and not on the emotional response of the victim (Breslau & Kessler, 2001; McNally, 2008; Shalev, 2009).

A major change occurred with *DSM-IV-TR*. Not only was there a broadening of the range of experiences that could now be used to diagnose PTSD, but it was also required that the person's response involve "intense fear, helplessness or horror." Qualifying events could now include learning about the death of a close friend or relative (as long as the death was sudden and unexpected), being diagnosed with a life-threatening illness, or learning about traumatic events experienced by others. In short, there was a change in emphasis from the characteristics of the stressor to the experience of the victim. Rather than conceptualizing PTSD as a normal response to an *abnormal* stressor, in *DSM-IV*, PTSD was viewed as a *pathological response* to an extreme form of stress (McNally, 2008).

The implications of these changes were not trivial. Using the wider variety of stressors permitted in *DSM-IV*, a survey of community residents revealed that the vast majority (89.6%) reported that they had been exposed to a traumatic event that (given also the required level of emotional response and presence of other symptoms) would potentially qualify them for PTSD diagnosis (Breslau & Kessler, 2001). In most cases, the traumatic event was learning of the sudden and unexpected death of a loved one.

Moreover, females who reported traumatic events were much more likely than males to also report that they had had an emotional reaction that was severe enough for them to qualify for the PTSD diagnosis. So not only was the definition of a traumatic event broadened, but the kind of emotional response that qualifies for PTSD was much more likely to be reported by women than by men (Pratchett et al., 2010).

In *DSM-5*, the diagnostic criteria for PTSD have been tightened. The traumatic event must now be experienced by the person directly, either because the event happens to you or because you witness, in person, something traumatic happening to someone else. No longer is it possible to experience trauma indirectly through electronic media (which could occur when someone watches television footage of a terrible event). As before, there is also a provision for experiencing trauma by learning of the death of another person. However, the person must be a close friend or relative and their death must have been violent or accidental. Yet another change is the removal of the requirement that the person respond in a particular way (i.e., with fear, helplessness, or horror) because this confounds the response with the event itself (McNally, 2009) and also makes it more likely that women will receive the diagnosis. Defining trauma exposure is difficult to do. Nonetheless, we believe that the modifications that have been made to the *DSM* criteria are good overall. Tightening the diagnostic criteria in these ways means that PTSD is more likely to remain a distinct diagnosis reserved for people who have experienced devastating life events. No longer will it be possible to diagnose PTSD in people who merely watch traumatic events on their computer or television screens and are very distressed by what they see.

## Acute Stress Disorder

The diagnosis of PTSD requires that symptoms must last for at least 1 month. What this means is that, in the study just described, the women who had symptoms within 2 weeks of the assault would not be diagnosed with PTSD. Instead, the diagnosis would be **acute stress disorder**. Acute stress disorder is a diagnostic category that can be used when symptoms develop shortly after experiencing a traumatic event and last for at least 2 days. The existence of this diagnosis means that people with symptoms do not have to wait a whole month to be diagnosed with PTSD. Instead they can receive treatment as soon as they experience symptoms (Cardéna & Carlson, 2011). Moreover, if symptoms persist beyond 4 weeks, the diagnosis can be changed from acute stress disorder to posttraumatic stress disorder. Studies show that people who develop an acute stress disorder shortly after traumatic event are indeed at increased risk of developing PTSD (Kleim et al., 2007). This highlights the importance of early intervention.

Of course, PTSD is not the only disorder that can develop after a traumatic experience. Bryant and colleagues (2010) conducted a prospective study of a large sample of people who were injured in accidents. They were assessed at the time of their injury and then followed up 3 and 12 months later. The investigators found that, 12 months after injury, 31 percent of patients reported a psychiatric disorder, and 22 percent of them had a disorder they had never experienced before. The most common disorders were depression (9%), generalized anxiety disorder (9%), and PTSD (6%).

## Clinical Description

In PTSD a traumatic event is thought to cause a *pathological memory* that is at the center of the characteristic clinical symptoms associated with the disorder (McNally, 2013). These memories are often brief fragments of the experience and often concern events that happened just before the moment with the largest emotional impact (e.g., “Perpetrator standing at the window with the knife,” Hackman et al., 2004). In *DSM-5*, the clinical symptoms of PTSD are grouped into four main areas. These concern the following:

1. **Intrusion:** Recurrent reexperiencing of the traumatic event through nightmares, intrusive images, and physiological reactivity to reminders of the trauma. (In *DSM-IV* ruminate thoughts about the trauma were also considered to reflect intrusion. This is not the case in *DSM-5*).
2. **Avoidance:** Avoidance of thoughts, feelings or reminders of the trauma.
3. **Negative cognitions and mood:** This includes such symptoms as feelings of detachment as well as negative emotional states such as shame or anger, or distorted blame of oneself or others.
4. **Arousal and reactivity:** Hypervigilance, excessive response when startled, aggression, and reckless behavior.

These are illustrated in the following case.

→ **Abducted and Terrorized** Mr. A. was a married accountant, the father of two, in his early 30s. One night, while out running an errand, he was attacked by a group of young men. They forced him into their car and took him to a deserted country road. There they pulled him from the car and began beating and kicking him. They took his wallet, began taunting him about its contents (they had learned his name, his occupation, and the names of his wife and children), and threatened to go to his home and harm his family. Finally, after brutalizing him for several hours, they tied him to a tree. One man held a gun to his head. Mr. A. begged and pleaded for his life; then the armed assailant pulled the trigger. The gun was empty, but at the moment the trigger was pulled, Mr. A. defecated and urinated in his pants. Then the men untied him and left him on the road.

Mr. A. slowly made his way to a gas station and called the police. [One of the authors] was called to examine him and did so at intervals for the next 2 years. The diagnosis was PTSD. Mr. A. had clearly experienced an event outside the range of normal human experience and was reexperiencing the event in various ways: intrusive recollections, nightmares, flashbacks, and extreme fear upon seeing groups of tough-looking young men. He was initially remarkably numb in other respects: He felt estranged and detached. He withdrew from his family, lost interest in his job, and expected to die in the near future. Mr. A. also showed symptoms of increased physiological arousal. His sleep was poor, he had difficulty concentrating, and he was easily startled. When Mr. A. first spoke about his abduction in detail he actually soiled himself at the moment he described doing so during the original traumatic experience.

Mr. A. received treatment from a psychiatrist for the next 2 years. This consisted of twice-weekly individual psychotherapy as well as antidepressant medications. A focus of the therapy was the sense of shame and guilt Mr. A. felt over his behavior during his abduction. He wished he had been more stoic and had not pleaded for his life. With the help of his therapist, Mr. A. came to see that his murderous rage at his abductors was understandable, as was his desire for revenge. He was also able to accept that his response to his experience was likely similar to how others might have responded if faced with the same circumstances. By the end of treatment Mr. A. was almost without symptoms, although he still became somewhat anxious when he saw some groups of young men. Most important, his relationship with his wife and children was warm and close, and he was again interested in his work.

## Prevalence of PTSD in the General Population

Estimates from the National Comorbidity Survey-Replication (NCS-R) suggest that the lifetime prevalence of PTSD in the United States is 6.8 percent (Kessler, Berglund, Demler, et al., 2005b). However, this figure obscures the sex difference in the prevalence of PTSD. The NCS-R data show that the lifetime

prevalence of PTSD is higher in women. Over the course of their lives, 9.7 percent of women and 3.6 percent of men will develop this disorder.

The difference in the prevalence of PTSD in men and women is interesting, not least because studies show that men are much more likely to be exposed to traumatic events (Tolin & Foa, 2006). Some have suggested that the sex difference reflects the fact that women are more likely to be exposed to certain kinds of traumatic experiences, such as rape, that may be inherently more traumatic (Cortina & Kubiak, 2006). However, even when the type of traumatic event is controlled for, women still show higher rates of PTSD and tend to have more severe symptoms (Tolin & Foa, 2006). This suggests that there are differences between men and women that may determine their risk of developing PTSD after experiencing trauma.

### Rates of PTSD After Traumatic Experiences

Disasters, both naturally occurring and human-caused, are far from rare occurrences. In a typical year countless people are exposed to the kinds of traumatic events that can cause PTSD. For example, more than 900 earthquakes with a magnitude between 5 and 8 on the Richter scale occur annually throughout the world (Naeem et al., 2011). Tsunamis also devastate coastal villages, and hurricanes, tornadoes, and floods destroy lives and livelihoods. Of course, some places are safer than others. Not surprisingly, rates of PTSD throughout the world tend to be lower in areas where people experience fewer natural disasters and where wars and organized violence are less common.

Traumatic stressors include combat, rape, and experiencing a natural disaster such as an earthquake, flood, tornado, or hurricane.

Estimates of the prevalence of PTSD vary widely across different studies (Sundin et al., 2010). One reason for this is that rates of PTSD seem to vary according to the type of trauma that is experienced. More specifically, traumatic events that result from human intent (such as rape) are more likely to cause PTSD than are traumatic events (such as accidents and natural disasters) that are not personal in nature (see Charuvastra & Cloitre, 2008). For example, Shalev and Freedman (2005) compared rates of PTSD after car accidents and after terrorist attacks in the same community in Israel. Interviews were conducted 1 week and 4 months after the traumatic event had occurred. Although there were no differences in the symptoms that people reported at the 1-week interview, at 4 months, rates of PTSD were much higher in the terrorist attack survivors than in those who had survived the car accidents. Traumatic events involving humans who do terrible things are perhaps even more difficult to come to terms with because they can destroy the sense of safety we often assume comes from being a member of a rule-abiding and lawful social group.

Another factor that is crucially important with respect to the development of PTSD is the degree of direct exposure to the traumatic event. After reviewing all published disaster research over a 25 year period, Neria, Nandi, and Galea (2008) have estimated that rates of PTSD range between 30 and 40 percent for adults who are directly exposed to disasters. The prevalence of PTSD in rescue workers, on the other hand, tends to be lower (5–10%), probably because they are not directly exposed to the traumatic event when it is happening. Nonetheless, these figures highlight the risk of PTSD in rescue workers. They also show that disasters leave large numbers of traumatized people in their wakes.

Finally, we should point out that difference in rates of PTSD across different studies may sometimes be linked to the way that PTSD is defined and the manner in which it is assessed. Estimates based on questionnaires tend to be higher than those based on clinical interviews. For example, in a study of Dutch veterans of the Iraq War, questionnaire assessments yielded rates of PTSD of 21 percent. However, when structured diagnostic interviews were used, only 4 percent of veterans met criteria for PTSD (Engelhard et al., 2007). Reasons for the overestimates when questionnaire measures are used include misunderstanding the meaning of items on the questionnaire, presence of symptoms that cause little impairment in functioning, as well as inclusion of symptoms that began at times other than during or after a traumatic event.

**THE TRAUMA OF MILITARY COMBAT** In a combat situation, with the continual threat of injury or death and repeated narrow escapes, a person's ordinary coping methods are relatively useless. The adequacy and security the person has known in the relatively safe and dependable civilian world are completely undermined. Combat brings with it constant fear, unpredictability,

many uncontrollable circumstances, and the necessity of killing. Other factors may further contribute to the overall stress experienced by soldiers. These include separations from loved ones, reductions in personal freedom, sleep deprivation, extreme and harsh climate conditions, and increased risk for disease.

Many people who have been involved in the turmoil of war experience devastating psychological problems for months or even years afterward (Garakani et al., 2004). During World War I, traumatic reactions to combat conditions were called “shell shock,” a term coined by a British pathologist, Col. Frederick Mott (1919), who regarded these reactions as organic conditions produced by minute brain hemorrhages. It was gradually realized, however, that only a small percentage of such cases represented physical injury. Most victims were suffering instead from the general combat situation, with its physical fatigue, ever-present threat of death or mutilation, and severe psychological shocks. During World War II, traumatic reactions to combat were known as *operational fatigue* and *war neuroses*, before finally being termed *combat fatigue* or *combat exhaustion* in the Korean and Vietnam Wars. Even the latter terms were none too aptly chosen because they implied that physical exhaustion played a more important role than was usually the case.

It has been estimated that in World War II, 10 percent of Americans in combat developed combat exhaustion. However, the actual incidence is not known because many soldiers received supportive therapy at their battalion aid stations and were returned to combat within a few hours. Recent evaluations of World War II psychiatric casualty files concluded that this practice of “forward psychiatry” was not effective at returning soldiers with shell shock to combat, but their improved mood and adjustment allowed them to be reassigned to noncombat roles, resulting in reduced manpower losses overall (Jones et al., 2007). In World War II, combat exhaustion was the greatest single cause of loss of personnel (Bloch, 1969).

#### MENTAL HEALTH CONSEQUENCES OF DEPLOYMENT TO

**IRAQ AND AFGHANISTAN** Almost 2 million members of the Armed Forces have deployed for operations in Iraq and Afghanistan (Department of Defense, 2010). During these deployments they are exposed to many traumatic experiences and have to function under conditions of sustained threat. The overwhelming majority (92%) of Army soldiers and Marines in Iraq report that they have been attacked or ambushed, and 86 percent report knowing someone who has been killed or seriously injured (Hoge et al., 2004). Not surprisingly, this takes its toll on their mental health.

The high prevalence of postdeployment mental disorders in these military personnel is now a major source of concern. One recent survey of over 289,328 Iraq and Afghanistan war veterans reported that 21.8 percent received diagnoses of PTSD and 17.4 percent were diagnosed with depression (Seal et al., 2009). Another study by Booth-Kewley and colleagues (2010) found that 17.1 percent of Marines reported symptoms of PTSD after

deployment in Iraq or Afghanistan. These figures are higher than the rates of PTSD reported for veterans of the Vietnam War (12–16%; Thompson et al., 2006) and Gulf War (12%; Kang et al., 2003). They are also higher than rates of PTSD in UK military personnel following deployment to Iraq or Afghanistan (4.8%; see Iversen et al., 2009). In addition to PTSD and depression, postdeployment rates of alcohol misuse and problems with aggression are also elevated (Thomas et al., 2010).

The high prevalence of mental disorders in men and women returning from Iraq and Afghanistan may be a consequence of longer and more frequent deployments. Some brigade combat teams have been deployed three or four times (Thomas et al., 2010). But other factors may also be involved. In 2006 concerns were raised in the media that military psychiatrists had been sending mentally unfit service members into combat. Later that same year, minimal mental health standards for deployment were developed by the Department of Defense (Warner et al., 2011). A prospective longitudinal study has now confirmed that psychiatric problems measured predeployment significantly increase the risk of developing PTSD postdeployment (Sandweiss et al., 2011). This highlights the importance of mental health screening prior to deployment and the need to provide additional resources and support for soldiers who may be most vulnerable.

The most methodologically rigorous study of PTSD in members of the armed forces who served in Iraq or Afghanistan was conducted by Smith et al. (2008). This large longitudinal study excluded people who had PTSD prior to their deployment. Overall, the rate of PTSD in the military personnel who were studied was 4.3 percent. As one might expect, the rate was higher (7.8%) for those exposed to combat and lower (1.4%) in those who did not have combat exposure.

There is also evidence that theater-specific duties may be shaping some of the symptoms that veterans have. In addition to PTSD, clinicians are now seeing veterans with compulsive checking behaviors, as in the following case example.

→ **Still Checking for Bombs** A 38-year-old married black army veteran of two deployments to Iraq came to the VA medical center stating, “My commanding officer suggested that I get help.” The patient’s primary duties during both of his tours included providing security for truck convoys by patrolling alongside them in an armed Humvee. In the course of his duties he was exposed to multiple life-threatening situations, witnessed an improvised explosive device detonate during a convoy, witnessed dead and mutilated bodies, witnessed a motor vehicle run over a little girl, and was responsible for checking the convoy trucks and accompanying vehicles for bombs. At the time of his contact with the clinic he was experiencing more than 10 direct intrusive memories. He engaged in avoidance through attempted thought suppression, doing his errands late at night to avoid people, and staying home as much as possible while not

at work. The patient also checked under the hood of his car for bombs every time he needed to drive. Although he knew that his checking was not normal and was embarrassed by it, he felt that the danger of someone placing a bomb under his car was too great not to check.

Source: Adapted from Tuerk et al., 2009.

The military is also now trying to cope with another serious problem—soldier suicide. In the 5-year period from 2005 through 2009, more than 1,100 members of the Armed Forces took their own lives—a rate equivalent to one suicide every 36 hours (Department of Defense, 2010). Most of these suicides result from self-inflicted gunshot wounds. Suicide rates in the U.S. Army are especially high. Clay's story serves as a tragic reminder of how destructive and invisible some of the wounds of war can be.

**→ A Warrior Takes His Own Life** Clay was a handsome and friendly 28-year-old. A former Marine corporal, he received a Purple Heart after taking a bullet in Iraq and later returned to combat in Afghanistan. After his deployment was over Clay became involved in humanitarian work in Chile and Haiti. He lobbied in Washington to improve the disability claims process for veterans and was chosen to appear in a public service announcement to remind veterans that they were not alone. But Clay's smiles and boundless energy were masks covering the emotional pain he lived with every day. Clay suffered from PTSD and depression. He also experienced survivor guilt, asking himself why he had survived when many people he had served with had died. One day in the early spring, Clay locked the door of his apartment and shot himself. His death leaves a void in the lives of his family and friends. It also highlights the need for renewed efforts within the military to address the growing problem of suicide by members of the armed forces. (Based on Helfling, 2011).

**PRISONERS OF WAR AND HOLOCAUST SURVIVORS** Among the most stressful and persistently troubling wartime experiences is that of being a prisoner of war (Beal, 1995; Page et al., 1997). Although some people have been able to adjust to the stress (especially when part of a supportive group), the toll on most prisoners is great. About 40 percent of the American prisoners in Japanese POW camps during World War II died during their imprisonment; an even higher proportion of prisoners of Nazi concentration camps died. Many survivors of Nazi concentration camps sustained residual organic and psychological damage, along with a lowered tolerance to stress of any kind. Symptoms were often extensive and commonly included anxiety, insomnia, headaches, irritability, depression, nightmares, impaired sexual potency, and diarrhea (which may accompany even relatively mild stress). Such symptoms were attributed not only to the psychological stressors

but also to biological stressors such as head injuries, prolonged malnutrition, and serious infectious diseases (Sigal et al., 1973; Warnes, 1973).

Among returning POWs, the effects of the psychological trauma they had experienced were often masked by the feelings of relief and jubilation that accompanied release from confinement. Even when there was little evidence of residual physical pathology, however, survivors of prisoner-of-war camps commonly showed impaired resistance to physical illness, low frustration tolerance, dependence on alcohol and drugs, irritability, and other indications of emotional instability (Chambers, 1952; Goldsmith & Cretekos, 1969; Hunter, 1978; Strange & Brown, 1970; Wilbur, 1973).

In a retrospective study of psychological maladjustment symptoms following repatriation, Engdahl and colleagues (1993) interviewed a large sample of former POWs and found that half of them reported symptoms that met standard criteria for PTSD in the year following their releases from captivity; nearly a third met PTSD criteria 40 to 50 years after their wartime experiences.

Another measure of the toll taken by the prolonged stress of being in a POW or concentration camp is the higher death rate after return to civilian life. Among returning World War II POWs from the Pacific area, Wolff (1960) found that within the first 6 years, nine times as many died from tuberculosis as would have been expected in civilian life; four times as many from gastrointestinal disorders; over twice as many from cancer, heart disease, and suicide; and three times as many from accidents. Many problems of adjustment and posttraumatic symptoms can be found in POWs years after their release (Sutker & Allain, 1995).

#### PSYCHOLOGICAL TRAUMA AMONG VICTIMS OF TORTURE

Among the most highly stressful experiences human beings have reported are those inhuman acts perpetrated upon them by other human beings in the form of systematic torture. From the beginning of human history to the present, some people have subjected others to pain, humiliation, and degradation for political or inexplicable personal reasons (Jaranson & Popkin, 1998). History and literature are full of personal accounts of intense suffering and lifelong dread resulting from maltreatment by ruthless captors. In addition, several empirical studies have reported on the prevalence of torture in the modern world: Allden and colleagues (1996) reported that 38 percent of Burmese political dissidents who escaped to Thailand had been tortured before their escape. Shrestha and colleagues (1998) compared Bhutanese survivors of torture in a Nepalese refugee camp with matched controls and found that torture survivors had more PTSD, anxiety, and depressive symptoms than the controls. Similar findings were reported by van Ommeren and colleagues (2001), who compared tortured and nontortured Bhutanese refugees and reported that those acknowledging being tortured had more PTSD and higher rates of lifetime mood and generalized anxiety disorders. Silove and colleagues (2002) also found higher PTSD

scores in a sample of Tamil torture victims living in Australia compared with refugees who had not been tortured. The case of Muhammad B. illustrates many of the symptoms that can follow systematic torture.

→ **Muhammad B.'s Captivity** Muhammad B., a 21-year-old Ethiopian refugee, lives with his mother, father, two younger brothers, and two younger sisters in a small center-city apartment building in a large Midwestern city. He works part time as a parking lot attendant and attends night school, majoring in business. Muhammad has been in the United States for 5 years after a very tumultuous period in his home country. He was held for interrogation, along with several other young people from his village, in a government prison compound for several months when he was 15 years old. The treatment the captives received was severe, including starvation and frequent physical punishment. During a 7-month period of confinement, he was interrogated, usually after a severe beating or after being shown the bodies of other prisoners, in an effort by his captors to obtain information about the whereabouts of antigovernment guerilla fighters. On one occasion he was questioned while one of the guards held a rifle barrel in his mouth, and on another occasion he was subjected to a "staged execution" in order to get him to talk. After the captors determined that he had no relevant information, he was released. His family was able to escape the country shortly afterward.

Since his release from imprisonment, Muhammad has experienced severe PTSD symptoms including night terrors, sleeping disturbances, attacks of intense anxiety, and depression. He reports almost constant headaches and pains in the hand that was broken by his captors.

Although Muhammad has been able to complete high school successfully in the United States and has accumulated a year of college credit going to school part time, his day-to-day functioning is characterized by disabling intrusive thoughts, anxiety, nightmares, and recurring depression.

Other symptoms experienced after torture have been well documented (Başoğlu & Mineka, 1992; Carlsson et al., 2006). They include physical symptoms (such as pain, nervousness, insomnia, tremors, weakness, fainting, sweating, and diarrhea), psychological symptoms (such as night terrors and nightmares, depression, suspiciousness, social withdrawal and alienation, irritability, and aggressiveness), cognitive impairments (such as trouble concentrating, disorientation, confusion, and memory deficits), and disturbed behaviors (such as aggressiveness, impulsivity, and suicidal attempts).

Başoğlu and colleagues (1994) reported the results of a unique empirical study in which 55 former Turkish prisoners who were political activists and had been tortured were compared with 55 political activists who had not been tortured.

The torture victims and control subjects were matched on demographic variables including age, gender, education level, ethnic status, and occupation. Standard assessment techniques, including a psychiatric interview and psychological tests, were also used.

One of the most interesting findings from this study was the relatively low rate of PTSD (33 percent) in the political activists who had been tortured. This is especially remarkable because they had been imprisoned for an average of almost 4 years, endured nearly 300 episodes of torture, and been tortured in many different ways. Victims who were able to assert some element of cognitive control over the circumstances (for example, those who were able to predict and ready themselves for the pain they were about to experience) tended to be less affected over the long term (see Başoğlu & Mineka, 1992; Başoğlu et al., 1997). These investigators concluded that prior knowledge of and preparedness for torture, strong commitment to a cause, immunization against traumatic stress as a result of repeated exposure, and strong social supports have protective value against PTSD in survivors of torture.

## Causal Factors in Posttraumatic Stress Disorder

The study of causal risk factors that might be involved in the development of PTSD has been a controversial area (McNally, 2008). There are two major reasons for this. First, the very notion of PTSD makes it explicit that PTSD is caused by experiencing trauma. So why should we look any further if we wish to know what causes PTSD? The second concern is that, if some people are more likely to develop PTSD in the face of severe stress than other people are, might this not lead to double victimization, with victims of trauma also being stigmatized and being blamed for the troubles that they have?

On the other side of the issue, we know that not everyone who is exposed to a traumatic event will develop PTSD. This suggests that some people may be more vulnerable to developing PTSD than others. In order to prevent and better treat this disorder, we therefore need to understand more about the factors that are involved in its development.

As we have already noted, the nature of the traumatic stressor and how directly it was experienced can account for much of the differences in stress response. For example, there is a close relationship between the total number of people killed and wounded and the number of psychiatric casualties in war (Jones & Wessely, 2002). Soldiers who report killing or being responsible for killing during their deployment are also more vulnerable to developing PTSD (Maugen, Lucenko et al., 2010b).

If the level of stress is high enough, then, the average person can be expected to develop some psychological difficulties (which may be either short-lived or long term) following a traumatic event. But why is the breaking point of one person

different from the breaking point of another? Some of the answers may lie in factors that we have discussed earlier in this chapter. In the sections below, we highlight some areas that appear to be important.

## Individual Risk Factors

When it comes to risk for PTSD, we need to keep two things in mind: As has been noted by researchers in this field, there is *risk for experiencing trauma* and there is also *risk for PTSD* given that there has been exposure to trauma (see McNally, 2013). Not everyone is at equal risk when it comes to the likelihood that she or he will experience a traumatic event. Certain occupations, such as being a soldier or a firefighter, carry more risk than others, such as being a librarian. Risk factors that increase the likelihood of being exposed to trauma include being male, having less than a college education, having had conduct problems in childhood, having a family history of psychiatric disorder, and scoring high on measures of extraversion and neuroticism (Breslau et al., 1991, 1995). Rates of exposure to traumatic events are also higher for black Americans than they are for white Americans.

Given that someone has been exposed to a traumatic event, what factors increase risk for *developing* PTSD? As we have already noted, being female is a risk factor. Other individual risk factors that have been identified by researchers include lower levels of social support, neuroticism (having a tendency to experience negative affect), having preexisting problems with depression and anxiety, as well as having a family history of depression, anxiety, and also substance abuse (see McNally, 2013; Wilk, Bliese, et al. 2010). Also relevant are the appraisals people make of their own stress symptoms shortly after the trauma. If people believe that their symptoms are a sign of personal weakness or if they believe that others will be ashamed of them because they are experiencing symptoms, they are at increased risk for developing PTSD, even when the level of initial symptoms is statistically controlled (Dunmore et al., 2001).

Certain occupations place people at higher risk of experiencing a traumatic event.

On the other side of the coin, are there factors that may be *protective* and buffer against PTSD? Good cognitive ability seems to be important here. Breslau et al., (2006) collected IQ data from 6-year-old children who lived in and around Detroit. When these children reached the age of 17, they were interviewed and assessed both for exposure to trauma and for PTSD. The children who at age 6 had IQ scores above 115 were less likely to have experienced a traumatic event by age 17; furthermore, if they *had* been exposed to trauma, they were at lower risk for developing PTSD. These findings suggest that having a higher IQ may be protective against experiencing trauma and developing PTSD because children who had average or below-average IQ scores were at similar risk for PTSD.

Similar findings have also been reported for Vietnam veterans. Kremen and colleagues (2007) collected information from a large sample of twins and also obtained information about their cognitive ability scores before they went to serve in Vietnam. All of the men involved in the study were subsequently exposed to traumatic events during their military service. Compared with men who had scored in the lowest quartile on the Armed Forces Qualification Test (a measure of cognitive ability), men who had scored in the highest quartile had a 48 percent *lower risk* of developing PTSD.

Why might higher pretrauma cognitive abilities provide protection against PTSD? One possibility is that individuals with more intellectual resources might be better able to create some meaning from their traumatic experiences and translate them into a personal narrative of some kind. Earlier in this chapter, we discussed the therapeutic benefits of systematically writing about distressing events (Pennebaker, 1997). Perhaps people with higher cognitive abilities are more naturally able to incorporate their traumatic experiences into their life narratives in ways that are ultimately adaptive and emotionally protective.

**BIOLOGICAL FACTORS** Given that PTSD is a stress disorder, it might be expected that people with this disorder would have high levels of stress hormones such as cortisol. However, this does not generally seem to be the case (Young & Breslau, 2004). Under conditions of imposed experimental stress (trauma reminders, cognitive challenges), people with PTSD do seem to show an exaggerated cortisol response (de Kloet et al., 2006). However, baseline levels of cortisol are often very similar in people with PTSD compared to those of healthy controls (Meewisse et al., 2007).

Gender may be an important factor here, however. Women with PTSD do seem to have higher levels of baseline cortisol than women without PTSD. This is not so for men with and without PTSD. Another interesting finding is that levels of cortisol tend to be lower in people with PTSD who have experienced physical or sexual abuse. In other words, the type of trauma may be an important factor (Meewisse et al., 2007). Although many

of the findings in this area are confusing, researchers are still exploring biological dysregulations in PTSD.

Another focus of research interest is gene–environment interactions. Earlier we discussed how people with a particular form of a particular gene (the 5HTTLPR, or serotonin transporter gene) seem to be more at risk for developing depression in the face of four or more life events. Data now suggest that this gene may also be a risk factor for the development of PTSD. Kilpatrick and colleagues (2007) collected DNA data and interviewed 589 adults from Florida 6 to 9 months after the 2004 hurricane season. The prevalence of post-hurricane PTSD in the sample overall was 3.2 percent. Risk factors for developing PTSD were a high level of exposure to the hurricanes and low levels of social support. However, people who had the high-risk (*s/s*) genotype of the serotonin-transporter gene were at especially high risk for the development of PTSD if they *also* had high hurricane exposure *and* low social support. For those in this group, the rate of PTSD was 14.8 percent—4.5 times higher. People with the *s/s* genotype were also more likely to develop depression if they had high hurricane exposure and low social support. These findings suggest that having the *s/s* form of the serotonin-transporter gene makes a bad situation worse. People with this genotype may be especially susceptible to the effects of traumatic stress, particularly if they also have low levels of social support.

What do we know about the brains of people with PTSD? Studies show that a brain area called the hippocampus seems to be reduced in size in people with PTSD. The hippocampus is a brain area known to be involved in memory. It is also a brain area known to be responsive to stress. In a landmark study, Gilbertson and colleagues (2002) measured the volume of the hippocampus in combat veterans with and without PTSD. The results showed that the veterans with PTSD had smaller hippocampal volumes than did the veterans without PTSD. The reason this study is so important, however, is that all the men were MZ (identical) twins. And when Gilbertson and colleagues looked at the volume of the hippocampus in the healthy co-twins of the combat veterans with PTSD, they found that these men *also had small hippocampal volumes*, just like their brothers. In contrast, the combat veterans who did not have PTSD, as well as their twins (who had not been involved in combat), had similar (and larger) hippocampal volumes. What these findings suggest, then, is that for reasons we do not yet understand, small hippocampal volume may be a vulnerability factor for developing PTSD in people who are exposed to trauma.

A major problem with research in this area is that many of the brain abnormalities associated with PTSD (including reduced hippocampal size) are also found in people who are depressed. Because PTSD and depression are highly comorbid and co-occurring disorders, it is therefore hard for researchers to be sure which brain abnormalities are specific to PTSD and which might stem from depression (Kroes et al., 2011). But perhaps it is a bit naïve to expect that PTSD would be

associated with brain abnormalities that are completely unique and distinct and that are not shared with any other disorders. We know that stress plays a role in the development of depression and the development of PTSD. We also know that stress (via glucocorticoids) has a negative impact on brain areas (like hippocampus) that are important for healthy emotional functioning. Why then should we not expect to see some commonalities when we look at people who have disorders in which stress is implicated?

## Sociocultural Factors

Being a member of a minority group seems to place people at higher risk for developing PTSD. DiGrande and colleagues (2011) studied 3,271 civilians who were evacuated from the World Trade Center towers on September 11, 2001. Two to three years after the attacks 15 percent of people were assessed as having PTSD. Compared with whites, African American and Hispanic survivors were more likely to have PTSD. Echoing the discussion of resilience earlier in this chapter, being more educated and having a higher annual income were also factors associated with lower rates of PTSD overall.

Returning to a negative and unsupportive social environment can also increase vulnerability to posttraumatic stress (Charuvastra & Cloitre, 2008). For example, in a 1-year follow-up of Israeli men who had been psychiatric war casualties during the Yom Kippur War, Merbaum (1977) found that not only did these men continue to show extreme anxiety, depression, and extensive physical complaints, but (in many instances) they also appeared to become more disturbed over time. Merbaum hypothesized that the men's further psychological deterioration was due to the negative attitudes of the community. In a country so reliant on the strength of its army for its survival, considerable stigma is attached to psychological breakdown in combat. Because of this stigma, many of the men were experiencing not only isolation within their communities but also self-recrimination about what they perceived as their own failure. These feelings exacerbated the soldiers' already stressful situations.

Sociocultural variables also appear to play a role in determining a person's adjustment to combat. Important factors include justification for the combat and how clear and acceptable the war's goals are to the person whose life is being put in harm's way (Hoge et al., 2004). Identification with the combat unit and quality of leadership also make a difference (Jones & Wessely, 2007).

Today, military psychiatrists apply techniques that have been learned over the past century to help reduce psychological casualties. Interventions that promote morale and encourage cohesion that were developed in World War II and the Korean and Vietnam Wars have proved effective at reducing psychological casualties occurring among U.S. troops during their deployments to the Afghanistan and Iraqi war zones (Ritchie, 2007). Strategically placed combat stress control teams deploy as soon as is practical after combat engagements to provide timely counseling to troops. To improve morale of troops, the military also made efforts to

Having access to the Internet improves the morale of soldiers during long deployments.

provide breaks from long engagements by having “safe” zones that include such improvements as air conditioning, regular mail delivery, and good food. One of the most effective morale builders among troops has been the availability of the Internet at most established facilities in both Iraq and Afghanistan.

### Long-Term Effects of Posttraumatic Stress

As we have already noted, soldiers who have experienced combat exhaustion may show symptoms of posttraumatic stress for sustained periods of time (Shalev, 2009; Solomon & Mikulincer, 2007). If it develops, PTSD can be a severe and chronic condition. Moreover, in some cases, soldiers who stood up exceptionally well during their deployments have experienced delayed PTSD upon their return home. The difficulties readjusting to life as a civilian after extended periods away from home cannot be underestimated. Feelings of responsibility associated with killing as well as feelings of guilt for having survived when friends and unit peers did not may also play a role here.

The nature and extent of PTSD is somewhat controversial, however (McNally, 2008). The delayed version of PTSD is less well defined and more difficult to diagnose than disorders that emerge shortly after the precipitating incident (Andrews et al., 2007). Moreover, with the exception of Vietnam veterans, cases of delayed-onset PTSD are exceedingly rare, with only one case of delayed PTSD being reported in a civilian study (Breslau et al., 1991). Reports of delayed stress syndrome among Vietnam combat veterans are often difficult to relate explicitly to combat stress because these people may also have other significant adjustment problems. Some authorities have questioned whether a delayed reaction should be diagnosed as PTSD at all; instead, some would categorize such a reaction as some other anxiety-based disorder. For example, people with adjustment difficulties may erroneously attribute their present problems to specific incidents from their past, such as experiences in combat.

Also troubling are findings that show that 7 percent of men seeking treatment for combat-related PTSD had either never

served in Vietnam or had not been in the military at all (Frueh et al., 2005). The wide publicity given to delayed PTSD and the potential for receiving service-connected disability payments may be relevant factors here. Based on their analysis of a large federal database, a group of labor economists has concluded that the enormous increase in PTSD disability claims made by Vietnam veterans results more from financial need than it does from psychiatric disorder (Agrist, Chen & Frandsen, 2010).

## Prevention and Treatment of Stress Disorders

### Prevention

One way to prevent PTSD is to reduce the frequency of traumatic events. Although natural disasters are inevitable, efforts could be made to reduce the access that adolescents have to firearms. This could reduce the frequency of school violence and shootings. Other changes in the law and in social policy might also yield beneficial effects.

It is also worth considering whether it is possible to prevent maladaptive responses to stress by preparing people in advance and providing them with information and coping skills. As we noted earlier, this approach has been found to be helpful for people experiencing the stress of major surgery. Other research further supports the idea that psychological preparedness can foster resilience in political activists who are arrested and tortured (Başoğlu et al., 1997). Adequate training and preparation for extreme stressors may also help soldiers, firefighters, and others for whom exposure to traumatic events is highly likely. Findings from a study that examined PTSD in rescue and recovery workers at the World Trade Center site are consistent with this (Perrin, DiGrande et al., 2007). Rates of PTSD differed markedly across occupations, with lower rates being reported in police (6.2 percent) and the highest rates being found in volunteers (21.2 percent) who had occupations that were completely unrelated to rescue and recovery work (e.g., finance or real estate).

The use of cognitive-behavioral techniques to help people manage potentially stressful situations or difficult events has been widely explored (Brewin & Holmes, 2003). This preventive strategy, often referred to as **stress-inoculation training**, prepares people to tolerate an anticipated threat by changing the things

## Does Playing Tetris After a Traumatic Event Reduce Flashbacks?

**F**lashbacks,” or intrusive memories, are a hallmark feature of PTSD. They often involve visual experiences where the person reexperiences the traumatic event. Because of this flashbacks can be very frightening. But can flashbacks be prevented?

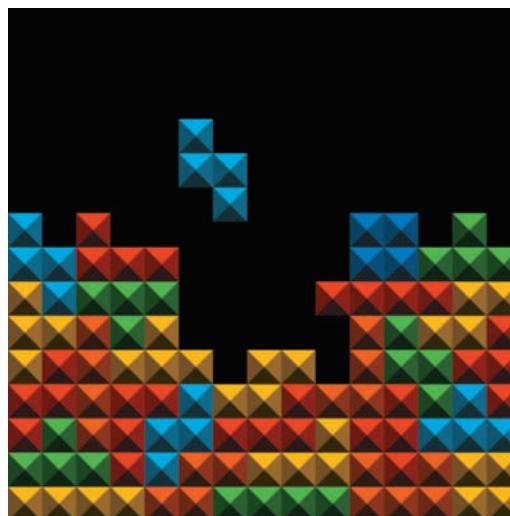

In a clever and creative study, Holmes and colleagues (2009) exposed a group of research participants to 12 minutes of graphic film footage depicting scenes of injury and death. Thirty minutes after seeing the footage, some participants played Tetris for 10 minutes while others (control condition) sat quietly for the same period of time. All participants then used a diary to record the number of flashbacks they experienced over the course of the following week. Compared to the participants in the control condition, those people who played Tetris after viewing the trauma film reported significantly fewer involuntary flashbacks (4.6 versus 12.8 for controls).

But why should this be? Forming a memory involves a neurobiological process. But in the early stages of this process (within the first six hours) the memory consolidation process can be disrupted. The brain also has a limited capacity. Because Tetris is a visuospatial task, playing Tetris shortly after the traumatic experience may disrupt the consolidation of traumatic visual memories. In other words, the new images of Tetris compete with the earlier visual images from the film, making the visual memories of the film less strong.

In other work, this same group of researchers have shown that simply being distracted after viewing the traumatic film does not reduce the frequency of later flashbacks (Holmes et al., 2010). In fact, participants who were assigned to a verbal task condition (playing Pub Quiz—a general knowledge, verbal computer game)

showed an *increased* number of flashbacks compared to both the group that played Tetris and the group that did nothing.

Taken together, the results of these interesting studies support the possibility that simple visuospatial tasks such as Tetris might have promise as a “cognitive vaccine” if they can be administered early enough. Importantly, although they experienced fewer intrusive flashbacks, people who played Tetris were still able to recall as many details from the film as people in the control group. In other words, their factual memories of the film remained intact. This is obviously important from the perspective of legal proceedings, where victims of trauma might need to testify about the events that they had experienced.

People who played Tetris after viewing a traumatic film reported fewer involuntary flashbacks the following week.

they say to themselves before or during a stressful event. As helpful as these approaches are, however, it is almost impossible to be prepared psychologically for most disasters or traumatic situations, which by their nature are often unpredictable and uncontrollable.

Given this, what might be done to help people who have just experienced a traumatic event? How might we reduce risk for PTSD? Strange as it may seem, there is reason to believe that playing Tetris might have some benefits (see The World Around Us box above).

### Treatment for Stress Disorders

As we have already discussed, many people who are exposed to a traumatic stressor will experience symptoms and then gradually begin to recover without any professional help. After the terrorist

attacks at the World Trade Center, grief and crisis counselors flocked to New York City because it was expected that countless numbers of people would be seeking psychological assistance. Relatively few people sought professional help, however, and millions of dollars that had been allocated to cover the costs of providing free counseling went unspent (McNally et al., 2003). With time, and with the help of friends and family, it is quite typical for traumatized people to recover naturally.

**TELEPHONE HOTLINES** National and local telephone hotlines provide help for people under severe stress and for people who are suicidal. In addition, there are specific hotlines for victims of rape and sexual assault and for runaways who need help. Many of these hotlines are staffed by volunteers. How skilled

and knowledgeable the volunteer is plays an important role in how satisfied users are with the hotline (Finn et al., 2010). Studies also suggest that the most positive outcomes come when helpers show empathy and respect for callers (Mishara et al., 2007).

**CRISIS INTERVENTION** Crisis intervention has emerged in response to especially stressful situations, be they disasters or family situations that have become intolerable (Brown, et al., 2013; Callahan, 2009; Krippner et al., 2012). Short-term crisis therapy is of brief duration and focuses on the immediate problem with which an individual or family is having difficulty (Scott & Stradling, 2006). Although medical problems may also require emergency treatment, therapists are concerned here with problems of an emotional nature. A central assumption in crisis-oriented therapy is that the individual was functioning well psychologically before the trauma. Thus therapy is focused only on helping the person through the immediate crisis, not on “remaking” her or his personality.

In such crisis situations, a therapist is usually very active, helping to clarify the problem, suggesting plans of action, providing reassurance, and otherwise providing needed information and support. A single-session behavioral treatment has been shown to lower fears and provide an increased sense of control among earthquake trauma victims (Başoğlu et al., 2007). Although people are far from better after this single session, they receive knowledge and learn skills that will help them gain better control over their lives in the ensuing weeks and months.

### Psychological Debriefing

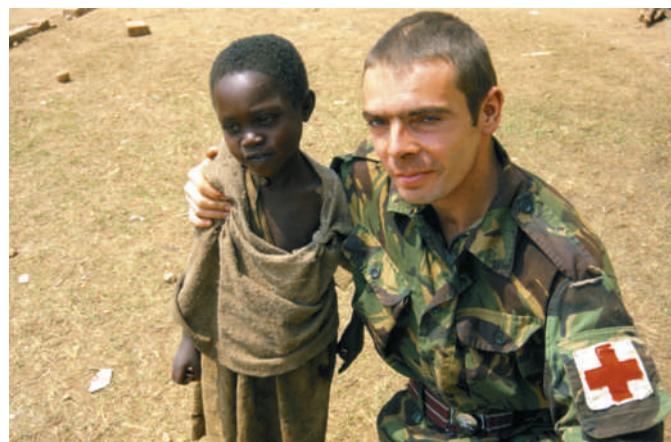

Psychological debriefing approaches are designed to help and speed up the healing process in people who have experienced disasters or been exposed to other traumatic situations (Day, 2007). As a central strategy, traumatized victims are

provided with emotional support and encouraged to talk about their experiences during the crisis (Dattilio & Freeman, 2007). The discussion is usually quite structured, and common reactions to the trauma are normalized. Some believe that this form of counseling (much of which is conducted by people who are not mental health professionals) should be mandated for disaster victims in order to prevent PTSD (Conlon & Fahy, 2001). Indeed, a small industry has sprung up to provide debriefing services, and disaster scenes are often swarmed by well-intentioned service providers—many of whom have little or no mental health training.

One form of psychological debriefing is Critical Incident Stress Debriefing (CISD; see McNally et al., 2003). A single session of CISD lasts between 3 and 4 hours and is conducted in a group format, usually 2 to 10 days after a “critical incident” or trauma.

Psychological debriefing is currently quite controversial. Reviews of the literature have generally failed to support the clinical effectiveness of the approach (Bisson et al., 2009; Devilly et al., 2006; McNally et al., 2003). Although those who experience the **debriefing sessions** often report satisfaction with the procedure and with the organization’s desire to provide assistance, no well-controlled study has shown that it reduces symptoms of PTSD or hastens recovery in civilians (see Adler et al., 2008).

Clearly, trauma survivors should not be left alone to pick up the pieces of their lives. As we noted earlier, lack of social support is a risk factor for the development of PTSD. Moreover, providing the right kind of social support may facilitate recovery. The most appropriate crisis intervention methods may not be those that follow an explicit protocol and urge emotional expression even when the trauma survivor is not ready. Rather, the most beneficial interventions may be those that focus explicitly on the needs of the individual and time their approaches accordingly. As Foa (cited in McNally et al., 2003) has wisely suggested, in the aftermath of a trauma, survivors should follow their own natural inclination and talk (or not talk) with the people they want to talk to. In a related vein, therapists should take their lead from the trauma survivor, engaging in active listening, being supportive, but not directing or pushing for more information than the survivor wishes to provide. Caring, kindness, and common sense can go a long way to helping trauma survivors along the path to healing.

In the immediate aftermath of a crisis, people need practical assistance as well as emotional support.

**MEDICATIONS** As we have seen, persons experiencing traumatic situations usually report intense feelings of anxiety or depression, numbing, intrusive thoughts, and sleep disturbance. Several medications can be used to provide relief for intense PTSD symptoms. Antidepressants, for example, are sometimes helpful in alleviating PTSD symptoms of depression, intrusion, and avoidance (Reinecke et al., 2007). In some cases, antipsychotic medications, like those used to treat disorders such as schizophrenia, are used (Bartzokis et al., 2005; David et al.,

2004). However, there is still some doubt about the extent to which medications are effective in the treatment of PTSD symptoms (Ehlers, 2000; Jaranson et al., 2001).

**COGNITIVE-BEHAVIORAL TREATMENTS** If you watch a scary movie over and over again what happens? Over time, the fear decreases and the movie becomes less frightening to you. One behaviorally oriented treatment strategy that is now being used for PTSD is **prolonged exposure** (Cloitre, 2009). It operates on exactly the same principle. The patient is asked to vividly recount the traumatic event over and over until there is a decrease in his or her emotional responses. This procedure also involves repeated or extended exposure, either *in vivo* or in the imagination, to feared (but objectively harmless) stimuli that the patient is avoiding because of trauma-related fear (Foa & Rauch, 2004; Powers et al., 2010). Prolonged exposure can also be supplemented by other behavioral techniques (Taylor, 2010). For example, relaxation

training might also be used to help the person manage anxiety following a traumatic event.

Because prolonged exposure therapy involves persuading clients to confront the traumatic memories they fear, the therapeutic relationship may be of great importance in this kind of clinical intervention (Charuvastra & Cloitre, 2008). The client has to trust in the therapist enough to engage in the exposure treatment. In all clinical work, it is important that the therapist provides a safe, warm, and supportive environment that can facilitate clinical change. For those who have been traumatized, and who may have extreme issues with trust, having a capable, understanding, and caring therapist may be especially necessary.

Prolonged exposure is an effective treatment for PTSD (Doane et al., 2010; Powers et al., 2010). In a recent study involving women who had served in the military, ten 90-minute treatment sessions led to a reduction of symptoms and a decrease in the number of women meeting diagnostic criteria for PTSD compared to a sample of women who had received a form of treatment that focused on their current life problems

## the WORLD around us

### Virtual Reality Exposure Treatment for PTSD in Military Personnel

Large numbers of military personnel begin showing signs of PTSD within 6 months of deploying (Milliken et al., 2007). However, because of stigma, many soldiers are reluctant to seek help. As one Marine explained, "I didn't want it put on my military record that I was crazy" (Halpern, 2008).

A much-needed development in this regard is the use of computer simulations and virtual reality to provide a form of exposure therapy. Although such approaches are not new, technological advances now allow for the virtual reality programs to be customized to reflect the individual soldier's traumatic experience as closely as possible. With the click of a mouse, the therapist can add such trauma-related cues as vibrations of the ground, the smell of smoke, and the sound of AK-47 fire. Treatment is typically short term (4 weeks), consisting of four to six 90-minute individual sessions. The first session is devoted to obtaining sufficient details of the trauma (time of day, weather conditions, location, sounds, smells, etc.) to make the virtual reality experience as realistic as possible. As the therapy progresses, new cues may be added to the program to provide further exposure experiences.

Early reports suggest that virtual reality exposure treatment is associated with substantial decreases in PTSD symptoms and improvements in overall functioning (Gerardi et al., 2008; Reger &

Virtual reality treatment is well received by soldiers.

Gahm, 2008). Importantly, virtual reality treatment approaches are also well received by soldiers and preferred over traditional talk therapy (Wilson et al., 2008). As one soldier put it, virtual reality "sounded pretty cool" (see Halpern, 2008). Given the growing numbers of veterans now being diagnosed with PTSD, any form of treatment that is well received by soldiers and provides relief from debilitating symptoms cannot come a moment too soon.

(Schnurr et al., 2007). However, one problem with prolonged exposure therapy is that it tends to have a higher dropout rate than other approaches. This no doubt is because it is difficult for people with PTSD to be exposed to their traumatic memories. Another current issue of concern is how long the treatment effects last. In the study just described, the longer-term effects of the prolonged exposure treatment were less robust than expected.

Recognizing the need for improvements in the treatment of PTSD, other approaches are now being developed. Ehlers and colleagues (2005) have developed a treatment for PTSD that is based on a cognitive model of the disorder. More specifically, it is thought that PTSD becomes persistent when people who have experienced trauma make excessively negative and idiosyncratic appraisals of what has happened to them in a way that creates a sense of a serious, current threat. For example, a bus driver who was assaulted by one of his passengers believed he was a terrible father who had failed his children because he had asked the passenger to buy a ticket before the passenger attacked him (Ehlers & Clark, 2008). Cognitive therapy for PTSD is designed to modify excessively negative appraisals of the trauma or its consequences, decrease the threat that patients experience when they have memories of the traumatic event, and remove problematic cognitive and behavioral strategies.

Evidence suggests that this treatment approach is very effective. In three different studies comparing patients who received cognitive therapy with patients assigned to a waiting list control group, rates of recovery were significantly higher in the cognitive therapy group and ranged from 71 to 89 percent. The drop-out rate was also very low. In fact, the only patient who dropped out of the treatment was a woman who moved abroad (Ehlers & Clark, 2008). Moreover, these treatment gains appear to continue after treatment has ended. Another exciting new treatment development that seems to be well received by clients is virtual reality exposure therapy (see The World Around Us box above).

### Challenges in Studying Disaster Victims

Conducting research into disasters is extremely difficult to implement for a number of reasons. It is virtually impossible to have an ideal, well-controlled, and well-funded experiment set up “awaiting a disaster.” One cannot easily predict natural disasters such as a tornado or fire, so it is difficult to have qualified staff ready to conduct the research immediately after the disaster strikes. Good research also requires careful definition of the variables concerned and meticulous attention to

methodological detail. But in disaster situations the extraneous conditions are difficult if not impossible to control. Often in disaster situations (e.g., airplane crashes), therapy sessions are conducted in noisy, makeshift locations such as crew lounges, hallways, and gate areas. Moreover, federal disaster funds are typically only available for immediate intervention and cannot be used for long-term care or evaluation research (Pfefferbaum et al., 1999).

All of these factors make it difficult to learn how best to help people who have been traumatized or who are in crisis. Nonetheless, a great deal of good research is now being conducted. The more we understand the mechanisms through which trauma can create pathological memories that will not abate, the more we will be able to help the large numbers of people who need help both now and in the future.

### Trauma and Physical Health

If stress is linked to problems with physical health, what role does trauma play in our physical well-being? In asking this question we come full circle, recognizing the importance of the mind–body connection. Although questions like this are only now beginning to attract empirical attention, we end with an interesting finding: In a sample of HIV-positive men and women, previous trauma (occurring years before the study and usually during childhood) was highly predictive of death from HIV and also from other causes (Leserman et al., 2007). In other words, traumatic events are not only bad for the mind. A history of trauma also predicts mortality. Although the mechanisms for this are far from clear, they again highlight the role that stress and trauma play in both physical health and psychological well-being.

#### in review

- What forms of cognitive-behavioral treatments are effective for patients with PTSD?
- Why is the therapeutic relationship so important in the treatment of chronic PTSD?

## UNRESOLVED issues

### Why Is the Study of Trauma so Contentious?

Unlike other research topics, the field of traumatic stress study is characterized by passionate and highly divisive argument. For example, although researchers routinely seek to identify risk factors for the development of various disorders such as depression or eating disorders, the idea that there could be individual risk factors for PTSD (apart from exposure to the traumatic event itself) was a taboo topic for many years. The reason it was unacceptable was because it was viewed as "blaming the victim." There were also concerns that the study of vulnerability factors might provide the federal government with an excuse to deny treatment and benefits to Vietnam veterans. In other words, advocacy, rather than science was the priority.

Now, of course, the study of individual vulnerability factors for PTSD is an active area of research. Nonetheless, individual scientists in this area are still subjected to attacks when they present findings that some in the trauma field do not want to hear (Satel, 2007). A case in point is the reanalysis of data from the National Vietnam Veterans Readjustment Study. This suggested that the originally reported estimates of PTSD might have been too high. Rather than engage in discourse about the methodology of the study or the statistical analysis used, prominent members of the

audience instead chose to attack the presenter, coming close to accusing him of lying (Satel, 2007).

This is not an isolated example. After scholars published a meta-analysis that revealed that there was only a weak association between childhood sexual abuse and later psychopathology (Rind, Tromovitch & Bauserman, 1998) there was a huge outcry from experts in the trauma field. The American Psychological Association made efforts to distance itself from the conclusions made by the authors and eventually Congress weighed in, issuing a formal condemnation of the article (see Lilienfeld, 2002). In another case, some scholars were accused of "minimization or outright denial of human suffering" (Marshall, 2006, p. 629) after they referred to the transient rise in stress reactions following the 9/11 terrorist attacks as normal emotional responses (see McNally, 2013).

Science searches for truth. And, as McNally (2013) notes, advocacy for victims of trauma is best served by scientific inquiry that is free of ideology. If certain assumptions are off-limits to investigation or critique, no one is well served. Advocates for trauma victims are no doubt well-intentioned. But when advocacy determines what scientific findings are or are not acceptable, do we not all lose?

## summary

### 5.1 What is stress?

- When challenges to our physical or emotional well being exceed our coping abilities or resources, we experience stress. Stress can result from negative or positive situations. Key factors involved in making one situation more stressful than another include how severe the stressor is, how long it lasts, when it occurs, how much it impacts our lives, how expected it is and how much control we have over the situation.
- Stress takes its toll on our physical and psychological well-being.

### 5.2 How does the body respond to stress?

- When we are stressed, the autonomic nervous system responds in a variety of ways. One consequence of stress is increased production of cortisol. High levels of this stress

hormone may be beneficial in the short term but problematic over the longer term.

- Stress compromises immune functioning. Psychoneuroimmunology is a developing field concerned with the interactions between the nervous system and the immune system
- In the immune system, specialized white blood cells called B-cells and T-cells respond to antigens such as viruses and bacteria. They are assisted by natural killer cells, granulocytes, and macrophages.
- Cytokines are chemical messengers that allow the brain and the immune system to communicate with each other. Some cytokines respond to a challenge to the immune system by causing an inflammatory response. Other cytokines, called anti-inflammatory cytokines, dampen the response that the immune system makes when it is challenged.

### 5.3 What role does our emotional state play in our physical health?

- Negative emotional states, such as being under a lot of stress or having low social support, can impair the functioning of the immune system and the cardiovascular system, leaving a person

more vulnerable to disease, infection, and problems such as hypertension and cardiovascular disease.

- Many physical illnesses seem to be linked to chronic negative emotions such as anger, anxiety, and depression. Hostility is well established as an independent risk factor for CHD. The same is true of depression.

#### 5.4 What mental disorders are explicitly recognized as being triggered by stress?

- The *DSM-5* classifies people's psychological problems in response to stressful situations under two general categories: adjustment disorders and posttraumatic stress disorder.
- Several relatively common stressors (prolonged unemployment, loss of a loved one through death, and marital separation or divorce) may produce a great deal of stress and psychological maladjustment, resulting in adjustment disorder.
- More intense psychological disorders in response to trauma or excessively stressful situations (such as military combat, being held hostage, or torture) may be categorized as posttraumatic stress disorder.
- A new diagnostic category called "Trauma- and stressor-related disorders has been added to *DSM-5*. Several disorders (including PTSD) that were formally in the Anxiety Disorders section of the *DSM* have been moved into this new category

#### 5.5 What are the clinical features of posttraumatic stress disorder?

- PTSD can involve a variety of symptoms including intrusive memories or recurrent and distressing dreams about the event, avoidance of stimuli associated with the trauma, negative cognitions or impaired memory about aspects of the traumatic event, and increased arousal or reactivity.
- Many factors influence a person's response to stressful situations. The impact of stress depends not only on its severity but also

on the person's preexisting vulnerabilities. Resilience is the most common long-term trajectory.

- Although it is very common to experience psychological symptoms after a traumatic event, these often fade with time. Most people exposed to traumatic events do not develop PTSD. The prevalence of PTSD in the general population is 6.8 percent.
- If symptoms begin 6 months or more after the traumatic event, the diagnosis is delayed posttraumatic stress disorder.

#### 5.6 What are the risk factors for PTSD?

- Factors that increase a person's risk of experiencing traumatic events include certain occupations (e.g., firefighter), being male, not having a college education, conduct problems in childhood, high levels of extraversion and neuroticism, as well as a family history of psychiatric problems.
- Factors that increase the risk of developing PTSD are being female and having low levels of social support; higher levels of neuroticism; a family history of depression, anxiety, and substance abuse; as well as preexisting problems with anxiety and depression.
- Women with PTSD have higher baseline cortisol levels than women who do not have PTSD. This is not the case for men with PTSD. Under conditions of stress, people with PTSD show an exaggerated cortisol response.
- Having the s/s genotype of the serotonin-transporter gene may increase vulnerability to PTSD in the face of trauma exposure. Smaller hippocampal volume is also a biological vulnerability factor.

#### 5.7 What treatment approaches are used for PTSD?

- Medications are sometimes used in the treatment of PTSD. Psychological treatments include prolonged exposure therapy and cognitive therapy. A new approach that appears promising is the use of virtual reality exposure therapy.

## learning objectives

### 6.1

What are the essential features of anxiety disorders?

### 6.2

Describe the clinical features of specific and social phobias.

### 6.3

Why do anxiety disorders develop?

### 6.4

What are the clinical features of panic disorder?

### 6.5

What factors are implicated in the development of panic disorder?

### 6.6

Describe the clinical aspects of generalized anxiety disorder.

### 6.7

How are anxiety disorders treated?

### 6.8

What are the clinical features of obsessive-compulsive disorder and how is this disorder treated?

### 6.9

Describe three obsessive-compulsive related disorders.

→ **Leni: Worried About Worrying So Much** Leni is a 24-year-old graduate student. Although she is doing exceptionally well in her program, for the past year she has worried constantly that she will fail and be thrown out. When her fellow students and professors try to reassure her, Leni worries that they are just pretending to be nice to her because she is such a weak student. Leni also worries about her mother becoming ill and about whether she is really liked by her friends. Although Leni is able to acknowledge that her fears are excessive (she has supportive friends, her mother is in good health, and, based on her grades, Leni is one of the top students in her program), she still struggles to control her worrying. Leni has difficulty sleeping, often feels nervous and on edge, and experiences a great deal of muscle tension. When her friends suggested she take a yoga class to try and relax, Leni even began to worry about that, fearing that she would be the worse student in the class. “I know it makes no sense,” she says, “But that’s how I am. I’ve always been a worrier. I even worry about worrying so much!”

Anxiety involves a general feeling of apprehension about possible future danger, and fear is an alarm reaction that occurs

in response to immediate danger. Today the *DSM* has identified a group of disorders—known as the *anxiety disorders*—that share obvious symptoms of clinically significant fear or anxiety. Anxiety disorders affect approximately 25 to 29 percent of the U.S. population at some point in their lives and are the most common category of disorders for women and the second most common for men (Kessler et al., 1994; Kessler, Berglund, Delmar, et al., 2005). In any 12-month period, about 18 percent of the adult population suffers from at least one anxiety disorder (Kessler, Chiu, et al., 2005c). Anxiety disorders create enormous personal, economic, and health care problems for those affected. Some years ago several studies estimated that the anxiety disorders cost the United States somewhere between \$42.3 billion and \$47 billion in direct and indirect costs (about 30 percent of the nation’s total mental health bill of \$148 billion in 1990; Greenberg et al., 1999; Kessler & Greenberg, 2002). The figure is no doubt even higher now. Anxiety disorders are also associated with an increased prevalence of a number of medical conditions including asthma, chronic pain, hypertension, arthritis, cardiovascular disease, and irritable bowel syndrome (Roy-Byrne et al., 2008) and people with anxiety disorders are very high users of medical services (e.g., Chavira et al., 2009).

In this chapter, we describe a number of different anxiety disorders. We also focus on **obsessive-compulsive disorder (OCD)**. **Obsessions** are persistent and highly recurrent intrusive thoughts or images that are experienced as disturbing and inappropriate. People affected by such obsessions try to resist or suppress them, or to neutralize them with some other thought or action. Compulsions are repetitive behaviors (such as hand-washing or checking) that the person feels must be performed in response to the obsession. Compulsions are sometimes performed as lengthy rituals. These behaviors have the goal of preventing or reducing distress or preventing some dreaded outcome from occurring.

Historically, anxiety and obsessive-compulsive disorders were considered to be classic neurotic disorders. Although individuals with **neurotic disorders** show maladaptive and self-defeating behaviors, they are not incoherent, dangerous, or out of touch with reality. To Freud, these neurotic disorders developed when intrapsychic conflict produced significant anxiety. Anxiety was, in Freud’s formulation, a sign of an inner battle or conflict between some primitive desire (from the id) and prohibitions against its expression (from the ego and superego). Sometimes this anxiety was overtly expressed (as in those disorders known today as the anxiety disorders). In certain other neurotic disorders, however, he believed that the anxiety might not be obvious, either to the person involved or to others, if psychological defense mechanisms were able to deflect or mask it. The term *neurosis* was dropped from the *DSM* in 1980. In addition, in *DSM-III*, some disorders that did not involve obvious anxiety symptoms were reclassified as either dissociative or somatoform disorders (some neurotic disorders were absorbed into the mood disorders category as well—see Chapters 7

and 8). This change was made to group together smaller sets of disorders that shared more obvious symptoms and features. In *DSM-5* this trend has gone a step further. Obsessive-compulsive disorder is no longer classified as an anxiety disorder. Instead, it is now listed in a new *DSM-5* category called **obsessive-compulsive and related disorders** (see Thinking Critically about *DSM-5*).

We begin by discussing the nature of fear and anxiety as emotional and cognitive states and patterns of responding, each of which has an extremely important adaptive value but to which humans at times seem all too vulnerable. We will then move to a discussion of the anxiety disorders. Finally, we consider OCD and other disorders from the new obsessive-compulsive and related disorders category.

## The Fear and Anxiety Response Patterns

There has never been complete agreement about how distinct the two emotions of fear and anxiety are from each other. Historically, the most common way of distinguishing between the fear and anxiety response patterns has been whether there is a clear and obvious source of danger that would be regarded as real by most people. When the source of danger is obvious, the experienced emotion has been called fear (e.g., “I’m afraid of snakes”). With anxiety, however, we frequently cannot specify clearly what the danger is (e.g., “I’m anxious about my parents’ health”).

### Fear

In recent years, however, many prominent researchers have proposed a more fundamental distinction between the fear and anxiety response patterns (e.g., Barlow, 1988, 2002; Bouton, 2005; Grillon, 2008; McNaughton, 2008). According to these theorists, fear is a basic emotion (shared by many animals) that involves activation of the “fight-or-flight” response of the autonomic nervous system. This is an almost instantaneous reaction to any imminent threat such as a dangerous predator or someone pointing a loaded gun.

Its adaptive value as a primitive alarm response to imminent danger is that it allows us to escape. When the fear response occurs in the absence of any obvious external danger, we say the person has had a spontaneous or uncued **panic attack**. The symptoms of a panic attack are nearly identical to those experienced during a state of fear except that panic attacks are often accompanied by a subjective sense of impending doom, including fears of dying, going crazy, or losing control. These latter cognitive symptoms do not generally occur during fear states. Thus fear and panic have three components:

1. cognitive/subjective components (“I feel afraid/terrified”; “I’m going to die”)
2. physiological components (such as increased heart rate and heavy breathing)
3. behavioral components (a strong urge to escape or flee; Lang, 1968, 1971)

## THINKING CRITICALLY about DSM-5

### Why Is OCD No Longer Considered to Be an Anxiety Disorder?

DSM-5

In *DSM-5*, obsessive-compulsive disorder was removed from the anxiety disorders category and placed into a new category called “obsessive-compulsive and related disorders.” (As you already know from Chapter 5, PTSD was also removed and put into a new category called “trauma and stressor-related disorders.”)

One reason for moving OCD into the new category was that anxiety is not generally used as an indicator of OCD severity. Indeed, for people with certain forms of OCD such as symmetry-related obsessions and compulsions, anxiety is not even a prominent symptom. It was also noted that anxiety occurs in a wide range of disorders, so the presence of some anxiety is not a valid reason to regard OCD an anxiety disorder. Indeed Stein et al. (2010) wrote that “the highly stereotyped, driven, repetitive, and nonfunctional quality of compulsive behaviors differentiate OCD from normal acts and from the types of avoidance that occur in other anxiety disorders” (p. 497).

Yet another reason is that the neurobiological underpinnings of OCD appear to be rather different from those of other anxiety disorders, focusing on frontal-striatal neural circuitry including the orbitofrontal cortex, anterior cingulate cortex, and striatum (especially the caudate nucleus). Studies examining the “OCD-related disorders” such as body dysmorphic disorder (obsessing about perceived or imagined flaws in physical appearance) and trichotillomania (chronic hair pulling) also suggest shared involvement of frontal-striatal neural circuitry. Finally, other anxiety disorders respond to a wider range of medication treatments than does OCD, which seems to respond selectively to selective serotonin reuptake inhibitors.

How compelling do these reasons sound to you? What kinds of research findings might further support the grouping of OCD with related disorders such as hoarding or trichotillomania? On the contrary, what research findings might incline you to think that it was wrong to remove OCD from the anxiety disorders category?

Fear or panic is a basic emotion that is shared by many animals, including humans, and may activate the fight-or-flight response of the sympathetic nervous system. This allows us to respond rapidly when faced with a dangerous situation, such as being threatened by a predator. In humans who are having a panic attack, there is no external threat; panic occurs because of some misfiring of this response system.

These components are only “loosely coupled” (Lang, 1985), which means that someone might show, for example, physiological and behavioral indications of fear or panic without much of the subjective component, or vice versa.

## Anxiety

In contrast to fear and panic, the anxiety response pattern is a complex blend of unpleasant emotions and cognitions that is both more oriented to the future and much more diffuse than fear (Barlow, 1988, 2002). But like fear, it has not only cognitive/subjective components but also physiological and behavioral components. At the cognitive/subjective level, anxiety involves negative mood, worry about possible future threats or danger, self-preoccupation, and a sense of being unable to predict the future threat or to control it if it occurs. At a physiological level, anxiety often creates a state of tension and chronic overarousal, which may reflect risk assessment and readiness for dealing with danger should it occur (“Something awful may happen, and I had better be ready for it if it does”). Although there is no activation of the fight-or-flight response as there is with fear, anxiety does prepare or prime a person for the fight-or-flight response should the anticipated danger occur. At a behavioral level, anxiety may create a strong tendency to avoid situations where danger might be encountered, but there is not the immediate behavioral urge to flee with anxiety as there is with fear (Barlow, 1988, 2002). Support for the idea that anxiety is descriptively and functionally distinct from fear or panic comes both from complex statistical analyses of subjective reports of panic and anxiety and from a great deal of neurobiological evidence (e.g., Bouton, 2005; Bouton et al., 2001; Davis, 2006; Grillon, 2008).

The adaptive value of anxiety may be that it helps us plan and prepare for possible threat. In mild to moderate degrees, anxiety actually enhances learning and performance. For example, a mild amount of anxiety about how you are going to do on your next exam, or in your next tennis match, can actually be helpful. But although anxiety is often adaptive in mild or

moderate degrees, it is maladaptive when it becomes chronic and severe, as we see in people diagnosed with anxiety disorders.

Although there are many threatening situations that provoke fear or anxiety unconditionally, many of our sources of fear and anxiety are learned. Years of human and nonhuman animal experimentation have established that the basic fear and anxiety response patterns are highly conditionable (e.g., Fanselow & Ponnusamy, 2008; Lipp, 2006). That is, previously neutral and novel stimuli (conditioned stimuli) that are repeatedly paired with, and reliably predict, frightening or unpleasant events such as various kinds of physical or psychological trauma (unconditioned stimulus) can acquire the capacity to elicit fear or anxiety themselves (conditioned response). Such conditioning is a completely normal and adaptive process that allows all of us to learn to anticipate upcoming frightening events if they are reliably preceded by a signal. Yet this normal and adaptive process can also lead in some cases to the development of clinically significant fears and anxieties, as we will see.

For example, a girl named Angela sometimes saw and heard her father physically abuse her mother in the evening. After this happened four or five times, Angela started to become anxious as soon as she heard her father’s car arrive in the driveway at the end of the day. In such situations a wide variety of initially neutral stimuli may accidentally come to serve as cues that something threatening and unpleasant is about to happen—and thereby come to elicit fear or anxiety themselves. Our thoughts and images can also serve as conditioned stimuli capable of eliciting the fear or anxiety response pattern. For example, Angela came to feel anxious even when thinking about her father.

## in review

- Compare and contrast fear or panic with anxiety, making sure to note that both emotions involve three response systems.
- Explain the significance of the fact that both fear and anxiety can be classically conditioned.

## Overview of the Anxiety Disorders and Their Commonalities

**Anxiety disorders** all have unrealistic, irrational fears or anxieties of disabling intensity as their principal and most obvious manifestation. Among the disorders recognized in *DSM-5* are:

1. specific phobia
2. social anxiety disorder (social phobia)
3. panic disorder
4. agoraphobia
5. generalized anxiety disorder

As seen in the following brief overview, people with these varied disorders differ from one another both in terms of the relative preponderance of fear or panic versus anxiety symptoms that they experience and in the kinds of objects or situations that most concern them. For example, people with *specific* or *social*

phobias exhibit many anxiety symptoms about the possibility of encountering their phobic situation, but they may also experience a fear or panic response when they actually encounter the situation. People with *panic disorder* experience both frequent panic attacks and intense anxiety focused on the possibility of having another one. People with *agoraphobia* go to great lengths to avoid a variety of feared situations, ranging from open streets, bridges, and crowded public places. By contrast, people with *generalized anxiety disorder* (like Leni in the case study that opened this chapter) mostly experience a general sense of diffuse anxiety and worry about many potentially bad things that may happen; some may also experience an occasional panic attack, but it is not a focus of their anxiety. It is also important to note that many people with one anxiety disorder will experience at least one more anxiety disorder and/or depression either concurrently or at a different point in their lives (e.g., Brown & Barlow, 2002, 2009; Kessler, Berglund, Demler, et al., 2005).

Given these commonalities across the anxiety disorders, it should come as no surprise that there are some important similarities in the basic causes of these disorders (as well as many differences). Among biological causal factors, we will see that there are genetic contributions to each of these disorders and that at least part of the genetic vulnerability may be nonspecific, or common across the disorders (e.g., Barlow, 2002; Craske & Waters, 2005). In adults, the common genetic vulnerability is manifested at a psychological level at least in part by the important personality trait called *neuroticism*—a proneness or disposition to experience negative mood states that is a common risk factor for both anxiety and mood disorders (e.g., Klein et al., 2009). The brain structures most centrally involved in most disorders are generally in the limbic system (often known as the “emotional brain”) and certain parts of the cortex, and the neurotransmitter substances that are most centrally involved are gamma aminobutyric acid (GABA), norepinephrine, and serotonin (see Chapter 3).

Among common psychological causal factors, we will see that classical conditioning of fear, panic, or anxiety to a range of stimuli plays an important role in many of these disorders (Forsyth et al., 2006; Mineka & Oehlberg, 2008; Mineka & Zinbarg, 1996, 2006). In addition, people who have perceptions of a lack of control over either their environments or their own emotions (or both) seem more vulnerable to developing anxiety disorders. The development of such perceptions of uncontrollability depends heavily on the social environment people are raised in, including parenting styles (Chorpita & Barlow, 1998; Craske & Waters, 2005; Mineka & Zinbarg, 2006; Hudson & Rapee, 2009). For certain disorders, faulty or distorted patterns of cognition also may play an important role. Finally, the sociocultural environment in which people are raised also has prominent effects on the kinds of objects and experiences people become anxious about or come to fear. Ultimately what we must strive for is a good biopsychosocial understanding of how all these types of causal factors interact with one another in the development of anxiety disorders.

Finally, as we will see, there are many commonalities across the effective treatments for the various anxiety disorders (e.g., Barlow, 2004; Campbell-Sills & Barlow, 2007). For each disorder, graduated exposure to feared cues, objects, and situations—until fear or anxiety begins to habituate—constitutes the single most powerful therapeutic ingredient. Further, for certain disorders the addition of cognitive restructuring techniques can provide added benefit. What these cognitive restructuring techniques for different disorders have in common is that they help the individual understand his or her distorted patterns of thinking about anxiety-related situations and how these patterns can be changed. Medications can also be useful in treating all disorders except specific phobias, and nearly all tend to fall into two primary medication categories: antianxiety medications (anxiolytics) and antidepressant medications.

We now turn to a more detailed discussion of each disorder, highlighting their common and their distinct features as well as what is known about their causes. We start with phobic disorders—the most common anxiety disorders. A **phobia** is a persistent and disproportionate fear of some specific object or situation that presents little or no actual danger and yet leads to a great deal of avoidance of these feared situations. As we will see in our discussion of *DSM-5*, there are three main categories of phobia: (1) specific phobia, (2) social phobia, and (3) agoraphobia.

### in review

- What is the central feature of all anxiety disorders? That is, what do they have in common?
- What differentiates the anxiety disorders from one another?
- What are some common kinds of biological and psychosocial causes of the different anxiety disorders?
- What is the most important ingredient across effective psychosocial treatments for the anxiety disorders?

## Specific Phobias

A person is diagnosed as having a **specific phobia** if she or he shows strong and persistent fear that is triggered by the presence of a specific object or situation (see *DSM-5* box for diagnostic criteria). When individuals with specific phobias encounter a phobic stimulus, they often show an immediate fear response that often resembles a panic attack except for the existence of a clear external trigger (APA, 2013). Not surprisingly, such individuals also experience anxiety if they anticipate they may encounter a phobic object or situation and so go to great lengths to avoid encounters with their phobic stimulus. Indeed, they often even avoid seemingly innocent representations of it such as photographs or television images. For example, claustrophobic persons may go to great lengths to avoid entering a closet or an elevator, even if this means climbing many flights

- A. Marked fear or anxiety about a specific object or situation (e.g., flying, heights, animals, receiving an injection, seeing blood).  
**Note:** In children, the fear or anxiety may be expressed by crying, tantrums, freezing, or clinging.
- B. The phobic object or situation almost always provokes immediate fear or anxiety.
- C. The phobic object or situation is actively avoided or endured with intense fear or anxiety.
- D. The fear or anxiety is out of proportion to the actual danger posed by the specific object or situation and to the sociocultural context.
- E. The fear, anxiety, or avoidance is persistent, typically lasting for 6 months or more.

- F. The fear, anxiety, or avoidance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- G. The disturbance is not better explained by the symptoms of another mental disorder, including fear, anxiety, and avoidance of situations associated with panic-like symptoms or other incapacitating symptoms (as in agoraphobia); objects or situations related to obsessions (as in obsessive-compulsive disorder); reminders of traumatic events (as in posttraumatic stress disorder); separation from home or attachment figures (as in separation anxiety disorder); or social situations (as in social anxiety disorder).

of stairs or turning down jobs that might require them to take an elevator. Generally, people with specific phobias recognize that their fear is somewhat excessive or unreasonable although occasionally they may not have this insight.

This avoidance is a cardinal characteristic of phobias; it occurs both because the phobic response itself is so unpleasant and because of the phobic person's irrational appraisal of the likelihood that something terrible will happen. Table 6.1 on page 168 lists the five subtypes of specific phobias recognized in *DSM-5*, along with some examples.

People with claustrophobia may find elevators so frightening that they go to great lengths to avoid them. If for some reason they have to take an elevator, they will be very frightened and have thoughts about the elevator falling, the doors never opening, or there not being enough air to breathe.

The following case is typical of specific phobia:

→ **A Pilot's Wife's Fear** Mary, a married mother of three, was 47 at the time she first sought treatment for both claustrophobia and acrophobia. She reported having been intensely afraid of enclosed spaces (claustrophobia) and of heights (acrophobia) since her teens. She remembered having been locked in closets by her older siblings when she was a child; the siblings also confined her under blankets to scare her and added to her fright by showing her pictures of spiders after releasing her from under the blankets. She traced the onset of her claustrophobia to those traumatic incidents, but she had no idea why she was afraid of heights. While her children had been growing up, she had been a housewife and had managed to live a fairly normal life in spite of her two specific phobias. However, her children were now grown, and she wanted to find a job outside her home. This was proving to be very difficult because she could not take elevators and was frightened being on anything other than the first floor of an office building. Moreover, her husband had for some years been working for an airline, which entitled him to free airline tickets. The fact that Mary could not fly (due to her phobias) had become a sore point in her marriage because they both wanted to be able to take advantage of these free tickets to see distant places. Thus, although she had had these phobias for many years, they had become truly disabling only in recent years as her life circumstances had changed and she could no longer easily avoid heights or enclosed spaces.

**TABLE 6.1**  
**Subtypes of Specific Phobias in DSM-5**

Phobia Type	Examples
Animal	Snakes, spiders, dogs, insects, birds
Natural Environment	Storms, heights, water
Blood-Injection-Injury	Seeing blood or an injury, receiving an injection, seeing a person in a wheelchair
Situational	Public transportation, tunnels, bridges, elevators, flying, driving, enclosed spaces
Other	Choking, vomiting, "space phobia" (fear of falling down if away from walls or other support)

Source: Adapted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Text Revision, fifth edition (Copyright © 2013). American Psychiatric Association.

If people who suffer from phobias attempt to approach their phobic situation, they are overcome with fear or anxiety, which may vary from mild feelings of apprehension and distress (usually while still at some distance) to full-fledged activation of the fight-or-flight response. Regardless of how it begins, phobic behavior tends to be reinforced because every time the person with a phobia avoids a feared situation his or her anxiety decreases. In addition, the secondary benefits derived from being disabled, such as increased attention, sympathy, and some control over the behavior of others, may also sometimes reinforce a phobia.

One category of specific phobias that has a number of interesting and unique characteristics is **blood-injection-injury phobia**. It probably occurs in about 3 to 4 percent of the population (Ayala et al., 2009; Öst & Hellström, 1997). People afflicted with this phobia typically experience at least as much (if not more) disgust as fear (Schienle et al., 2005; Teachman & Saporito, 2009). They also show a unique physiological response when confronted with the sight of blood or injury. Rather than showing the simple increase in heart rate and blood pressure seen when most people with phobias encounter their phobic object, these people show an initial acceleration, followed by a dramatic drop in both heart rate and blood pressure. This is very frequently accompanied by nausea, dizziness, or fainting, which do not occur with other specific phobias (Öst & Hellström, 1997; Page & Tan, 2009).

Interestingly, people with this phobia show this unique physiological response pattern only in the presence of blood and injury stimuli; they exhibit the more typical physiological response pattern characteristic of the fight-or-flight response to their other feared objects (see Dahlloef & Öst, 1998; Öst & Hugdahl, 1985). From an evolutionary and functional standpoint, this unique physiological response pattern may have evolved for a specific purpose: By fainting, the person being attacked might inhibit further attack, and if an attack did occur, the drop in blood pressure would minimize blood loss (Craske, 1999; Marks & Nesse, 1991). This type of phobia appears to be highly heritable (Czajkowski et al., 2011).

In blood-injection-injury phobia, the afflicted person experiences disgust and fear at the sight of someone receiving an injection. When confronted with the sight of blood or injury, people with this phobic disorder often experience nausea, dizziness, and fainting.

### Prevalence, Age of Onset, and Gender Differences

Specific phobias are quite common. Results of the National Comorbidity Survey-Replication, which used *DSM-IV* criteria, revealed a lifetime prevalence rate of about 12 percent (Kessler, Chiu, et al., 2005c). Among people with one specific phobia, over 75 percent have at least one other specific fear that is excessive (Curtis, Magee, et al., 1998). The relative gender ratios vary considerably according to the type of specific phobia, but phobias are always considerably more common in women than in men. For example, about 90 to 95 percent of people with animal phobias are women, but the gender ratio is less than 2:1 for blood-injection-injury phobia. The average age of onset for different types of specific phobias also varies widely. Animal phobias usually begin in childhood, as do blood-injection-injury phobias and dental phobias. However, other phobias such as claustrophobia and driving phobia tend to begin in adolescence or early adulthood (Barlow, 2002; Öst, 1987).

### Psychological Causal Factors

A variety of psychological causal factors have been implicated in the origins of specific phobias, ranging from deep-seated

psychodynamic conflicts to relatively straightforward traumatic conditioning of fear and a multitude of individual differences in who is at risk for such conditioning.

**PSYCHOANALYTIC VIEWPOINT** According to the psychoanalytic view, phobias represent a defense against anxiety that stems from repressed impulses from the id. Because it is too dangerous to “know” the repressed id impulse, the anxiety is displaced onto some external object or situation that has some symbolic relationship to the real object of the anxiety (Freud, 1909). However, this prototypical psychodynamic account of how phobias are acquired was long criticized as being far too speculative, and an alternative, simpler account from learning theory was first proposed by Wolpe and Rachman (1960), which has now been further refined and expanded as discussed below.

**PHOBIAS AS LEARNED BEHAVIOR** As an alternative to psychoanalytic accounts, Wolpe and Rachman (1960) developed an account based on learning theory, which sought to explain the development of phobic behavior through classical conditioning. Numerous other theorists in the 1960s and 1970s also agreed that the principles of classical conditioning appeared to account for the acquisition of irrational fears and phobias. The fear response can readily be conditioned to previously neutral stimuli when these stimuli are paired with traumatic or painful events. We would also expect that, once acquired, phobic fears would generalize to other, similar objects or situations. Recall, for example, that Mary’s claustrophobia had probably been caused by multiple incidents as a child when her siblings locked her in closets and confined her under blankets to scare her. But as an adult, Mary feared elevators and caves as well as other enclosed places. The powerful role of classical conditioning in the development of phobias was supported in a survey by Öst and Hugdahl (1981), who administered questionnaires to 106 adult phobic clients that concerned, among other things, the purported origins of their fears (see Mineka & Sutton, 2006, for a review). Fifty-eight percent cited traumatic conditioning experiences as the sources of their phobias. Some of these traumatic conditioning events were simply uncued panic attacks, which are now known to effectively condition fear (e.g., Acheson et al., 2007; Forsyth & Eifert, 1998).

**Vicarious Conditioning** Direct traumatic conditioning in which a person has a terrifying experience in the presence of a neutral object or situation is not the only way that people can learn irrational, phobic fears. Simply watching a phobic person behaving fearfully with his or her phobic object can be distressing to the observer and can result in fear being transmitted from one person to another through vicarious or observational classical conditioning. In addition, watching a

nonfearful person undergoing a frightening experience can also lead to vicarious conditioning. For example, one man, as a boy, had witnessed his grandfather vomit while dying. Shortly after this traumatic event (his grandfather’s distress while dying) the boy had developed a strong and persistent vomiting phobia. Indeed, when this man was in middle age he even contemplated suicide one time when he was nauseated and feared vomiting (Mineka & Zinbarg, 2006). Related experimental findings have been observed in laboratory analogue studies of human children. For example, two studies showed that 7- to 9-year-old children who saw pictures of an unfamiliar animal (an Australian marsupial) paired 10 times with fearful facial expressions showed increased fear beliefs and behavioral avoidance of this conditioned stimulus (CS) relative to children who saw the unfamiliar animal paired with happy facial expressions. These effects persisted for at least one week (Askew & Field, 2007; see Askew & Field, 2008, for a review).

Animal research using rhesus monkeys has increased our confidence that vicarious conditioning of intense fears can indeed occur. In these experiments, Mineka and Cook and their colleagues (e.g., Cook & Mineka, 1989; Mineka & Cook, 1993; Mineka, Davidson, et al., 1984) showed that laboratory-reared monkeys who were not initially afraid of snakes rapidly developed a phobic-like fear of snakes simply through observing a wild-reared monkey behaving fearfully with snakes. Significant fear was acquired after only 4 to 8 minutes of exposure to the wild-reared monkey with snakes, and there were no signs that the fear had diminished 3 months later. The monkeys could also learn the fear simply through watching a videotape of the wild-reared model monkey behaving fearfully with snakes. This suggests that the mass media also play a role in the vicarious

Monkeys who watch a model monkey (such as the one illustrated here) behaving fearfully with a live boa constrictor will rapidly acquire an intense fear of snakes themselves. Fears can thus be learned vicariously without any direct traumatic experience.

conditioning of fears and phobias in people (Cook & Mineka, 1990; Mineka & Sutton, 2006).

**Individual Differences in Learning** Does the direct and vicarious conditioning model really explain the origins of most phobias? Given all the traumas that people undergo, why don't more people develop phobias (Mineka & Oehlberg, 2008; Mineka & Zinbarg, 1996, 2006; Rachman, 1990)? The answer seems to be, at least in good part, that differences in life experiences among individuals strongly affect whether or not conditioned fears or phobias actually develop. For example, years of positive experiences with friendly dogs before being bitten by one will probably keep a dog bite victim from developing a full-blown dog phobia. Thus, to understand individual differences in the development and maintenance of phobias, we need to understand the role of the different life experiences of people who undergo the same trauma.

Some life experiences may serve as risk factors and make certain people more vulnerable to phobias than others, and other experiences may serve as protective factors for the development of phobias (Mineka & Sutton, 2006). For example, children who have had more previous nontraumatic experiences with a dentist are less likely to develop dental anxiety after a bad and painful experience than are children with fewer previous nontraumatic experiences (Kent, 1997; Ten Berge et al., 2002). This shows the importance of the individual's prior familiarity with an object or situation in determining whether a phobia develops following a fear-conditioning experience. Moreover, Mineka and Cook (1986) showed that monkeys who first simply watched nonfearful monkeys behaving nonfearfully with snakes were immunized against acquiring a fear of snakes when they later saw fearful monkeys behaving fearfully with snakes. By analogy, if a child has extensive exposure to a nonfearful parent behaving nonfearfully with the phobic object (e.g., spiders) or situation (e.g., heights) of the other, phobic parent, this may serve as a protective factor and immunize the child against the effects of later seeing the phobic parent

behaving fearfully with the phobic object (Mineka & Oehlberg, 2008; Mineka & Sutton, 2006). Eglinton and Rapee (2007) reported related results in an analogue study of human toddlers who either watched their mothers reacting positively to a snake or spider, or watched the snake or spider alone. Subsequently both groups of toddlers watched an experimenter reacting with fear and disgust toward the stimulus. Those in the group who had first watched their mother behaving positively acquired less fear than those who had first watched the stimulus alone.

Events that occur during a conditioning experience, as well as before it, are also important in determining the level of fear that is conditioned. For example, experiencing an inescapable and uncontrollable event, such as being attacked by a dog that one cannot escape from after being bitten, is expected to condition fear much more powerfully than experiencing the same intensity of trauma that is escapable or to some extent controllable (e.g., by running away after the attack; Mineka, 1985a; Mineka & Zinbarg, 1996, 2006). In addition, the experiences that a person has after a conditioning experience may effect the strength and maintenance of the conditioned fear (Rescorla, 1974; White & Davey, 1989). For example, the *inflation effect* suggests that a person who acquired, a mild fear of driving following a minor crash might be expected to develop a full-blown phobia if he or she later were physically assaulted, even though no automobile was present during the assault (Dadds et al., 2001; Mineka, 1985b; Mineka & Zinbarg, 1996, 2006). Even verbal information that later alters one's interpretation of the dangerousness of a previous trauma can inflate the level of fear (e.g., being told, "You're lucky to be alive because the man who crashed into your car last week had lost his license due to a record of drunk driving leading to fatal car crashes"; Dadds et al., 2001). Another way in which fear of a CS can be inflated following conditioning is if the organism later is exposed to uncontrollable stress (Baratta et al., 2007). These examples show that the factors involved in the origins and maintenance of fears and phobias are more complex than suggested by the traditional, simplistic conditioning view, although they are nevertheless consistent with contemporary views of conditioning (Mineka & Oehlberg, 2008; see also Coelho & Purkis, 2009; Laborda & Miller, 2011).

It has also been shown that our cognitions, or thoughts, can help maintain our phobias once they have been acquired. For example, people with phobias are constantly on the alert for their phobic objects or situations and for other stimuli relevant to their phobia (McNally & Reese, 2009). Nonphobic persons, by contrast, tend to direct their attention away from threatening stimuli (see Mineka, Rafaeli, & Yovel, 2003). In addition, phobics also markedly overestimate the probability that feared objects have been, or will be, followed by frightening events. This cognitive bias may help maintain or strengthen phobic fears with the passage of time (Muhlberger et al., 2006; Öhman & Mineka, 2001; Tomarken, Mineka, & Cook, 1989).

A person who has had good experiences with a potentially phobic stimulus, such as the little girl playing here with her dog, is likely to be immunized from later acquiring a fear of dogs even if she has a traumatic encounter with one.

**Evolutionary Preparedness for Learning Certain Fears and Phobias** Consider the observation that people are much more likely to have phobias of snakes, water, heights, and enclosed spaces than of motorcycles and guns, even though the latter objects may be at least as likely to be associated with trauma. This is because our evolutionary history has affected which stimuli we are most likely to come to fear. Primates and humans seem to be evolutionarily prepared to rapidly associate certain objects—such as snakes, spiders, water, and enclosed spaces—with frightening or unpleasant events (e.g., Mineka & Öhman, 2002; Öhman, 1996; Seligman, 1971). This **prepared learning** occurs because, over the course of evolution, those primates and humans who rapidly acquired fears of certain objects or situations that posed real threats to our early ancestors may have enjoyed a selective advantage. Thus “prepared” fears are not inborn or innate but rather are easily acquired or especially resistant to extinction. Guns and motorcycles, by contrast, were not present in our early evolutionary history and so did not convey any such selective advantage.

There is now a large amount of experimental evidence supporting the preparedness theory of phobias. In one important series of experiments using human subjects, Öhman and his colleagues (see Öhman, 1996; Öhman, 2009; Öhman & Mineka, 2001, for reviews) found that fear is conditioned more effectively to fear-relevant stimuli (slides of snakes and spiders) than to fear-irrelevant stimuli (slides of flowers and mushrooms). These researchers also found that once the individuals acquired the conditioned responses to fear-relevant stimuli, these responses (including activation of the relevant brain area, the amygdala) could be elicited even when the fear-relevant stimuli (but not the fear-irrelevant stimuli) were presented subliminally (i.e., presentation was so brief that the stimuli were not consciously perceived; e.g., Carlsson et al., 2004; Öhman et al., 2007). This subliminal activation of responses to phobic stimuli may help to account for certain aspects of the irrationality of phobias. That is, people with phobias may not be able to control their fear because the fear may arise from cognitive structures that are not under conscious control (Öhman & Mineka, 2001; Öhman & Soares, 1993).

Another series of experiments showed that lab-reared monkeys in a vicarious conditioning paradigm can easily acquire fears of fear-relevant stimuli such as toy snakes and toy crocodiles but not of fear-irrelevant stimuli such as flowers and a toy rabbit (Cook & Mineka, 1989, 1990). Thus, both monkeys and humans seem selectively to associate certain fear-relevant stimuli with threat or danger. Moreover, these lab-reared monkeys had had no prior exposure to any of the stimuli involved (e.g., snakes or flowers) before participating in these experiments. Thus, the monkey results support the evolutionarily based preparedness hypothesis even more strongly than the human experiments. For example, human subjects (unlike the lab-reared monkeys) might show superior conditioning to snakes or

spiders because of preexisting negative associations to snakes or spiders rather than because of evolutionary factors (Mineka & Öhman, 2002).

## Biological Causal Factors

Genetic and temperamental variables affect the speed and strength of conditioning of fear (e.g., Gray, 1987; Hettema et al., 2003; Oehlberg & Mineka, 2011). That is, depending on their genetic makeup or their temperament and personality (all of which are clearly related; see Chapter 3), people are more or less likely to acquire fears and phobias. For example, Lonsdorf and colleagues (2009) found that individuals who are carriers of one of the two variants on the serotonin-transporter gene (the *s* allele, which has been linked to heightened neuroticism) show superior fear conditioning relative to individuals who do not carry the *s* allele. However, those with one of two variants of a different gene (the COMT met/met genotype) did not show superior conditioning but did show enhanced resistance to extinction (see also Lonsdorf & Kalisch, 2011). Relatedly, Kagan and his colleagues (2001) found that *behaviorally inhibited* toddlers (who are excessively timid, shy, easily distressed, etc.) at 21 months of age were at higher risk of developing multiple specific phobias by 7 to 8 years of age than were uninhibited children (32 versus 5 percent). The average number of reported fears in the inhibited group was three to four per child (Biederman et al., 1990).

Several behavior genetic studies also suggest a modest genetic contribution to the development of specific phobias. For example, a large female twin study found that monozygotic (identical) twins were more likely to share animal phobias and situational phobias (such as of heights or water) than were dizygotic (nonidentical) twins (Kendler et al., 1999b). Very similar results were later also found for men (Hettma et al., 2005). However, the same studies also found evidence that nonshared environmental factors (i.e., individual specific experiences not shared by twins) also played a very substantial role in the origins of specific phobias, a result that supports the idea that phobias are learned behaviors. Another study found that the heritability of animal phobias was separate from the heritability of complex phobias such as social phobia and agoraphobia (Czajkowski et al., 2011).

## Treatments

A form of behavior therapy called **exposure therapy**—which is the best treatment for specific phobias—involves controlled exposure to the stimuli or situations that elicit phobic fear (Choy et al., 2007; Craske & Mystkowsky, 2006). Clients are gradually placed—symbolically or increasingly under “real-life” conditions—in those situations they find most frightening. In treatment, clients are encouraged to expose themselves (either alone or with the aid of a therapist or friend) to their feared

One variation on exposure therapy is called participant modeling. Here the therapist models how to touch and pick up a live tarantula and encourages the spider-phobic client to imitate her behavior. This treatment is graduated, with the client's first task being simply to touch the tarantula from the outside of the cage, then to touch the tarantula with a stick, then with a gloved hand, then with a bare hand, and finally to let the tarantula crawl over his hand. This is a highly effective treatment, with the most spider-phobic clients being able to reach the top of the hierarchy within 60 to 90 minutes.

situations for long enough periods of time so that their fear begins to subside. One variant on this procedure, known as *participant modeling*, is often more effective than exposure alone. Here the therapist calmly models ways of interacting with the phobic stimulus or situation (Bandura, 1977, 1997). These techniques enable clients to learn that these situations are not as frightening as they had thought and that their anxiety, while unpleasant, is not harmful and will gradually dissipate (Craske & Mystkowsky, 2006; Craske & Rowe, 1997). The new learning is probably mediated by changes in brain activation in the amygdala, which is centrally involved in the emotion of fear.

For certain phobias such as small-animal phobias, flying phobia, claustrophobia, and blood-injury phobia, exposure therapy is often highly effective when administered in a single long session (of up to 3 hours) (Öst, 1997; Öst et al., 2001). This can be an advantage because some people are more likely to seek treatment if they have to go only once. This treatment has also been shown to be highly effective in youth with specific phobias (e.g., Ollendick et al., 2009).

An example of the use of exposure therapy comes from the treatment of Mary, the housewife whose acrophobia and claustrophobia we described earlier.

→ **Mary's Treatment** Treatment consisted of 13 sessions of graduated exposure exercises in which the therapist accompanied Mary first into mildly fear-provoking situations and then gradually into more and more fear-provoking situations. Mary also engaged in homework, doing these exposure exercises by herself. The prolonged *in vivo* ("real-life") exposure sessions lasted as long as necessary for her anxiety to subside. Initial sessions focused on Mary's claustrophobia and on getting her to be able to ride for a few floors in an elevator, first with the therapist and then alone. Later she took longer elevator rides in taller buildings. Exposure for the acrophobia consisted of walking around the periphery of the inner atrium on the top floor of a tall hotel and, later, spending time at a mountain vista overlook spot. The top of the claustrophobia hierarchy consisted of taking a tour of an underground cave. After 13 sessions, Mary successfully took a flight with her husband to Europe and climbed to the top of many tall tourist attractions there.

Recently, some therapists have begun to use virtual reality environments to simulate certain kinds of phobic situations,

New treatments using virtual reality environments allow therapists to simulate certain kinds of phobic situations, such as standing at heights or sitting in airplanes, in a contrived setting.

such as heights and airplanes, as places to conduct exposure treatment. If such techniques were highly effective and widely available, there would be no need to conduct treatment in real situations (such as real airplanes or tall buildings). About a dozen controlled studies have yielded very promising results. Moreover, although the results are not yet entirely conclusive, it appears that the relative efficacy of virtual reality versus live exposure is comparable (e.g., Choy et al., 2007; Parsons & Rizzo, 2008; Rothbaum et al., 2006).

Some researchers have also tried combining cognitive restructuring techniques or medications with exposure-based techniques to see if this can produce additional gains. In general, studies using cognitive techniques alone have not produced results as good as those using exposure-based techniques, and the addition of cognitive techniques has generally not added much (Craske & Mystkowski, 2006; Wolitzky-Taylor et al., 2008). Similarly, medication treatments are ineffective by themselves, and there is even some evidence that antianxiety medications may interfere with the beneficial effects of exposure therapy (Antony & Barlow, 2002; Choy et al., 2007). Recently, however, some studies have shown that a drug called *d-cycloserine*, which is known to facilitate extinction of conditioned fear in animals (e.g., Davis et al., 2005; Davis et al., 2006), may enhance the effectiveness of small amounts of exposure therapy for fear of heights in a virtual reality environment (Ressler et al., 2004; Norberg et al., 2008). *D-cy whole* by itself, however, has no effect. These results are very promising, but much more work is necessary before it will be known how useful this drug will be in enhancing the effects of exposure therapy for many different kinds of phobias.

### in review

- What are the five subtypes of specific phobias?
- Describe the original classical conditioning explanation for the origins of specific phobias as well as how vicarious conditioning may be involved.

- Explain several sources of individual differences in learning that have improved and expanded the basic conditioning hypothesis of phobia acquisition.
- Explain how evolutionary factors have influenced which objects and situations we are most likely to learn to fear.
- Describe the most effective treatment for specific phobias.

## Social Phobias

**Social phobia** (or social anxiety disorder), as the *DSM-5* describes it, is characterized by disabling fears of one or more specific social situations (such as public speaking, urinating in a public bathroom, or eating or writing in public; see the *DSM-5* box). In these situations, a person fears that she or he may be exposed to the scrutiny and potential negative evaluation of others or that she or he may act in an embarrassing or humiliating manner. Because of their fears, people with social phobias either avoid these situations or endure them with great distress. Intense fear of public speaking is the single most common type of social phobia. *DSM-5* also identifies two subtypes of social phobia, one of which centers on performance situations such as public speaking and one of which is more general and includes nonperformance situations (such as eating in public).

Indeed, people with the more general subtype of social phobia often have significant fears of most social situations (rather than simply a few) and often also have a diagnosis of avoidant personality disorder (see Chapter 10; e.g., Skodol et al., 1995; Stein & Stein, 2008).

### Prevalence, Age of Onset, and Gender Differences

The diagnosis of social phobia is very common and occurs even in famous performers such as Barbra Streisand and Carly Simon. The National Comorbidity Survey-Replication estimated that about 12 percent of the population will qualify for a diagnosis of social phobia at some point in their lives (Kessler, Berglund, Demler, et al., 2005; Ruscio et al., 2008). This disorder is somewhat more common among women than men (about 60 percent of sufferers are women). Unlike specific phobias, which most often originate in childhood, social phobias typically begin somewhat later, during early or middle adolescence or certainly by early adulthood (Bruce et al., 2005; Ruscio et al., 2008).

Nearly two-thirds of people with social phobia suffer from one or more additional anxiety disorders at some point in their lives, and about 50 percent also suffer from a depressive disorder at the same time (Kessler, Chiu, et al., 2005; Ruscio et al., 2008). Approximately one-third abuse alcohol to reduce their anxiety and help them face the

Intense fear of public speaking is the single most common social phobia.

situations they fear (for example, drinking before going to a party; Magee et al., 1996). Moreover, because of their distress and avoidance of social situations, people with social phobia, on average, have lower employment rates and lower socioeconomic status, and approximately one-third have severe impairment in one or more domains of their life (Harvey et al., 2005; Ruscio et al., 2008). Finally, the disorder is remarkably persistent, with one study finding that only 37 percent recovered spontaneously over a 12-year period (Bruce et al., 2005).

The case of Paul is typical of social phobia (except that not all people with social phobia have full-blown panic attacks, as Paul did, in their socially phobic situations).

→ **A Surgeon's Social Phobia** Paul was a single white male in his mid-30s when he first presented for treatment. He was a surgeon who reported a 13-year history of social phobia. He had very few social outlets because of his persistent concerns that people would notice how nervous he was in social situations, and he had not dated in many years. Convinced that people would perceive him as foolish or crazy, he particularly worried that people would notice how his jaw tensed up when around other people. Paul frequently chewed gum in public situations, believing that this kept his face from looking distorted. Notably, he had no particular problems talking with people in professional situations. For example, he was quite calm talking with patients before and after surgery. During surgery, when his face was covered with a mask, he also had no trouble carrying out surgical tasks or interacting with the other surgeons and nurses in the room. The trouble began when he left the operating room and had to make small talk—and eye contact—with the other doctors and nurses or with the patient's family. He frequently had panic attacks in these social situations. During the panic attacks he experienced heart palpitations, fears of "going crazy," and a sense of his mind "shutting down." Because the panic attacks occurred only in social situations, he was diagnosed as having social phobia rather than panic disorder.

Paul's social phobia and panic had begun about 13 years earlier when he was under a great deal of stress. His family's business had failed, his parents had divorced, and his mother had had a heart attack. It was in this context of multiple stressors that a personally traumatic incident probably triggered the onset of his social phobia. One day he had come home from medical school to find his best friend in bed with his fiancée. About a month later he had his first panic attack and started avoiding social situations.

## Psychological Causal Factors

Social phobias generally involve learned behaviors that have been shaped by evolutionary factors. Such learning is most likely to occur in people who are genetically or temperamentally at risk.

**SOCIAL PHOBIAS AS LEARNED BEHAVIOR** Like specific phobias, social phobias often seem to originate from simple instances of direct or vicarious classical conditioning such as experiencing or witnessing a perceived social defeat or humiliation, or being or witnessing the target of anger or criticism (Harvey et al., 2005; Mineka & Zinbarg, 1995, 2006; Tillfors, 2004). In two studies, 56 to 58 percent of people with social phobia recalled and identified direct traumatic experiences as having been involved in the origin of their social phobias (Öst & Hugdahl, 1981; Townsley et al., 1995). Another study reported that 92 percent of an adult sample of people with social phobia reported a history of severe teasing in childhood, compared to only 35 percent in a group of people with obsessive-compulsive disorder (McCabe et al., 2003). Moreover, a recent laboratory study of people with social phobia revealed that they showed especially robust conditioning of fear when the unconditioned stimulus was socially relevant (critical facial expressions and verbal insults) as opposed to more nonspecifically negative stimuli (such as unpleasant odors and painful pressure) (Lissek et al., 2008).

Öst and Hugdahl (1981) reported that another 13 percent of their subjects recalled vicarious conditioning experiences of some sort. One study interviewed a group of people with social phobia about their images of themselves in socially phobic situations and asked where those images had originated (Hackmann et al., 2000). Ninety-six percent of these people remembered some socially traumatic experience that was linked to their own current image of themselves in socially phobic situations. The themes of these memories included having been "criticized for having an anxiety symptom" (e.g., being red or blushing), and having felt "self-conscious and uncomfortable in public as a consequence of past criticism" such as "having previously been bullied and called a 'nothing'" (Hackmann et al., 2000, p. 606).

People with generalized social phobia also may be especially likely to have grown up with parents who were emotionally cold, socially isolated, and avoidant. Not surprisingly, such parents

- A. Marked fear or anxiety about one or more social situations in which the individual is exposed to possible scrutiny by others. Examples include social interactions (e.g., having a conversation, meeting unfamiliar people), being observed (e.g., eating or drinking), and performing in front of others (e.g., giving a speech).
 

**Note:** In children, the anxiety must occur in peer settings and not just during interactions with adults.
- B. The individual fears that he or she will act in a way or show anxiety symptoms that will be negatively evaluated (i.e., will be humiliating or embarrassing; will lead to rejection or offend others).
- C. The social situations almost always provoke fear or anxiety.
 

**Note:** In children, the fear or anxiety may be expressed by crying, tantrums, freezing, clinging, shrinking, or failing to speak in social situations.
- D. The social situations are avoided or endured with intense fear or anxiety.
- E. The fear or anxiety is out of proportion to the actual threat posed by the social situation and to the sociocultural context.

- F. The fear, anxiety, or avoidance is persistent, typically lasting for 6 months or more.
- G. The fear, anxiety, or avoidance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- H. The fear, anxiety, or avoidance is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or another medical condition.
- I. The fear, anxiety, or avoidance is not better explained by the symptoms of another mental disorder, such as panic disorder, body dysmorphic disorder, or autism spectrum disorder.
- J. If another medical condition (e.g., Parkinson's disease, obesity, disfigurement from burns or injury) is present, the fear, anxiety, or avoidance is clearly unrelated or is excessive.

devalued sociability and did not encourage their children to go to social events. All these factors thus provided ample opportunity for vicarious learning of social fears (Harvey et al., 2005; Morris, 2001; Rapee & Melville, 1997). Harvey and colleagues (2005) also found that many people with social phobia reported that the onset of their social phobia had occurred during a time when they were having problems with their peers such as not fitting in. Nevertheless, as with specific phobias, it is important to recognize that not everyone who experiences direct or vicarious conditioning in social situations, or who grows up with socially avoidant parents, or who has problems with peers, develops social phobia. This is because individual differences in experiences play an important role in who develops social phobia, as is the case with specific phobias.

#### **SOCIAL FEARS AND PHOBIAS IN AN EVOLUTIONARY**

**CONTEXT** Social fears and phobias by definition involve fears of members of one's own species. By contrast, animal fears and phobias usually involve fear of potential predators. Although animal fears probably evolved to trigger activation of the fight-or-flight response to potential predators, Öhman and colleagues proposed that social fears and phobias evolved as a byproduct of dominance hierarchies that are a common social arrangement among animals such as primates (Dimberg & Öhman, 1996; Öhman et al., 1985). Dominance hierarchies are established

through aggressive encounters between members of a social group, and a defeated individual typically displays fear and submissive behavior but only rarely attempts to escape the situation completely. Thus, these investigators argued, it is not surprising that people with social phobia endure being in their feared situations rather than running away and escaping them, as people with animal phobias often do (see also Longin et al., 2010; Öhman, 2009).

If social phobias evolved as a byproduct of dominance hierarchies, it is not surprising that humans have an evolutionarily based predisposition to acquire fears of social stimuli that signal dominance and aggression from other humans. These social stimuli include facial expressions of anger or contempt, which on average all humans seem to process more quickly and readily than happy or neutral facial expressions (Öhman et al., 2001; Öhman, 2009; Schupp et al., 2004). In a series of experiments that paralleled ones for specific phobias, Öhman and colleagues demonstrated that subjects develop stronger conditioned responses when slides of angry faces are paired with mild electric shocks than when happy or neutral faces are paired with the same shocks (Dimberg & Öhman, 1996). Indeed, even very brief subliminal (not consciously perceived) presentations of the angry face that had been paired with shock were sufficient to activate the conditioned responses (e.g., Parra et al., 1997), probably because even these subliminal angry faces activate

the amygdala—the central structure involved in fear learning (Öhman et al., 2007). Relatedly, recent results have also shown that people who have social phobia show greater activation of the amygdala (and other brain areas involved in emotion processing) in response to negative facial expressions (such as angry faces) than do normal controls (Goldin et al., 2009; Phan et al., 2006). Such results may help explain the seemingly irrational quality of social phobia, in that the angry faces are processed very quickly and an emotional reaction can be activated without a person's awareness of any threat. The hyperactivity to negative facial expressions is paralleled by heightened neural responses to criticism (Blair et al., 2008; see Shin & Liberzon, 2009, for a review).

#### PERCEPTIONS OF UNCONTROLLABILITY AND UNPREDICTABILITY

**UNPREDICTABILITY** Being exposed to uncontrollable and unpredictable stressful events (such as parental separation and divorce, family conflict, or sexual abuse) may play an important role in the development of social phobia (Mathew et al., 2001; Mineka & Zinbarg, 1995, 2006; Rapee & Spence, 2004). In the case of Paul, the precipitating event seemed to be finding his fiancée in bed with his best friend. Perceptions of uncontrollability and unpredictability often lead to submissive and unassertive behavior, which is characteristic of socially anxious or phobic people. This kind of behavior is especially likely if the perceptions of uncontrollability stem from an actual social defeat, which is known in animals to lead to both increased submissive behavior and increased fear (Mineka & Zinbarg, 1995, 2006). Consistent with this, people with social phobia have a diminished sense of personal control over events in their lives (Leung & Heimberg, 1996). This diminished expectation of personal control may develop, at least in part, as a function of having been raised in families with somewhat overprotective (and sometimes rejecting) parents (Lieb et al., 2000).

**COGNITIVE BIASES** Cognitive factors also play a role in the onset and maintenance of social phobia. Beck and Emery (1985) suggested that people with social phobia tend to expect that other people will reject or negatively evaluate them. They argued that this leads to a sense of vulnerability when they are around people who might pose a threat. Clark and Wells (1995; Wells & Clark, 1997) later further proposed that these danger schemas of socially anxious people lead them to expect that they will behave in an awkward and unacceptable fashion, resulting in rejection and loss of status. Such negative expectations lead to their being preoccupied with bodily responses and with stereotyped, negative self-images in social situations; to their overestimating how easily others will detect their anxiety; and to their misunderstanding how well they come across to others (Hirsch et al., 2004). Such intense self-preoccupation during social situations, even to the point of attending to their own heart rate, interferes with their ability to interact skillfully (Hirsch et al., 2003; Pineles & Mineka, 2005). A vicious cycle may evolve: Social phobics'

inward attention and somewhat awkward behavior may lead others to react to them in a less friendly fashion, confirming their expectations (D. M. Clark, 1997; Clark & McManus, 2002).

Another cognitive bias seen in social phobia is a tendency to interpret ambiguous social information in a negative rather than a benign manner (e.g., when someone smiles at you, does it mean they like you or that they think you're foolish?). Moreover, it is the negatively biased interpretations that socially anxious people make that are what is remembered (Hertel et al., 2008). It has also been suggested that these biased cognitive processes combine to maintain social phobia and possibly even contribute to its development (Hirsch, Clark, & Mathews, 2006).

#### Biological Causal Factors

**GENETIC AND TEMPERAMENTAL FACTORS** The most important temperamental variable is *behavioral inhibition*, which shares characteristics with both neuroticism and introversion (Bienvenu et al., 2007). Behaviorally inhibited infants who are easily distressed by unfamiliar stimuli and who are shy and avoidant are more likely to become fearful during childhood and, by adolescence, to show increased risk of developing social phobia (Hayward et al., 1998; Kagan, 1997). For example, one classic study was conducted on behavioral inhibition as a risk factor in a large group of children, most of whom were already known to be at risk for anxiety because their parents had an emotional disorder. Among these children, those who had been assessed as being high on behavioral inhibition between 2 and 6 years of age were nearly three times more likely to be diagnosed with social phobia (22 percent) even in middle childhood (average age of 10) than were children who were low on behavioral inhibition at 2 to 6 years (8 percent; Hirshfeld-Becker et al., 2007; see also Hayward et al., 1998). In another study, 60 children were assessed yearly for behavioral inhibition from grades 1 to 9. If they showed chronically

Infants and young children who are fearful and easily distressed by novel people or situations are sometimes high on the temperamental variable called behavioral inhibition. Such infants show an increased risk of developing social phobia in adolescence.

high levels of behavioral inhibition throughout this time period, 50 percent had developed social anxiety disorder by grade 9. By contrast, none had developed social anxiety disorder in the group with chronic low behavioral inhibition (Essex et al., 2010).

Results from several studies of twins have also shown that there is a modest genetic contribution to social phobia; estimates are that about 30 percent of the variance in liability to social phobia is due to genetic factors (Hettema et al., 2005; Smoller et al., 2008). Nevertheless, these studies suggest that an even larger proportion of variance in who develops social phobia is due to nonshared environmental factors, which is consistent with a strong role for learning.

## Treatments

**COGNITIVE AND BEHAVIORAL THERAPIES** There are very effective forms of behavior therapy and cognitive-behavior therapy for social phobia. As for specific phobias, behavioral treatments were developed first and generally involve prolonged and graduated exposure to social situations that evoke fear. More recently, as research has revealed the underlying distorted cognitions that characterize social phobia, **cognitive restructuring** techniques have been added to the behavioral techniques, generating a form of cognitive-behavioral therapy (Barlow et al., 2007). In cognitive restructuring the therapist attempts to help clients with social phobia identify their underlying negative, automatic thoughts ("I've got nothing interesting to say" or "No one is interested in me"). After helping clients understand that such automatic thoughts (which usually occur just below the surface of awareness but can be accessed) often involve cognitive distortions, the therapist helps the clients change these inner thoughts and beliefs through logical reanalysis. The process of logical reanalysis might involve asking oneself questions to challenge the automatic thoughts: "Do I know for certain that I won't have anything to say?" "Does being nervous have to lead to or equal looking stupid?"

In one highly effective version of such treatments, clients may be assigned exercises in which they manipulate their focus of attention (internally versus externally) to demonstrate to themselves the adverse effects of internal self-focus. They may also receive videotaped feedback to help them modify their distorted self-images. Such techniques have now been very successfully applied to the treatment of social phobia (Clark, Ehlers, et al., 2003, 2006; Heimberg, 2002; Mörtberg et al., 2007). Many studies over the years have shown that exposure therapy and cognitive-behavioral therapy produce comparable results. However, one study suggests that this new, very effective variant on cognitive treatment may be more effective than exposure therapy (Clark et al., 2006). Moreover, at least one study has now shown that simply training individuals with social phobia to disengage from negative social cues during a 15-minute lab task that is repeated 8 times over 4 to 6 weeks produced such remarkable reductions in social anxiety symptoms that nearly 3 out of 4 of the participants no longer met criteria for social anxiety disorder (Schmidt et al., 2009).

An example of successful combined treatment can be seen in the case of Paul, the surgeon described earlier who had social phobia.

→ **Paul's Treatment** Since the onset of his social phobia 13 years earlier, Paul had taken an antidepressant at one point. The drug had helped stop his panic attacks, but he continued to fear them intensely and still avoided social situations. Thus, there was little effect on his social phobia. He had also been in supportive psychotherapy, which had helped his depression at the time but not his social phobia or his panic. When he went for treatment at an anxiety clinic, he was not on any medication or in any other form of treatment. Treatment consisted of 14 weeks of cognitive-behavioral therapy. By the end of treatment, Paul was not panicking at all and was quite comfortable in most social situations that he had previously avoided. He was seeing old friends whom he had avoided for years because of his anxiety, and he was beginning to date. Indeed, he even asked his female therapist for a date during the last treatment session! Although such a request was clearly inappropriate, it did indicate how much progress he had made.

.....

**MEDICATIONS** Unlike specific phobias, social phobias can also sometimes be treated with medications. The most effective and widely used medications are several categories of antidepressants (including the monoamine oxidase inhibitors [MAOIs] and the selective serotonin reuptake inhibitors [SSRIs] discussed extensively in Chapters 7 and 16; Ipser et al., 2008; Roy-Byrne & Cowley, 2007). In some studies, the effects of these antidepressant medications have been comparable to those seen with cognitive-behavioral treatments. However, in several studies, the newer version of cognitive-behavior therapy discussed earlier produced much more substantial improvement than did medication (e.g., Clark, Ehlers, et al., 2003). Moreover, the medications must be taken over a long period of time to help ensure that relapse does not occur (Blanco et al., 2002; Stein & Stein, 2008). A distinct advantage of behavioral and cognitive-behavioral therapies over medications, then, is that they generally produce more long-lasting improvement with very low relapse rates; indeed, clients often continue to improve after treatment is over. Finally, several studies have also suggested that when d-cycloserine (discussed with treatment of specific phobias) is added to exposure therapy, the treatment gains occur more quickly and are more substantial (e.g., Guastella et al., 2008).

## in review

- What are the primary diagnostic criteria for social phobia and its two subtypes?
- Identify three of the psychological causal factors for social phobia and two of the biological causal factors.
- Describe the major treatment approaches used for social phobias.

## Panic Disorder

Diagnostically, **panic disorder** is defined and characterized by the occurrence of panic attacks that often seem to come “out of the blue.” According to the *DSM-5* criteria for panic disorder, the person must have experienced recurrent, unexpected attacks and must have been persistently concerned about having another attack or worried about the consequences of having an attack for at least a month (often referred to as anticipatory anxiety). For such an event to qualify as a full-blown panic attack, there must be abrupt onset of at least 4 of 13 symptoms, most of which are physical, although three are cognitive: (1) depersonalization (a feeling of being detached from one’s body) or derealization (a feeling that the external world is strange or unreal); (2) fear of dying; or (3) fear of “going crazy” or “losing control” (see the *DSM-5* box for diagnostic criteria). Panic attacks are fairly brief but intense, with symptoms developing abruptly and usually reaching peak intensity within 10 minutes; the attacks usually subside in 20 to 30 minutes and rarely last more than an hour. Periods of anxiety, by contrast, do not usually have such an abrupt onset and are more long lasting.

Panic attacks are often “unexpected” or “uncued” in the sense that they do not appear to be provoked by identifiable aspects of the immediate situation. Indeed, they sometimes occur in situations in which they might be least expected, such as during relaxation or during sleep (known as *nocturnal panic*). In

other cases, however, panic attacks are said to be situationally predisposed, occurring only sometimes while the person is in a particular situation such as while driving a car or being in a crowd.

Because most symptoms of a panic attack are physical, it is not surprising that as many as 85 percent of people having a panic attack may show up repeatedly at emergency rooms or physicians’ offices for what they are convinced is a medical problem—usually cardiac, respiratory, or neurological (White & Barlow, 2002; see also Korczak et al., 2007). Of course, medical causes have to be ruled out. However, if a person experiences panic attacks and becomes very concerned about having additional attacks or worries about the possible consequences of the attack (e.g., having a heart attack or going crazy), a diagnosis of panic disorder will eventually be given.

Unfortunately, a correct diagnosis is often not made for years due to the normal results on numerous costly medical tests. Further complications arise because cardiac patients are at a nearly twofold elevated risk for developing panic disorder (Korczak et al., 2007). Prompt diagnosis and treatment is also important because panic disorder causes approximately as much impairment in social and occupational functioning as that caused by major depressive disorder (Roy-Byrne et al., 2008) and because panic disorder can contribute to the development or worsening of a variety of medical problems (White & Barlow, 2002).

### criteria for Panic Disorder

- A. Recurrent unexpected panic attacks. A panic attack is an abrupt surge of intense fear or intense discomfort that reaches a peak within minutes, and during which time four (or more) of the following symptoms occur:

**Note:** The abrupt surge can occur from a calm state or an anxious state.

1. Palpitations, pounding heart, or accelerated heart rate.
2. Sweating.
3. Trembling or shaking.
4. Sensations of shortness of breath or smothering.
5. Feelings of choking.
6. Chest pain or discomfort.
7. Nausea or abdominal distress.
8. Feeling dizzy, unsteady, light-headed, or faint.
9. Chills or heat sensations.
10. Paresthesias (numbness or tingling sensations).
11. Derealization (feelings of unreality) or depersonalization (being detached from oneself).
12. Fear of losing control or “going crazy.”
13. Fear of dying.

**Note:** Culture-specific symptoms (e.g., tinnitus, neck soreness, headache, uncontrollable screaming or crying) may be seen.

### DSM-5

Such symptoms should not count as one of the four required symptoms.

- B. At least one of the attacks has been followed by 1 month (or more) of one or both of the following:

1. Persistent concern or worry about additional panic attacks or their consequences (e.g., losing control, having a heart attack, “going crazy”).
2. A significant maladaptive change in behavior related to the attacks (e.g., behaviors designed to avoid having panic attacks, such as avoidance of exercise or unfamiliar situations).
- C. The disturbance is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or another medical condition (e.g., hyperthyroidism, cardiopulmonary disorders).
- D. The disturbance is not better explained by another mental disorder (e.g., the panic attacks do not occur only in response to feared social situations, as in social anxiety disorder; in response to circumscribed phobic objects or situations, as in specific phobia; in response to obsessions, as in obsessive-compulsive disorder; in response to reminders of traumatic events, as in posttraumatic stress disorder; or in response to separation from attachment figures, as in separation anxiety disorder).

The case of Mindy Markowitz is typical:

→ **Art Director's Panic Attacks** Mindy Markowitz is an attractive ... 25-year-old art director ... who comes to an anxiety clinic ... seeking treatment for "panic attacks" that have occurred with increasing frequency over the past year, often two or three times a day. These attacks begin with a sudden, intense wave of "horrible fear" that seems to come out of nowhere, sometimes during the day, sometimes waking her from sleep. She begins to tremble, is nauseated, sweats profusely, feels as though she is choking, and fears that she will lose control and do something crazy, like run screaming into the street....

Mindy has had panic attacks intermittently over the 8 years since her first attack, sometimes not for many months, but sometimes, as now, several times a day. There have been extreme variations in the intensity of the attacks, some being so severe and debilitating that she has had to take a day off from work.

Mindy has always functioned extremely well in school, at work, and in her social life, apart from her panic attacks. . . . She is a lively, friendly person ... who has never limited her activities . . . She says . . . she is as likely to have an attack at home in her own bed as on the subway, so there is no point in avoiding the subway. . . . [Wherever] she has an attack . . . she says, "I just tough it out."

## Agoraphobia

Historically, agoraphobia was thought to involve a fear of the *agora*—the Greek word for public places of assembly (Marks, 1987). In **agoraphobia** the most commonly feared and avoided situations include streets and crowded places such as shopping malls, movie theaters, and stores. Standing in line can be particularly difficult (see Table 6.2 on p. 180 for commonly avoided situations). What is the common theme that underlies this seemingly diverse cluster of fears? Sometimes, agoraphobia develops as a complication of having panic attacks in one or more such situations. Concerned that they may have a panic attack or get sick, people with agoraphobia are anxious about being in places or situations from which escape would be physically difficult or psychologically embarrassing, or in which immediate help would be unavailable if something bad happened (see the *DSM-5* box for diagnostic criteria). Typically people with agoraphobia are also frightened by their own bodily sensations, so they also avoid activities that will create arousal such as exercising, watching scary movies, drinking caffeine, and even engaging in sexual activity.

As agoraphobia first develops, people tend to avoid situations in which attacks have occurred, but usually the avoidance gradually spreads to other situations where attacks might occur. In moderately severe cases, people with agoraphobia may be anxious even when venturing outside their homes alone. In very severe cases, agoraphobia is an utterly disabling disorder in which

### criteria for Agoraphobia

DSM-5

- A. Marked fear or anxiety about two (or more) of the following five situations:
  1. Using public transportation (e.g., automobiles, buses, trains, ships, planes).
  2. Being in open spaces (e.g., parking lots, marketplaces, bridges).
  3. Being in enclosed places (e.g., shops, theaters, cinemas).
  4. Standing in line or being in a crowd.
  5. Being outside of the home alone.
- B. The individual fears or avoids these situations because of thoughts that escape might be difficult or help might not be available in the event of developing panic-like symptoms or other incapacitating or embarrassing symptoms (e.g., fear of falling in the elderly; fear of incontinence).
- C. The agoraphobic situations almost always provoke fear or anxiety.
- D. The agoraphobic situations are actively avoided, require the presence of a companion, or are endured with intense fear or anxiety.
- E. The fear or anxiety is out of proportion to the actual danger posed by the agoraphobic situations and to the sociocultural context.
- F. The fear, anxiety, or avoidance is persistent, typically lasting for 6 months or more.
- G. The fear, anxiety, or avoidance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- H. If another medical condition (e.g., inflammatory bowel disease, Parkinson's disease) is present, the fear, anxiety, or avoidance is clearly excessive.
- I. The fear, anxiety, or avoidance is not better explained by the symptoms of another mental disorder—for example, the symptoms are not confined to specific phobia, situational type; do not involve only social situations (as in social anxiety disorder); and are not related exclusively to obsessions (as in obsessive-compulsive disorder), perceived defects or flaws in physical appearance (as in body dysmorphic disorder), reminders of traumatic events (as in posttraumatic stress disorder), or fear of separation (as in separation anxiety disorder).

**Note:** Agoraphobia is diagnosed irrespective of the presence of panic disorder. If an individual's presentation meets criteria for panic disorder and agoraphobia, both diagnoses should be assigned.

**TABLE 6.2**  
**Situations Frequently Avoided by People with Agoraphobia**

Crowds	Standing in line
Theaters	Restaurants
Shopping malls	Sports arenas
Cars and buses	Trains and airplanes
Bridges	Tunnels
Escalators	Elevators
Being home alone	Being far away from home
Aerobic exercise	Sauna baths
Getting angry	Sexual activity
Watching exciting or scary movies	

a person cannot go beyond the narrow confines of home—or even particular parts of the home.

The case of John D. is typical of someone with both panic disorder and agoraphobia.

→ **John D.** John D. was a 45-year-old married Caucasian man with three sons. Although well educated and successful ... John had been experiencing difficulties with panic attacks for 15 years ... experiencing two to five panic attacks per month. The previous week John had had a panic attack while driving with his family to a computer store. He recollects that before the panic attack he might have been "keyed up" over the kids making a lot of noise in the back seat; the attack began right after he had quickly turned around to tell the kids to "settle down." Immediately after he turned back to look at the road, John felt dizzy. As soon as he noticed this, John experienced a rapid and intense surge of other sensations including sweating, accelerated heart rate, hot flushes, and trembling. Fearing that he was going to crash the car, John quickly pulled to the side of the road ....

John was having only a few panic attacks per month, but he was experiencing a high level of anxiety every day, focused on the possibility that he might have another panic attack at any time. Indeed, John had developed extensive apprehension or avoidance of driving, air travel, elevators, wide-open spaces, taking long walks alone, movie theaters, and being out of town.

[His] first panic attack had occurred 15 years ago. John had fallen asleep on the living room sofa at around 1:00 A.M. after returning from a night of drinking with some of his friends. Just after awakening at 4:30, John felt stomach pains and a pulsating sensation in the back of his neck. All of a sudden, John noticed that his heart was racing, too.... Although he did not know what he was suffering from, John was certain that he was dying.

John remembered having a second panic attack about a month later. From then on, the panic attacks began to occur more regularly. When the panic attacks became recurrent, John started to avoid situations in which the panic attacks had occurred as well

as situations in which he feared a panic attack was likely to occur. On three occasions during the first few years of his panic attacks, John went to the emergency room of his local hospital because he was sure that his symptoms were a sign of a heart attack.

Source: Adapted from Brown & Barlow, 2001, pp. 19–22.

Agoraphobia is a frequent complication of panic disorder. The case of John D. is typical. However, many patients with agoraphobia do not experience panic. Recognizing this, in *DSM-5* agoraphobia is now listed as a distinct disorder. As agoraphobia develops, there is often a gradually spreading fearfulness in which more and more aspects of the environment outside the home become threatening. The most recent estimate of the lifetime prevalence of agoraphobia without panic from the National Comorbidity Survey-Replication is 1.4 percent (e.g., Kessler, Chiu, et al., 2006).

### Prevalence, Age of Onset, and Gender Differences

Many people suffer from panic disorder and from agoraphobia. The National Comorbidity Survey-Replication study found that approximately 4.7 percent of the adult population has had panic disorder with or without agoraphobia at some time in their lives, with panic disorder without agoraphobia being more common (Kessler, Chiu, et al., 2005c). Panic disorder with or without agoraphobia often starts in the late teenage years, but the average age of onset is 23 to 34 years. However, it can begin, especially for women, in a person's 30s or 40s (Hirschfeld, 1996; Kessler, Chiu, et al., 2006). Once panic disorder develops, it tends to have a chronic and disabling course, although the intensity of symptoms often waxes and wanes over time (Keller et al., 1994; White & Barlow, 2002). Indeed, one 12-year longitudinal study found that less than 50 percent of patients with panic disorder with agoraphobia had recovered in 12 years, and 58 percent of those who had recovered at some point had had a recurrence (new onset; Bruce et al., 2005). Panic disorder is about twice as prevalent in women as in men (Eaton et al., 1994; White & Barlow, 2002). Agoraphobia also occurs much more frequently in women than in men, and the percentage of women increases as the extent of agoraphobic avoidance increases. Among people with severe agoraphobia, approximately 80 to 90 percent are female (Bekker, 1996; White & Barlow, 2002). Table 6.3 outlines gender differences in the prevalence of other anxiety disorders for comparison purposes.

The most common explanation of the pronounced gender difference in agoraphobia is a sociocultural one (McLean & Anderson, 2009). In our culture (and many others as well), it is more acceptable for women who experience panic to avoid the situations they fear and to need a trusted companion to accompany them when they enter feared situations. Men who experience panic are more prone to "tough it out" because of societal expectations and their more assertive, instrumental approach to life (Bekker, 1996). Although there is very little research on this topic, one study consistent with this idea was

**TABLE 6.3****Gender Differences in the Anxiety Disorders: Lifetime Prevalence Estimates**

Disorder	Prevalence in Men (%)	Prevalence in Women (%)	Ratio
Specific phobias	6.7	15.7	2.34
Social phobia	11.1	15.5	1.4
Panic disorder	2.0	5.0	2.5
Generalized anxiety disorder	3.6	6.6	1.8

Note: Because these figures are from different studies and may not be strictly comparable, they should be taken as approximations of current estimates of gender differences.

Sources: Eaton et al. (1994); Karno et al. (1988); Kessler et al. (1994, 1995); Magee et al. (1996).

conducted by Chambless and Mason (1986), who administered a sex-role scale to both male and female agoraphobics and found that the less “masculine” one scored on the scale, the more extensive the agoraphobic avoidance, for both males and females. Another study found that cultures and societies that delineate rigid gender roles at a sociocultural level tend to have higher levels of agoraphobia. In addition, some evidence indicates that men with panic disorder may be more likely to self-medicate with nicotine or alcohol as a way of coping with and enduring panic attacks rather than developing agoraphobic avoidance (Starcevic et al., 2008).

### Comorbidity with Other Disorders

The National Comorbidity Survey-Replication found that 83 percent of people with panic disorder have at least one comorbid disorder (Kessler, Chiu, et al., 2006). Most commonly these include generalized anxiety disorder, social phobia, specific phobia, PTSD, depression, and substance-use disorders (especially smoking and alcohol dependence; Bernstein et al., 2006; Kessler, Chiu, et al., 2006; Zvolensky & Bernstein, 2005). It is estimated that 50 to 70 percent of people with panic disorder will experience serious depression at some point in their lives (Kessler, Chiu, et al., 2006). They may also meet criteria for dependent or avoidant personality disorder (see Chapter 10). The issue of whether people with panic disorder show an increased risk of suicidal ideation and suicide attempts has been quite controversial, with a number of studies suggesting that any increased risk is due to indirect factors such as comorbid depression and substance abuse, which are known risk factors themselves (e.g., Vickers & McNally, 2004). However, two recent very large epidemiological studies (one in the United States, which had nearly 10,000 adults from the National Comorbidity Survey-Replication study, and one including over 100,000 people from 21 countries) have indeed found that panic disorder is associated with increased risk for suicidal ideation and attempts independent of its relationship with comorbid disorders (Nock et al., 2009; Nock et al., 2010).

### The Timing of a First Panic Attack

Although panic attacks themselves appear to come “out of the blue,” the first one frequently occurs following feelings of distress or some highly stressful life circumstance such as loss of a loved one, loss of an important relationship, loss of a job, or criminal victimization (see Barlow, 2002; Klauke et al., 2010, for reviews). Although not all studies have found this, some have estimated that approximately 80 to 90 percent of clients report that their first panic attack occurred after one or more negative life events.

Nevertheless, not all people who have a panic attack following a stressful event go on to develop full-blown panic disorder. Current estimates from the recent National Comorbidity Survey-Replication are that nearly 23 percent of adults have experienced at least one panic attack in their lifetimes, but most have not gone on to develop full-blown panic disorder (Kessler, Chiu, et al., 2006). People who have other anxiety disorders or major depression often experience occasional panic attacks as well (Barlow, 2002; Kessler, Chiu, et al., 2006). Given that panic attacks are much more frequent than panic disorder, this leads us to an important question: What causes full-blown panic disorder to develop in only a subset of these people? Several different prominent theories about the causes of panic disorder have addressed this question.

### Biological Causal Factors

**GENETIC FACTORS** According to family and twin studies, panic disorder has a moderate heritable component (e.g., Kendler et al., 1992b, 1992c; Kendler et al., 2001; Norrholm & Ressler, 2009). In a large twin study, Kendler and colleagues (2001) estimated that 33 to 43 percent of the variance in liability to panic disorder was due to genetic factors. As noted earlier, this genetic vulnerability is manifested at a psychological level at least in part by the important personality trait called neuroticism (which is in turn related to the temperamental construct of behavioral inhibition). Recently, several studies have begun to identify which specific genetic polymorphisms are responsible for this moderate heritability (e.g., Strug et al., 2010), either alone or in interaction

People with severe agoraphobia are often fearful of venturing out of their homes into public places, in part because of their fear of having a panic attack in a place in which escape might prove physically difficult or psychologically embarrassing. They may even become housebound unless accompanied by a spouse or trusted companion.

with certain types of stressful life events (e.g., Klauke et al., 2010), but this preliminary work needs to be replicated.

Some studies have suggested that this heritability is at least partly specific for panic disorder (rather than for all anxiety disorders; see Barlow, 2002, for a review), but one large female twin study suggested that there is overlap in the genetic vulnerability factors for panic disorder and phobias (Kendler, Walters, et al., 1995). This would be consistent with some preliminary evidence that people with a history of social or specific phobia are at heightened risk for developing panic disorder (Biederman et al., 2006). However, another study suggests overlap in the genetic vulnerability for panic disorder, generalized anxiety disorder, and agoraphobia (Hettema, Prescott, et al., 2005). Only further research can resolve these inconsistencies in findings (e.g., Norrholm & Ressler, 2009).

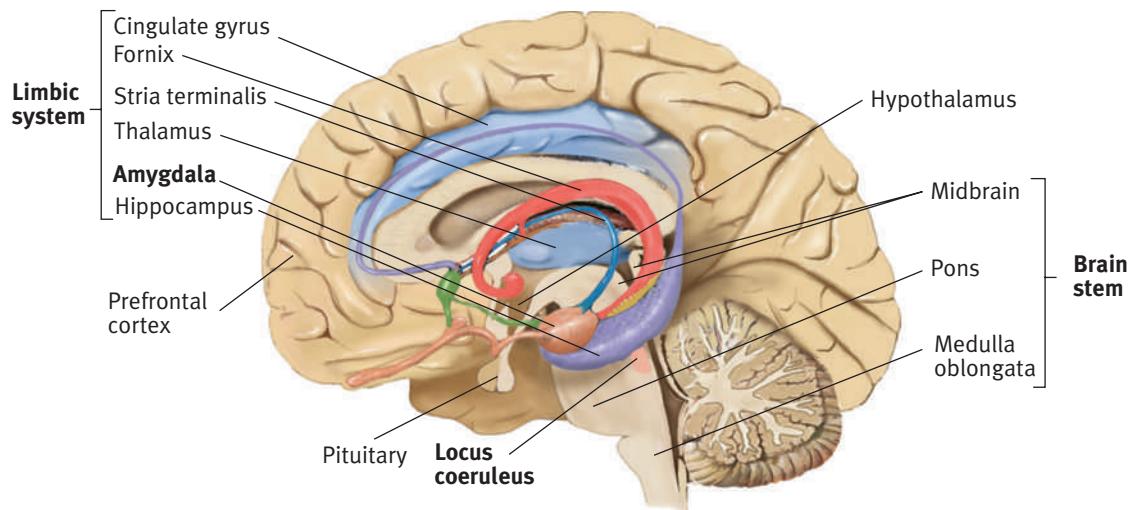

**PANIC AND THE BRAIN** One relatively early prominent theory about the neurobiology of panic attacks implicated the *locus coeruleus* in the brain stem (see Figure 6.1 on p. 183) and a particular neurotransmitter—norepinephrine—that is centrally involved in brain activity in this area (e.g., Goddard et al., 1996). However, today it is recognized that it is increased activity in the amygdala that plays a more central role in panic attacks than does activity in the locus coeruleus. The

**amygdala** is a collection of nuclei in front of the hippocampus in the limbic system of the brain that is critically involved in the emotion of fear. Stimulation of the central nucleus of the amygdala is known to stimulate the locus coeruleus as well as the other autonomic, neuroendocrine, and behavioral responses that occur during panic attacks (e.g., Gorman et al., 2000; LeDoux, 2000). Other recent research has also implicated the periaqueductal gray area in the midbrain (e.g., Del-Ben & Graeff, 2008; Graeff & Del-Ben, 2008).

Some research has suggested that the amygdala is the central area involved in what has been called a “fear network,” with connections not only to lower areas in the brain like the locus coeruleus but also to higher brain areas like the *prefrontal cortex* (e.g., Gorman et al., 2000). According to this view, panic attacks occur when the fear network is activated, either by cortical inputs or by inputs from lower brain areas. So according to this influential theory, panic disorder is likely to develop in people who have abnormally sensitive fear networks that get activated too readily to be adaptive. This theory about abnormally sensitive fear networks is also consistent with findings that individuals with panic disorder showed heightened startle responses to loud noise stimuli as well as slower habituation of such responding (Ludewig et al., 2005; see also Shin & Liberzon, 2010). Sakai and colleagues (2005), using functional neuroimaging techniques, also found support for this neuroanatomical hypothesis. Abnormally sensitive fear networks may have a partially heritable basis but may also develop as a result of repeated stressful life experiences, particularly early in life (e.g., Gorman et al., 2000; Ladd et al., 2000).

But panic attacks are only one component of panic disorder. People with panic disorder also become anxious about the possibility of another attack, and those with agoraphobia also engage in phobic avoidance behavior (e.g., Gorman et al., 1989, 2000). Different brain areas are probably involved in these different aspects of panic disorder. The panic attacks themselves arise from activity in the amygdala, either by cortical inputs (e.g., evaluating a stimulus as highly threatening) or by activity coming from more downstream areas like the locus coeruleus. For people who have one or more panic attacks and who go on to develop significant conditioned anxiety about having another one in particular contexts, the *hippocampus* (also a part of the *limbic system*, below the cortex, which is very involved in the learning of emotional responses; see Figure 6.1) is thought to generate this conditioned anxiety (e.g., Charney et al., 1998; Gray & McNaughton, 1996, 2000) and is probably also involved in the learned avoidance associated with agoraphobia (Gorman et al., 2000). Finally, the cognitive symptoms that occur during panic attacks (fears of dying or of losing control) and overreactions to the danger posed by possibly threatening bodily sensations are likely to be mediated by higher cortical centers (see Gorman et al., 2000; Etkin, 2010).

**BIOCHEMICAL ABNORMALITIES** Over 30 years ago, Klein (1981) and others (Sheehan, 1982, 1983) argued that panic attacks are alarm reactions caused by biochemical dysfunctions.

**FIGURE 6.1**

**A Biological Theory of Panic, Anxiety, and Agoraphobia.** According to one theory, panic attacks may arise from abnormal activity in the amygdala, a collection of nuclei in front of the hippocampus in the limbic system. The anticipatory anxiety that people develop about having another panic attack is thought to arise from activity in the hippocampus of the limbic system, which is known to be involved in the learning of emotional responses. Agoraphobic avoidance, also a learned response, may also involve activity of the hippocampus and higher cortical centers (Gorman et al., 2000).

This hypothesis initially appeared to be supported by numerous studies over the past 40 years, showing that people with panic disorder are much more likely to experience panic attacks when they are exposed to various biological challenge procedures than are normal people or people with other psychiatric disorders. For example, some of these laboratory tests involve infusions of sodium lactate (a substance resembling the lactate our bodies produce during exercise; e.g., Gorman et al., 1989), inhaling air with altered amounts of carbon dioxide (e.g., Woods et al., 1987), or ingesting large amounts of caffeine (e.g., Uhde, 1990). In each case, such procedures produce panic attacks in panic disorder clients at a much higher rate than in normal subjects (see Barlow, 2002, for review). There is a broad range of these so-called **panic provocation procedures**, and some of them are associated with quite different and even mutually exclusive neurobiological processes. Thus, no single neurobiological mechanism could possibly be implicated (Barlow 2002; Roy-Byrne et al., 2006). However, as explained later in the section on causal factors, simpler biological and psychological explanations can account for this pattern of results. These alternative explanations stem from the observation that what all these biological challenge procedures have in common is that they put stress on certain neurobiological systems, which in turn produce intense physical symptoms of arousal (such as increased heart rate, respiration, and blood pressure).

At present, two primary neurotransmitter systems are most implicated in panic attacks—the noradrenergic and the serotonergic systems (Gorman et al., 2000; Graeff & Del-Ben, 2008; Neumeister et al., 2004). Noradrenergic activity in certain brain

areas can stimulate cardiovascular symptoms associated with panic (Gorman et al., 2000). Increased serotonergic activity also decreases noradrenergic activity. This fits with results showing that the medications most widely used to treat panic disorder today (the selective serotonin reuptake inhibitors—SSRIs) seem to increase serotonergic activity in the brain but also to decrease noradrenergic activity. By decreasing noradrenergic activity, these medications decrease many of the cardiovascular symptoms associated with panic that are ordinarily stimulated by noradrenergic activity (Gorman et al., 2000).

The inhibitory neurotransmitter GABA has also been implicated in the anticipatory anxiety that many people with panic disorder have about experiencing another attack. GABA is known to inhibit anxiety and has been shown to be abnormally low in certain parts of the cortex in people with panic disorder (Goddard, Mason, et al., 2001, 2004).

## Psychological Causal Factors

### COMPREHENSIVE LEARNING THEORY OF PANIC

**DISORDER** Certain investigators have proposed a comprehensive learning theory of panic disorder that accounts for most of the known findings about panic disorder (Bouton, Mineka, & Barlow, 2001; see also Barlow, 2002; Bouton, 2005; Mineka & Zinbarg, 2006). Along with advances in the study of classical conditioning, this theory builds on the earlier theory that initial internal bodily sensations of anxiety or arousal (such as heart palpitations) effectively become interoceptive conditioned stimuli associated with higher levels of anxiety or arousal (Goldstein &

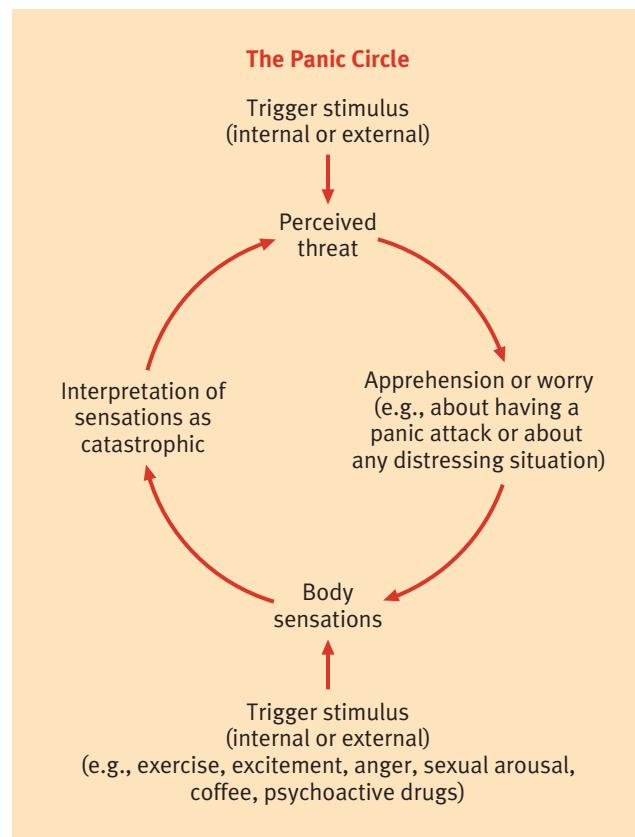

Chambless, 1978). According to this theory, initial panic attacks become associated with initially neutral internal (interoceptive) and external (exteroceptive) cues through an **interoceptive conditioning** (or **exteroceptive conditioning**) process (e.g., Acheson et al., 2007; Forsyth & Eifert, 1998). One primary effect of this conditioning is that anxiety becomes conditioned to these CSs, and the more intense the panic attack, the more robust the conditioning that will occur (Forsyth et al., 2000). Other types of instrumental and avoidance learning are also involved but will not be explained here.

This conditioning of anxiety to the internal or external cues associated with panic thus sets the stage for the development of two of the three components of panic disorder: anticipatory anxiety and sometimes agoraphobic fears. Specifically, when people experience their initial panic attacks (which are terrifying emotional events replete with strong internal bodily sensations), interoceptive and exteroceptive conditioning can occur to multiple different kinds of cues, ranging from heart palpitations and dizziness to shopping malls. Because anxiety becomes conditioned to these CSs, anxious apprehension about having another attack, particularly in certain contexts, may develop, as may agoraphobic avoidance of contexts in which panic attacks might occur in a subset of individuals. Moreover, a recent study demonstrated that once an individual has developed panic disorder they show greater generalization of conditioned responding to other similar cues than do controls without panic disorder (Lissek et al., 2010). In individuals who have panic disorder, a recent study showed that extinction of conditioned anxiety responses occurs more slowly than in normal controls (Michael, Blechert, et al., 2007). Because extinction involves inhibitory learning, which seems to be impaired in panic disorder, it is not surprising that individuals with panic disorder also show impaired discriminative conditioning because of their deficits in learning that a CS is a safety cue (Lissek et al., 2009).

However, another important effect is that panic attacks themselves (the third component of panic disorder) are also likely to be conditioned to certain internal cues. This leads to the occurrence of panic attacks that seemingly come out of the blue when people unconsciously experience certain internal bodily sensations (CSs). For example, one young man with panic disorder who was particularly frightened of signs that his heart was racing experienced a surprising and unexpected panic attack after hearing that his favorite presidential candidate had won. The panic attack thus occurred when he was happy and excited (which is what made it so surprising for him). However, from the standpoint of this theory, the attack was actually not surprising. Because the man was excited, his heart was racing, which probably served as an internal CS that triggered the panic (Mineka & Zinbar, 2006). This theory also underscores why not everyone who experiences an occasional panic attack goes on to develop panic disorder. Instead, people with certain genetic, temperamental or personality, or cognitive-behavioral vulnerabilities will show stronger conditioning of both anxiety and panic (Barlow, 2002; Bouton et al.,

2001; Mineka & Zinbar, 2006). For example, the personality variable that clearly serves as a risk variable is neuroticism.

**COGNITIVE THEORY OF PANIC** An earlier cognitive theory of panic disorder proposed that individuals with panic disorder are hypersensitive to their bodily sensations and are very prone to giving them the direst possible interpretation (Beck & Emery, 1985; D. M. Clark, 1986, 1997). Clark referred to this as a tendency to catastrophize about the meaning of their bodily sensations. For example, a person who develops panic disorder might notice that his heart is racing and conclude that he is having a heart attack, or notice that he is dizzy, which may lead to fainting or to the thought that he may have a brain tumor. These very frightening thoughts may cause many more physical symptoms of anxiety, which further fuel the catastrophic thoughts, leading to a vicious circle culminating in a panic attack (see Figure 6.2). The person is not necessarily aware of making these catastrophic interpretations; rather, the thoughts are often just barely out of the realm of

**FIGURE 6.2**

**The Panic Circle.** Any kind of perceived threat may lead to apprehension or worry, which is accompanied by various bodily sensations. According to the cognitive model of panic, if a person then catastrophizes about the meaning of his or her bodily sensations, this will raise the level of perceived threat, thus creating more apprehension and worry as well as more physical symptoms, which fuel further catastrophic thoughts. This vicious circle can culminate in a panic attack. The initial physical sensations need not arise from the perceived threat (as shown at the top of the circle) but may come from other sources (exercise, anger, psychoactive drugs, etc., as shown at the bottom of the circle). (Adapted from D. M. Clark, 1986, 1997.)

awareness (Rapee, 1996). These *automatic thoughts*, as Beck calls them, are in a sense the triggers of panic. Although it is not yet clear how the tendency to catastrophize develops, the cognitive model proposes that only people with this tendency to catastrophize go on to develop panic disorder (e.g., D. M. Clark, 1997).

Several lines of evidence are consistent with the cognitive theory of panic disorder. For example, people with panic disorder are much more likely to interpret their bodily sensations in a catastrophic manner (e.g., see D. M. Clark, 1997; Teachman et al., 2007), and the greater the tendency to do so, the greater the severity of panic (Casey et al., 2005). The model also predicts that changing their cognitions about their bodily symptoms should reduce or prevent panic. Evidence that cognitive therapy for panic works is consistent with this prediction (D. M. Clark et al., 1994, 1999). In addition, a brief explanation of what to expect in a panic provocation study can apparently prevent or reduce panic symptoms (D. M. Clark, 1997). People with panic disorder either were given a brief, but detailed, explanation of what physical symptoms to expect from an infusion of sodium lactate and why they should not worry about these symptoms, or were given a minimal explanation. The people with the cognitive rationale about what to expect were significantly less likely to say that they had had the subjective experience of a panic attack in response to the lactate (30 percent) than were control individuals (90 percent) (see Schmidt et al., 2006, for related results).

**LEARNING AND COGNITIVE EXPLANATIONS OF RESULTS FROM PANIC PROVOCATION STUDIES** Earlier, we noted that there are simpler psychological explanations that provide a common mechanism for understanding how so many varied panic provocation agents can all provoke panic at high rates in people

with panic disorder. Because these agents produce arousal, they mimic the physiological cues that normally precede a panic attack or may be taken as a sign of some other impending catastrophe (Barlow, 2002; Bouton et al., 2001; Margraf et al., 1986a, 1986b). People with panic disorder already start at a higher level of arousal than others and are very familiar with these early warning cues. Thus, according to the cognitive theory, people with panic attacks frequently misinterpret these symptoms as the beginning of a panic attack or a heart attack, which in turn induces the vicious circle of panic described in the previous section; this would not happen in controls who do not have the same tendency to catastrophize. Alternatively, according to the learning theory of panic disorder, it would be only those with panic disorder for whom these cues might serve as interoceptive CSs that can trigger anxiety and panic because of their prior associations with panic.

The key difference between these two theories in explaining the results of panic provocation studies lies in the great importance that the cognitive model places on the meaning that people attach to their bodily sensations; they will experience panic only if they make catastrophic interpretations of certain bodily sensations. Such catastrophic cognitions are not necessary with the interoceptive conditioning model because anxiety and panic attacks can be triggered by unconscious interoceptive (or exteroceptive) cues (Bouton et al., 2001). Thus the learning theory model is better able to explain the occurrence of the panic attacks that often occur without any preceding negative (catastrophic) automatic thoughts, as well as the occurrence of nocturnal panic attacks that occur during sleep; the occurrence of both of these kinds of attacks is difficult for the cognitive model to explain (see the Developments in Research box below).

## developments in RESEARCH

### Nocturnal Panic Attacks

Although the majority of panic attacks experienced by people with panic disorder occur during waking hours, approximately 50 to 60 percent of people report that they have experienced a panic attack during sleep at least once (Barlow, 2002; O'Mahony & Ward, 2003). Nocturnal panic refers to waking from sleep in a state of panic. It seems to occur with some regularity in about 20 to 40 percent of people with panic disorder and is frequently associated with insomnia and frequent awakenings during sleep (Craske et al., 2002; Overbeek et al., 2005; Papadimitriou & Linkowski, 2005). Although one might think that such panic attacks occur in response to nightmares, considerable research shows that this is not the case. Sleep has five stages that occur in a fairly invariant sequence multiple times throughout the night: one stage called REM sleep (rapid eye movement sleep) when vivid dreaming occurs, and four stages of non-REM sleep (Stages 1–4) when vivid dreams do not occur. If nocturnal panic attacks occurred in response to dreams,

we would expect them to occur during REM sleep (when nightmares usually occur), but in fact they occur during Stage 2 and early Stage 3 sleep, usually a few hours after falling asleep.

It is important to note that nocturnal panic attacks are different from "sleep terrors" or "night terrors," which usually occur during Stage 4 sleep. Night terrors are usually experienced by children, who often scream and then fear that someone or something is chasing them around the room; however, they do not wake up (Barlow, 2002). Nocturnal panic attacks also differ from isolated sleep paralysis, which can sometimes occur during the transition from sleep to waking. It involves awareness of one's surroundings accompanied by a stark sense of terror (resembling that during a panic attack) and an inability to move, which seems to occur because the individuals are waking from REM (dream) sleep, when there is suppression of muscle activity below the neck (e.g., Hinton et al., 2005).

**ANXIETY SENSITIVITY AND PERCEIVED CONTROL** Other cognitive and learning explanations of panic and agoraphobia have looked at a number of different factors that can generally be explained within either the learning or cognitive perspective. For example, several researchers have shown that people who have high levels of anxiety sensitivity are more prone to developing panic attacks and perhaps panic disorder (McNally, 2002; Pagura et al., 2009). **Anxiety sensitivity** is a trait-like belief that certain bodily symptoms may have harmful consequences. Such a person would endorse statements such as, “When I notice that my heart is beating rapidly, I worry that I might have a heart attack.” In one important study, Schmidt and colleagues (1997) followed over 1,400 young adults undergoing basic military training for 5 weeks. They found that high levels of anxiety sensitivity predicted the development of spontaneous panic attacks during this highly stressful period. Several other studies examining the same issues obtained very similar results, thus boosting confidence in the reliability of anxiety sensitivity as a predictor of panic attacks (e.g., Hayward et al., 2000; Li & Zinbarg, 2007). However, Schmidt and colleagues (2006) have reported results showing that high anxiety sensitivity also serves to predict the onset of other anxiety disorders as well as panic attacks, thus raising some questions about the specificity of its role for panic versus other anxiety disorders (see also Starcevic & Berle, 2006).

In addition, several important studies have shown that simply having a sense of *perceived control*—for instance, over the amount of carbon-dioxide-altered air that is inhaled (a panic provocation procedure known frequently to bring on anxiety and panic)—reduces anxiety and even blocks panic (e.g., Sanderson et al., 1989; Zvolensky et al., 1998, 1999). In addition, if a person with panic disorder is accompanied by a “safe” person

Many people experiencing a panic attack mistake their symptoms (for example, chest pain and shortness of breath) for another medical problem—most often a heart attack.

when undergoing a panic provocation procedure, that person is likely to show reduced distress, lowered physiological arousal, and reduced likelihood of panic relative to someone who came alone (without a “safe” person; Carter et al., 1995). Moreover, a recent study has shown that anxiety sensitivity has a greater effect on panic symptoms in people with low perceived control (Bentley et al., 2012). Finally, individuals with panic disorder may also be protected against the development of agoraphobic avoidance if they have relatively high levels of perceived control over their emotions and threatening situations (Suarez et al., 2009; White et al., 2006).

### SAFETY BEHAVIORS AND THE PERSISTENCE OF PANIC

Why do people who have developed panic disorder continue to have panic attacks in spite of the fact that their direst predictions rarely, if ever, come true? Some people with panic disorder may, for example, have three or four panic attacks a week for 20 years; each time they may believe they are having a heart attack, and yet they never do. After experiencing hundreds or thousands of panic attacks without having a heart attack, one would think, from the cognitive perspective, that this catastrophic thought would have been proved wrong so many times that it would finally go away. However, evidence suggests that such disconfirmation does not occur because people with panic disorder frequently engage in safety behaviors (such as breathing slowly or carrying a bottle with anxiolytic medication) before or during an attack. They then mistakenly tend to attribute the lack of catastrophe to their having engaged in this safety behavior rather than to the idea that panic attacks actually do not lead to heart attacks. Similarly, people who think they may faint will tend to lean against solid objects (D. A. Clark, 1997; Salkovskis et al., 1996). Research suggests that it is important during treatment to identify these safety behaviors so that the person can learn to give them up and finally see that the feared catastrophe still does not occur. Indeed, a good number of studies have found that asking people to drop their safety behaviors during cognitive-behavioral treatment can increase the effectiveness of the treatment (e.g., Rachman et al., 2008).

### COGNITIVE BIASES AND THE MAINTENANCE OF PANIC

Finally, many studies have shown that people with panic disorder are biased in the way they process threatening information. Such people not only interpret ambiguous bodily sensations as threatening (D. A. Clark, 1997; Teachman et al., 2006), but they also interpret other ambiguous situations as more threatening than do controls. People with panic disorder also seem to have their attention automatically drawn to threatening information in their environment such as words that represent things they fear, such as palpitations, numbness, or faint (see Lim & Kim, 2005; Mathews & MacLeod, 2005; Mineka et al., 2003, for reviews). One study using fMRI techniques demonstrated that people with panic disorder showed greater activation to

threat words than did normals in brain areas involved in memory processing of threatening material (Maddock et al., 2003). Whether these information-processing biases are present before the disorder begins and help to cause it is as yet unclear, but these biases are certainly likely to help maintain the disorder once it has begun. For example, having one's attention automatically drawn to threatening cues in the environment is likely to provoke more attacks.

In summary, research into both biological and psychosocial factors involved in panic disorder has provided important insights into this disorder since it was first identified as a distinct disorder in 1980. It seems unlikely that research from either tradition alone will ever provide a complete account of this disorder, and we eagerly await more attempts at synthesizing these findings into a biopsychosocial theory.

## Treatments

**MEDICATIONS** Many people with panic disorder (with or without agoraphobia) are prescribed *anxiolytics* (antianxiety medications) from the benzodiazepine category such as alprazolam (Xanax) or clonazepam (Klonopin). These people frequently show some symptom relief from these medications, and many can function more effectively. One major advantage of these drugs is that they act very quickly (30–60 minutes) and so can be useful in acute situations of intense panic or anxiety. However, these anxiolytic medications can also have quite undesirable side effects such as drowsiness and sedation, which can lead to impaired cognitive and motor performance. Also, with prolonged use, most people using moderate to high doses develop physiological dependence on the drug, which results in withdrawal symptoms when the drug is discontinued (e.g., nervousness, sleep disturbance, dizziness, and further panic attacks). Withdrawal from these drugs can be very slow and difficult, and it precipitates relapse in a high percentage of cases (Pollack & Simon, 2009; Roy-Byrne & Cowley, 2007). These are the reasons why benzodiazepines are no longer considered as a first-choice treatment (Katon, 2006).

The other category of medication that is useful in the treatment of panic disorder and agoraphobia is the antidepressants (including primarily the tricyclics, the SSRIs, and most recently the serotonin-norepinephrine reuptake inhibitors—SNRIs). These medications have both advantages and disadvantages compared with anxiolytics. One major advantage is that they do not create physiological dependence in the way benzodiazepines can, and they also can alleviate any comorbid depressive symptoms or disorders (Pollack & Simon, 2009; Roy-Byrne & Cowley, 2007). However, it takes about 4 weeks before they have any beneficial effects, so they are not useful in an acute situation where a person is having a panic attack. Troublesome side effects (such as dry mouth, constipation, and blurred vision with the tricyclics, and interference with sexual arousal with the SSRIs) mean that large numbers of people refuse to take the medications or discontinue their use. Moreover, relapse rates when the drugs

are discontinued are quite high (although not as high as with the benzodiazepines; Roy-Byrne & Cowley, 2007).

Today the SSRIs are more widely prescribed than the tricyclics because the SSRIs are generally better tolerated by most patients. Moreover, both are generally preferred by physicians to benzodiazepines because of the risks associated with the latter (Roy-Byrne & Cowley, 2007).

## BEHAVIORAL AND COGNITIVE-BEHAVIORAL TREATMENTS

The original behavioral treatment for agoraphobia from the early 1970s involved prolonged exposure to feared situations, often with the help of a therapist or family member. Similar to what is done with specific and social phobias, the idea was to make people gradually face the situations they feared and learn that there was nothing to fear. Such exposure-based treatments were quite effective and helped about 60 to 75 percent of people with agoraphobia show clinically significant improvement (Barlow et al., 2007). These effects were generally well maintained at 2- to 4-year follow-up. But this left approximately 25 to 40 percent not improved to a *clinically significant* degree (Barlow et al., 2002).

One limitation of these original treatments was that they did not specifically target panic attacks. In the mid-1980s, two new techniques were developed as clinical researchers increasingly recognized the importance of panic attacks to most people with agoraphobia. One technique involves the variant on exposure known as *interoceptive exposure*, meaning deliberate exposure to feared internal sensations. The idea was that fear of these internal sensations should be treated in the same way that fear of external agoraphobic situations is treated—namely, through prolonged exposure to those internal sensations so that the fear may extinguish. For example, people are asked to engage in various exercises that bring on various internal sensations (e.g., spinning in a chair, hyperventilating, running in place) and to stick with those sensations until they subside, thereby allowing habituation of their fears of these sensations.

The second set of techniques that were developed is cognitive restructuring techniques, in recognition that catastrophic automatic thoughts may help maintain panic attacks. One kind of integrative cognitive-behavioral treatment for panic

### research CLOSE-UP

#### Clinically Significant

Not all statistically significant changes are of sufficient magnitude to be clinically significant. Clinical significance reflects how large the effects of a particular treatment or intervention are with respect to how much meaningful change they provide in a person's level of functioning or well-being.

disorder—*panic control treatment*—targets both agoraphobic avoidance and panic attacks. There are several aspects to PCT. First, clients are educated about the nature of anxiety and panic and how the capacity to experience both is adaptive. A second part of the treatment involves teaching people with panic disorder to control their breathing. Third, clients are taught about the logical errors that people who have panic disorders are prone to making and learn to subject their own automatic thoughts to a logical reanalysis. Finally, they are exposed to feared situations and feared bodily sensations to build up a tolerance to the discomfort. Generally, this integrative treatment produces better results than the original exposure-based techniques that focused exclusively on exposure to external situations (D. M. Clark, 1997; Arch & Craske, 2009). In many of the studies conducted using one of the variants on these treatments, 70 to 90 percent of people with panic disorder were panic free at the end of 8 to 14 weeks of treatment, and gains were well maintained at 1- to 2-year follow-up (Arch & Craske, 2008; McCabe & Gifford, 2009). Overall, the magnitude of improvement is often greater with these cognitive and behavioral treatments than with medications (Arch & Craske, 2009; Barlow et al., 2002). Moreover, these treatments have been extended and shown to be very useful in treating people who also have nocturnal panic (Arch & Craske, 2008).

What about the combination of antianxiety medication and cognitive-behavioral therapy? In the short term, such combined treatment sometimes produces a slightly superior result compared to either type of treatment alone (Barlow et al., 2007; Mitte, 2005). In addition, one study showed that those individuals who had received combined treatment showed fewer medication side effects and fewer dropouts than those who had used medication alone (Marcus, Gorman, et al., 2007). However, in the long term, after medication has been tapered (especially benzodiazepine medications), clients who have been on medication with or without cognitive or behavioral treatment seem to show a greater likelihood of relapse (Arch & Craske, 2008; Barlow et al., 2002; Marks et al., 1993). Perhaps this is because they have attributed their gains to the medication rather than to their personal efforts (Başoğlu et al., 1994; Mitte, 2005). The one medication that has shown promise for enhancing responsiveness to CBT of panic disorder is D-cyloserine—the same medication discussed earlier that can enhance the speed of treating specific and social phobias (Otto et al., 2009).

### in review

- You are experiencing a panic attack. What are your symptoms?
- Describe the major diagnostic features of both panic disorder and agoraphobia. Why do the two disorders often occur together?
- What biological causal factors have been implicated in panic disorder?
- Compare and contrast the learning or conditioning theory and cognitive models of panic disorder.
- Describe the major treatment approaches for panic disorder and their relative advantages and disadvantages.

## Generalized Anxiety Disorder

Most of us worry and get anxious occasionally, and anxiety is an adaptive emotion that helps us plan and prepare for possible threat. But for some people, anxiety and worry about many different aspects of life (including minor events) becomes chronic, excessive, and unreasonable. In these cases, **generalized anxiety disorder (GAD)** (formerly known as free-floating anxiety) may be diagnosed. *DSM-5* criteria specify that the worry must occur on more days than not for at least 6 months and that it must be experienced as difficult to control (see *DSM-5* criteria box). The worry must be about a number of different events or activities, and its content cannot be exclusively related to the worry associated with another concurrent disorder, such as the possibility of having a panic attack. The subjective experience of excessive worry must also be accompanied by at least three of six other symptoms, as listed in the table, such as muscle tension or being easily fatigued. There was much discussion among the task force working on revisions for *DSM-5* as to whether this is the optimal set of criteria for GAD (e.g., the 6-month duration requirement and the excessive worry requirement; e.g., Andrews et al., 2010; Lee et al., 2009; Ruscio et al., 2005) and whether this is the optimal name for the disorder (versus generalized worry disorder or pathological worry disorder) (Andrews et al., 2010). However, in the end a conservative approach was taken and no changes were made from *DSM-IV* to *DSM-5*.

The general picture of people suffering from generalized anxiety disorder is that they live in a relatively constant future-oriented mood state of anxious apprehension, chronic tension, worry, and diffuse uneasiness that they cannot control. They also show marked vigilance for possible signs of threat in the environment and frequently engage in subtle avoidance activities such as procrastination, checking, or calling a loved one

Muscle tension, restlessness, and difficulty concentrating are all symptoms that people with generalized anxiety disorder may have. Such individuals also worry excessively and are hypervigilant for possible signs of threat in their environment.

A. Excessive anxiety and worry (apprehensive expectation), occurring more days than not for at least 6 months, about a number of events or activities (such as work or school performance).

B. The individual finds it difficult to control the worry.

C. The anxiety and worry are associated with three (or more) of the following six symptoms (with at least some symptoms having been present for more days than not for the past 6 months):

**Note:** Only one item is required in children.

1. Restlessness or feeling keyed up or on edge.
2. Being easily fatigued.
3. Difficulty concentrating or mind going blank.
4. Irritability.
5. Muscle tension.
6. Sleep disturbance (difficulty falling or staying asleep, or restless, unsatisfying sleep).

D. The anxiety, worry, or physical symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

E. The disturbance is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or another medical condition (e.g., hyperthyroidism).

F. The disturbance is not better explained by another mental disorder (e.g., anxiety or worry about having panic attacks in panic disorder, negative evaluation in social anxiety disorder [social phobia], contamination or other obsessions in obsessive-compulsive disorder, separation from attachment figures in separation anxiety disorder, reminders of traumatic events in posttraumatic stress disorder, gaining weight in anorexia nervosa, physical complaints in somatic symptom disorder, perceived appearance flaws in body dysmorphic disorder, having a serious illness in illness anxiety disorder, or the content of delusional beliefs in schizophrenia or delusional disorder).

frequently to see if he or she is safe (Barlow, 2002; Barlow et al., 1996). Such anxious apprehension also occurs in other anxiety disorders (for example, the person with agoraphobia shows anticipatory anxiety about future panic attacks and about dying, and the person with social phobia is anxious about possible negative social evaluation). But this apprehension is the essence of GAD, leading Barlow and others to refer to GAD as the “basic” anxiety disorder (Roemer et al., 2002; Wells & Butler, 1997).  [Watch the Video Philip: Generalized Anxiety Disorder on MyPsychLab.](#)

The nearly constant worries of people with generalized anxiety disorder leave them continually upset and discouraged. In one study, the most common spheres of worry were found to be family, work, finances, and personal illness (Roemer et al., 1997). Not only do they have difficulty making decisions, but after they have managed to make a decision they worry endlessly, even after going to bed, over possible errors and unforeseen circumstances that may prove the decision wrong and lead to disaster. They have no appreciation of the logic by which most of us conclude that it is pointless to torment ourselves about possible outcomes over which we have no control. As two researchers in this area put it, “The result is that they fail to escape the illusory world created in their thoughts and images and rarely experience the present moment that possesses the potential to bring them joy” (Behar & Borkovec, 2006, p. 184). It is not surprising then that a recent study of the personal and economic burden of

GAD found that those with GAD experienced a similar amount of role impairment and lessened quality of life to those with major depression (Hofmann et al., 2010).

The case below is fairly typical of generalized anxiety disorder.

 **A Graduate Student with GAD** John was a 26-year-old, single graduate student in the social sciences at a prestigious university. He reported that he had had problems with anxiety nearly all his life, but they had become worse since he had left home and gone to an Ivy League college. During the past year his anxiety had seriously interfered with his functioning, and he worried about several different spheres of his life such as his own and his parents’ health. During one incident a few months earlier, he had thought that his heart was beating more slowly than usual, and he had experienced some tingling sensations; this led him to worry that he might die. In another incident he had heard his name spoken over a loudspeaker in an airport and had worried that someone at home must be dying. He was also very worried about his future because his anxiety had kept him from completing his master’s thesis on time. John also worried excessively about getting a bad grade even though he had never had one either in college or in graduate school. In classes he worried excessively about what the professor and other students thought of him. Although he had a number of

friends, he had never had a girlfriend because of his shyness about dating. He had no problem talking or socializing with women as long as it was not defined as a dating situation. He worried that he should date a woman only if he was quite sure, from the outset, that it could be a serious relationship. He also worried excessively that if a woman did not want to date him, it meant that he was boring.

In addition to his worries, which he perceived as uncontrollable, John reported muscle tension and becoming easily fatigued. He also reported great difficulty concentrating and a considerable amount of restlessness and pacing. At times he had difficulty falling asleep if he was particularly anxious, but at other times he slept excessively, in part to escape from his worries. He frequently experienced dizziness and palpitations, and in the past he had had full-blown panic attacks.

John's mother was also quite anxious and had been treated for panic disorder. John was obviously extremely bright and had managed to do very well in school in spite of his lifelong problems with anxiety. But as the pressures of finishing graduate school and starting his career loomed before him, and as he got older and had still never dated, the anxiety became so severe that he sought treatment.

### Prevalence, Age of Onset, and Gender Differences

Generalized anxiety disorder is a relatively common condition; current estimates from the National Comorbidity Survey-Replication are that approximately 3 percent of the population suffers from it in any 1-year period and 5.7 percent at some point in their lives (Kessler et al., 1994; Kessler, Berglund, Demler, et al., 2005; Kessler, Chiu, et al., 2005c). It also tends to be chronic. One 12-year follow-up study of people diagnosed with GAD found that 42 percent had not remitted 13 years later and of those who had remitted, nearly half had had a recurrence (Bruce et al., 2005; see also Hofmann et al., 2010). However, after age 50 the disorder seems to disappear for many people (Rubio & Lopez-Ibor, 2007). If it disappears it tends to be replaced by a somatic symptom disorder and characterized by physical symptoms and health concerns.

GAD is approximately twice as common in women as in men (a somewhat less dramatic difference than is seen with many specific phobias or severe agoraphobia; see Table 6.3 for summaries of gender differences in the different anxiety disorders). Although GAD is quite common, most people with this disorder manage to function (albeit with some role impairment) in spite of their high levels of worry and low perceived well-being (Hofmann et al., 2010; Stein et al., 2004). They are less likely to go to clinics for psychological treatment than are people with panic disorder or major depressive disorder, which are frequently more debilitating conditions. However,

people with GAD do frequently show up in physicians' offices with medical complaints (such as muscle tension or gastrointestinal and/or cardiac symptoms) and are known to be overusers of health care resources (similar to people with panic disorder; Greenberg et al., 1999; Hofmann et al., 2010; Katon et al., 2002).

Age of onset is often difficult to determine because 60 to 80 percent of people with GAD remember having been anxious nearly all their lives, and many others report a slow and insidious onset (Roemer et al., 2002; Wells & Butler, 1997). However, research has also documented that GAD often develops in older adults, for whom it is the most common anxiety disorder (e.g., Mackenzie et al., 2011; Stein, 2004).

### Comorbidity with Other Disorders

Generalized anxiety disorder often co-occurs with other disorders, especially other anxiety and mood disorders such as panic disorder, social phobia, specific phobia, PTSD, and major depressive disorder (Brown, Campbell, et al., 2001; Kessler, Chiu, et al., 2005c; Tyrer & Baldwin, 2006). In addition, many people with GAD (like John) experience occasional panic attacks without qualifying for a diagnosis of panic disorder (Barlow, 1988, 2002). Nor is it surprising that excessive use of tranquilizing drugs, sleeping pills, and alcohol often complicates the clinical picture in generalized anxiety disorder (Tyrer & Baldwin, 2006).

### Psychological Causal Factors

**THE PSYCHOANALYTIC VIEWPOINT** According to this viewpoint, generalized or free-floating anxiety results from an unconscious conflict between ego and id impulses that is not adequately dealt with because the person's defense mechanisms have either broken down or have never developed. Freud believed that it was primarily sexual and aggressive impulses that had been either blocked from expression or punished upon expression that led to free-floating anxiety. Defense mechanisms may become overwhelmed when a person experiences frequent and extreme levels of anxiety, as might happen if id impulses are frequently blocked from expression (e.g., under periods of prolonged sexual deprivation). According to this view, the primary difference between specific phobias and free-floating anxiety is that in phobias, the defense mechanisms of repression and displacement of an external object or situation actually work, whereas in free-floating anxiety these defense mechanisms do not work, leaving the person anxious nearly all the time. Unfortunately this viewpoint is not testable and has therefore been largely abandoned among clinical researchers.

## **PERCEPTIONS OF UNCONTROLLABILITY AND UNPREDICTABILITY**

Uncontrollable and unpredictable aversive events are much more stressful than controllable and predictable aversive events, so it is perhaps not surprising that the former create more fear and anxiety, as we discussed with specific and social phobias (Barlow, 2002; Craske & Waters, 2005; Mineka, 1985b; Mineka & Oehlberg, 2008; Mineka & Zinbarg, 1996, 2006). Conversely, experience with controlling aspects of one's life may immunize one against developing general anxiety (Chorpita, 2001; Mineka & Kelly, 1989).

This has led researchers to hypothesize that people with GAD may have a history of experiencing many important events in their lives as unpredictable or uncontrollable. For example, having a boss or spouse who has unpredictable bad moods or outbursts of temper for seemingly trivial reasons might keep a person in a chronic state of anxiety. Although the unpredictable and uncontrollable events involved in GAD are generally not as severe and traumatic as those involved in the origins of PTSD, there is some evidence that people with GAD may be more likely to have had a history of trauma in childhood than individuals with several other anxiety disorders (Borkovec et al., 2004; see also Kendler, Hettema, et al., 2003). Moreover, people with GAD clearly have far less tolerance for uncertainty than nonanxious controls and than people with panic disorder (Dugas et al., 2004, 2005; Koerner & Dugas, 2008). This low tolerance for uncertainty in people with GAD suggests that they are especially disturbed by not being able to predict the future (as none of us can; Roemer et al., 2002). Some findings also show the greater the intolerance of uncertainty, the more severe the GAD (Dugas et al., 2007). Intolerance for uncertainty also seems to be elevated in individuals with obsessive-compulsive disorder (e.g., Behar et al., 2008).

In addition, perhaps some of these people's intolerance for uncertainty, as well as their tension and hypervigilance (the sense of always looking for signs of threat), stems from their lacking safety signals in their environment. If a person mostly experiences predictable stressors (e.g., on Mondays the boss is always in a bad mood and is likely to be highly critical), he or she cannot only predict when something bad is likely to happen (e.g., Mondays at work) but can also feel safe when that signal is missing (a safety signal; e.g., Tuesdays through Fridays at work). But if another person has experienced many unpredictable or unsignaled stressors (e.g., the boss is in a bad mood and highly critical on random days of the week), she or he will not have developed safety signals for when it is appropriate to relax and feel safe, and this uncertainty may lead to chronic anxiety (Mineka, 1985a; Mineka & Zinbarg, 1996; Seligman & Binik, 1977). Thus a relative lack of safety signals may help explain why people with GAD feel constantly tense and vigilant for possible threats (Rapee, 2001).

## **A SENSE OF MASTERY: THE POSSIBILITY OF IMMUNIZING AGAINST ANXIETY**

A person's history of control over important aspects of his or her environment is another important experiential variable strongly affecting reactions to anxiety-provoking situations. Although we cannot study this experimentally in humans, we can learn a lot from laboratory analogue studies in animals. For example, one longitudinal experiment with infant rhesus monkeys found that infant monkeys reared with a sense of mastery and control over their environments for 7 to 10 months later adapted more readily to frightening events and novel anxiety-provoking situations than did monkeys reared in environments that were identical except for the experiences with control (Mineka, Gunnar, & Champoux, 1986; see also Chorpita & Barlow, 1998; Craske & Waters, 2005; Mineka & Zinbarg, 1996, 2006). In human children, experiences with control and mastery often also occur in the context of the parent-child relationship and so parents' responsiveness to their children's needs directly influences their children's developing sense of mastery (e.g., Chorpita, 2001; Craske & Waters, 2005; Mineka & Zinbarg, 1996, 2006). Unfortunately, parents of anxious children often have an intrusive, overcontrolling parenting style, which may serve only to promote their children's anxious behaviors by making them think of the world as an unsafe place in which they require protection and have little control themselves (Craske & Waters, 2005).

## **THE CENTRAL ROLE OF WORRY AND ITS POSITIVE FUNCTIONS**

The worry process is now considered the central feature of GAD and has been the focus of much research in the past 20 years. Here we will first consider the nature and functions of worry. Next, we will consider why worry comes to be such a self-sustaining process in some people and why it may be perceived to be uncontrollable.

Borkovec and colleagues (Borkovec, 1994; Borkovec et al., 2004; Behar & Borkovec, 2006) investigated both what people with GAD think the benefits of worrying are and what actual functions worry serves. Several of the benefits that people with GAD most commonly think derive from worrying are:

- Superstitious avoidance of catastrophe ("Worrying makes it less likely that the feared event will occur").
- Avoidance of deeper emotional topics ("Worrying about most of the things I worry about is a way to distract myself from worrying about even more emotional things, things that I don't want to think about").
- Coping and preparation ("Worrying about a predicted negative event helps me to prepare for its occurrence"; Borkovec, 1994, pp. 16–17; Borkovec et al., 2004).

There is some evidence that for a subset of people with GAD, these positive beliefs about worry play a key role in maintaining high levels of anxiety and worry, especially in early phases

of the development of GAD (Dugas et al., 2007). In addition, exciting new discoveries about the functions that worry actually serves help reveal why the worry process is so self-sustaining. When people with GAD worry, their emotional and physiological responses to aversive imagery are actually suppressed. This suppression of aversive emotional physiological responding may serve to reinforce the process of worry (that is, to increase its probability; Borkovec et al., 2004; McLaughlin et al., 2007). Because worry suppresses physiological responding, it also insulates the person from fully experiencing or processing the topic that she or he is worrying about, and it is known that such full processing is necessary if extinction of that anxiety is to occur. Thus the threatening meaning of the topic being worried about is maintained (Borkovec et al., 2004; Sibrava & Borkovec, 2006).

**THE NEGATIVE CONSEQUENCES OF WORRY** In spite of these positive functions that worry serves, some of its effects are clearly negative (Mineka, 2004; Mineka et al., 2002; Newman & Liera, 2011). For example, worry itself is certainly not an enjoyable activity and can actually lead to a greater sense of danger and anxiety (and lower positive mood) because of all the possible catastrophic outcomes that the worrier envisions (McLaughlin et al., 2007). In addition, people who worry about something tend subsequently to have more negative intrusive thoughts than people who do not worry. For example, Wells and Papageorgiou (1995) had people watch a gruesome film. Following the film, some were told to relax and settle down, some were told to imagine the events in the film, and some were told to worry in verbal form about the film. Over the next several days, people in the worry condition showed the most intrusive images from the film. In addition, another study showed that after engaging in worry individuals with GAD experience more intense negative emotions when reacting to a sad film (McLaughlin et al., 2007; see also Newman & Liera, 2011).

Finally, there is now considerable evidence that attempts to control thoughts and worry may paradoxically lead to increased experience of intrusive thoughts and enhanced perception of being unable to control them (Abramowitz et al., 2001; Wells, 1999; Wells & Butler, 1997). Somewhat paradoxically, these intrusive thoughts can serve as further trigger topics for more worry, and a sense of uncontrollability over worry may develop in people caught in this cycle that occurs in GAD. As we have noted, perceptions of uncontrollability are also known to be associated with increased anxiety, so a vicious circle of anxiety, worry, and intrusive thoughts may develop (Mineka, 2004; Mineka et al., 2002; Mineka & Zinbarg, 2006).

### COGNITIVE BIASES FOR THREATENING INFORMATION

Not only do people with GAD have frequent frightening thoughts, they also process threatening information in a biased way, perhaps because they have prominent danger schemas. Many

studies have shown that generally anxious people tend to preferentially allocate their attention toward threatening cues when both threat and nonthreat cues are present in the environment. Nonanxious people do not show a bias except under limited circumstances, in which they actually may show the opposite bias (see Bar-Haim et al., 2007; MacLeod & Mathews, 2012; Mathews & MacLeod, 2005). Further, this attentional vigilance for threat cues can occur at a very early stage of information processing, even before the information has entered the person's conscious awareness. If a person is already anxious, having her or his attention automatically focused on threat cues in the environment would seem only to maintain the anxiety or even make it worse. Moreover, recent evidence also strongly supports the idea that such attentional biases play a causal role in anxiety as well (e.g., MacLeod et al., 2004; MacLeod & Mathews, 2012; Mathews & MacLeod, 2002). For example, several studies have shown that training nonanxious individuals to show an attentional bias toward threat leads to their showing a greater increase in anxiety in stressful situations (e.g., MacLeod et al., 2002). Conversely, several other studies have shown that training anxious individuals to attend away from threat leads to a decrease in their anxiety symptom levels (e.g., MacLeod & Mathews, 2012).

Generally anxious people are also more likely than nonanxious people to think that bad things are likely to happen in the future (A. K. MacLeod, 1999), and they have a much stronger tendency to interpret ambiguous information in a threatening way. For example, when clinically anxious subjects read a series of ambiguous sentences (e.g., "The doctor examined little Emma's growth" or "They discussed the priest's convictions"), they are more likely than nonanxious controls to remember the threatening interpretation of each sentence (Eysenck et al., 1991; see also MacLeod et al., 2004; Mathews & MacLeod, 2005; Ouimet et al., 2009). This tendency to interpret ambiguous information negatively has actually been shown to increase anxiety in several situations, including watching a stressful video (Wilson et al., 2006).

In summary, several psychosocial variables seem to promote the onset of generalized anxiety as well as its maintenance. Experience with unpredictable and/or uncontrollable life events may create a vulnerability to anxiety and promote current anxiety. People also believe that worry serves a number of important functions, and it may actually be reinforced because it dampens physiological arousal. But worry also has some negative consequences, including the fact that worry begets further worry and creates a sense of perceived uncontrollability over the worry process, which further enhances anxiety. Finally, anxiety is associated with an automatic attentional and interpretive bias toward threatening information.

### Biological Causal Factors

**GENETIC FACTORS** Although evidence for genetic factors in GAD is mixed, there does seem to be a modest heritability, although perhaps smaller than that for most other anxiety

disorders except phobias (Hettema, Prescott, & Kendler, et al., 2001; Kendler et al., 1992a). Part of the problem for research in this area has been the evolving nature of our understanding of GAD and what its diagnostic criteria should be. Several large twin studies reveal exactly how heritability estimates vary as a function of one's definition of GAD (Hettema, Neale, & Kendler, et al., 2001; Kendler et al., 1992a). The largest and most recent of these twin studies using the *DSM-IV-TR* diagnostic criteria estimate that 15 to 20 percent of the variance in liability to GAD is due to genetic factors.

The evidence is increasingly strong that GAD and major depressive disorder have a common underlying genetic predisposition (Kendler, 1996; Kendler et al., 1992d; Kendler et al., 2007). What determines whether individuals with a genetic risk for GAD and/or major depression develop one or the other disorder seems to depend entirely on the specific environmental experiences they have (nonshared environment). At least part of this common genetic predisposition for GAD and major depression is best conceptualized as the basic personality trait commonly known as neuroticism (e.g., Clark, Watson, & Mineka, 1994; Hettema et al., 2004; Kendler et al., 2007).

### NEUROTRANSMITTER AND NEUROHORMONAL ABNORMALITIES

**A Functional Deficiency in GABA** In the 1950s, the benzodiazepine category of medications was found to reduce anxiety. This discovery was followed in the 1970s by the finding that these drugs probably exert their effects by stimulating the action of GABA, a neurotransmitter now strongly implicated in generalized anxiety (Davis, 2002; LeDoux, 2002; Nutt et al., 2006). It appears that highly anxious people have a kind of functional deficiency in GABA, which ordinarily plays an important role in the way our brain inhibits anxiety in stressful situations. The benzodiazepine drugs appear to reduce anxiety by increasing GABA activity in certain parts of the brain implicated in anxiety, such as the limbic system, and by suppressing the stress hormone cortisol. Whether the functional deficiency in GABA in anxious people causes their anxiety or occurs as a consequence of it is not yet known, but it does appear that this functional deficiency promotes the maintenance of anxiety.

More recently, researchers have discovered that another neurotransmitter—serotonin—is also involved in modulating generalized anxiety (Goodman, 2004; Nutt et al., 2006). At present, it seems that GABA, serotonin, and perhaps norepinephrine all play a role in anxiety, but the ways in which they interact remain largely unknown (LeDoux, 2002).

**The Corticotropin-Releasing Hormone System and Anxiety** An anxiety-producing hormone called corticotropin-releasing hormone (CRH) has also been strongly implicated as playing an important role in generalized anxiety (and depression;

Leonardo & Hen, 2006; Maier & Watkins, 2005). When activated by stress or perceived threat, CRH stimulates the release of ACTH (adrenocorticotropic hormone) from the pituitary gland, which in turn causes release of the stress hormone cortisol from the adrenal gland (Leonardo & Hen, 2006); cortisol helps the body deal with stress. The CRH hormone may play an important role in generalized anxiety through its effects on the bed nucleus of the *stria terminalis* (an extension of the amygdala; see Figure 6.1), which is now believed to be an important brain area mediating generalized anxiety (e.g., Davis, 2006; Lang et al., 2000).

### NEUROBIOLOGICAL DIFFERENCES BETWEEN ANXIETY AND PANIC

**As we noted at the beginning of this chapter, contemporary theorists are drawing several fundamental distinctions between fear, panic, and anxiety, including their neurobiological bases. Fear and panic involve activation of the fight-or-flight response, and the brain areas and neurotransmitters that seem most strongly implicated in these emotional responses are the amygdala (and locus coeruleus) and the neurotransmitters norepinephrine and serotonin. Generalized anxiety (or anxious apprehension) is a more diffuse emotional state involving arousal and a preparation for possible impending threat; and the brain area, neurotransmitters, and hormones that seem most strongly implicated are the limbic system (especially the bed nucleus of the stria terminalis, an extension of the amygdala), GABA, and CRH (Davis, 2006; Lang et al., 2000). Although serotonin may play a role in both anxiety and panic, it probably does so in somewhat different ways. Recently, people with GAD have been found to have a smaller left hippocampal region similar to what is seen with major depression (Hettema et al. 2012); this may represent a common risk factor for the two disorders.**

### Treatments

**MEDICATIONS** Many clients with generalized anxiety disorder consult family physicians, seeking relief from their “nerves” or anxieties or their various functional (psychogenic) physical problems. Most often in such cases, medications from the benzodiazepine (anxiolytic) category such as Xanax or Klonopin are used—and misused—for tension relief, reduction of other somatic symptoms, and relaxation. Their effects on worry and other psychological symptoms are not as great. Moreover, they can create physiological and psychological dependence and withdrawal and are therefore difficult to taper. A newer medication called buspirone (from a different medication category) is also effective, and it neither is sedating nor leads to physiological dependence. It also has greater effects on psychic anxiety than do the benzodiazepines. However, it may take 2 to 4 weeks to show results (Roy-Byrne & Cowley, 2002, 2007). Several categories of antidepressant medications like those used in the treatment of panic disorder are also useful in the treatment of GAD, and they also seem to have a greater effect on the psychological symptoms of GAD than do the benzodiazepines

(Goodman, 2004; Roy-Byrne & Cowley, 2002, 2007). However, they also take several weeks before their effects are apparent.

**COGNITIVE-BEHAVIORAL TREATMENT** Cognitive-behavioral therapy (CBT) for generalized anxiety disorder has become increasingly effective as clinical researchers have refined the techniques used. It usually involves a combination of behavioral techniques, such as training in applied muscle relaxation, and cognitive restructuring techniques aimed at reducing distorted cognitions and information-processing biases associated with GAD as well as reducing catastrophizing about minor events (Barlow, Allen, & Basden, 2007; Borkovec, 2006; Borkovec et al., 2002). GAD initially appeared to be among the most difficult of the anxiety disorders to treat, and to some extent this is still true. However, advances have been made, and a quantitative review of many controlled studies showed that CBT approaches resulted in large changes on most symptoms measured (Mitte, 2005). The magnitude of the changes seen with cognitive-behavioral treatment was at least as large as those seen with benzodiazepines, and it led to fewer dropouts (i.e., it was better tolerated). Finally, CBT has also been found to be useful in helping people who have used benzodiazepines for over a year to successfully taper their medications (Gosselin et al., 2006).

→ **CBT for John's GAD** The case of John, the graduate student with GAD discussed earlier, serves as an example of the success of cognitive-behavioral therapy with this condition. Before receiving cognitive-behavioral therapy, John had seen someone at a student counseling center for several months, but he hadn't found the "talk therapy" very useful. He had heard that cognitive-behavioral therapy might be useful and had sought such treatment. He was in treatment for about 6 months, during which time he found training in deep muscle relaxation helpful in reducing his overall level of tension. Cognitive restructuring helped reduce his worry levels about all spheres of his life. He still had problems with procrastinating when he had deadlines, but this too was improving. He also began socializing more frequently and had tentatively begun dating when treatment ended for financial reasons. He could now see that if a woman didn't want to go out with him again, this did not mean that he was boring but simply that they might not be a good match.

### in review

- What are the key characteristics of GAD, and what is its typical age of onset?
- Describe the various psychosocial causal factors that may be involved in GAD, and indicate what functions worry may serve for those with GAD.
- What are the major biological causal factors in GAD?
- Compare and contrast the biological and cognitive-behavioral treatments for GAD.

## Obsessive-Compulsive and Related Disorders

*DSM-5* now includes a new category of disorders called obsessive-compulsive and related disorders. This includes not only OCD but also new (related) disorders such as **hoarding disorder** and excoriation (skin picking) disorder. Also included in this section of *DSM-5* are body dysmorphic disorder and trichotillomania (compulsive hair-pulling).

### Obsessive-Compulsive Disorder

Obsessive-compulsive disorder (OCD) is defined by the occurrence of unwanted and intrusive obsessive thoughts or distressing images. These are usually accompanied by compulsive behaviors performed to undo or neutralize the obsessive thoughts or images or as a way of preventing some dreaded event or situation (see the *DSM-5* box for diagnostic criteria). More specifically, according to *DSM-5*, obsessions involve persistent and recurrent intrusive thoughts, images, or impulses that are experienced as disturbing, inappropriate, and uncontrollable. People who have such obsessions actively try to resist or suppress them or to neutralize them with some other thought or action. **Compulsions** can involve either overt repetitive behaviors that are performed as lengthy rituals (such as hand washing, checking, putting things in order over and over again). Compulsions may also involve more covert mental rituals (such as counting, praying, or saying certain words silently over and over again). A person with OCD usually feels driven to perform this compulsive, ritualistic behavior in response to an obsession, and there are often very rigid rules regarding exactly how the compulsive behavior should be performed. The compulsive behaviors are performed with the goal of preventing or reducing distress or preventing some dreaded event or situation. OCD is often one of the most disabling mental disorders in that it leads to a lower quality of life and a great deal of functional impairment (Stein et al., 2009).  Watch the Video *Dave: Obsessive-Compulsive Disorder* on [MyPsychLab](#).

In addition, the person must recognize that the obsession is the product of his or her own mind rather than being imposed from without (as might occur in schizophrenia). However, there is a continuum of "insight" among persons with obsessive-compulsive disorder about exactly how senseless and excessive their obsessions and compulsions are (Mathews, 2008; Ruscio et al., 2010). In a minority of cases, this insight is absent most of the time. Most of us have experienced minor obsessive thoughts, such as whether we remembered to lock the door or turn the stove off. In addition, most of us occasionally engage in repetitive or stereotyped behavior, such as checking the stove or the lock on the door or stepping over cracks on a sidewalk. With OCD, however, the thoughts are excessive and much more persistent and distressing, and the associated compulsive

acts interfere considerably with everyday activities. Indeed, the diagnosis requires that obsessions and compulsions must take at least 1 hour in a day, and in severe cases they may take most of the person's waking hours. Nevertheless, research indicates that normal and abnormal obsessions and compulsive behaviors exist on a continuum, differing primarily in the frequency and intensity of the obsessions and in the degrees to which the obsessions and compulsions are resisted and are troubling (e.g., Steketee & Barlow, 2002). Indeed, one recent study found that more than 25 percent of people in the NCS-R comorbidity study reported experiencing obsessions or compulsions at some time in their lives (Ruscio et al., 2010).

Many *obsessive thoughts* involve contamination fears, fears of harming oneself or others, and pathological doubt. Other fairly common themes are concerns about or need for symmetry (e.g., having magazines on a table arranged in a way that is "exactly right"), sexual obsessions, and obsessions concerning religion or aggression. These themes are quite consistent cross-culturally and across the life span (Pallanti, 2009; Steketee & Barlow, 2002). Obsessive thoughts involving themes of violence or aggression might include a wife being obsessed with the idea that she might poison her husband or child, or a daughter constantly imagining pushing her mother down a

flight of stairs. Even though such obsessive thoughts are only very rarely acted on, they remain a source of often excruciating torment to a person plagued with them. The following case of Mark is fairly typical of severe obsessive-compulsive disorder.

### → Obsessions About Confessing and Compulsive Checking

Mark was a 28-year-old single male who, at the time he entered treatment, suffered from severe obsessive thoughts and images about causing harm to others such as running over pedestrians while he was driving. He also had severe obsessions that he would commit a crime such as robbing a store of a large amount of money or poisoning family members or friends. These obsessions were accompanied by lengthy and excessive checking rituals. For example, one day when he drove, he began obsessing that he had caused an accident and hit a pedestrian at an intersection, and he felt compelled to spend several hours driving and walking around all parts of that intersection to find evidence of the accident.

At the time Mark went to an anxiety disorder clinic, he was no longer able to live by himself after having lived alone for

## criteria for Obsessive-Compulsive Disorder

DSM-5

### A. Presence of obsessions, compulsions, or both:

Obsessions are defined by (1) and (2):

1. Recurrent and persistent thoughts, urges, or images that are experienced, at some time during the disturbance, as intrusive and unwanted, and that in most individuals cause marked anxiety or distress.
2. The individual attempts to ignore or suppress such thoughts, urges, or images, or to neutralize them with some other thought or action (i.e., by performing a compulsion).

Compulsions are defined by (1) and (2):

1. Repetitive behaviors (e.g., hand washing, ordering, checking) or mental acts (e.g., praying, counting, repeating words silently) that the individual feels driven to perform in response to an obsession or according to rules that must be applied rigidly.
2. The behaviors or mental acts are aimed at preventing or reducing anxiety or distress, or preventing some dreaded event or situation; however, these behaviors or mental acts are not connected in a realistic way with what they are designed to neutralize or prevent, or are clearly excessive.

**Note:** Young children may not be able to articulate the aims of these behaviors or mental acts.

- B. The obsessions or compulsions are time-consuming (e.g., take more than 1 hour per day) or cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

- C. The obsessive-compulsive symptoms are not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or another medical condition.

- D. The disturbance is not better explained by the symptoms of another mental disorder (e.g., excessive worries, as in generalized anxiety disorder; preoccupation with appearance, as in body dysmorphic disorder; difficulty discarding or parting with possessions, as in hoarding disorder; hair pulling, as in trichotillomania [hair-pulling disorder]; skin picking, as in excoriation [skin-picking] disorder; stereotypies, as in stereotypic movement disorder; ritualized eating behavior, as in eating disorders; preoccupation with substances or gambling, as in substance-related and addictive disorders; preoccupation with having an illness, as in illness anxiety disorder; sexual urges or fantasies, as in paraphilic disorders; impulses, as in disruptive, impulse-control, and conduct disorders; guilty ruminations, as in major depressive disorder; thought insertion or delusional preoccupations, as in schizophrenia spectrum and other psychotic disorders; or repetitive patterns of behavior, as in autism spectrum disorder).

several years since college. He was a very bright young man with considerable artistic talent. He had finished college at a prestigious school for the arts and had launched a successful career as a young artist when the obsessions began in his early 20s.

At first, they were focused on the possibility that he would be implicated in some crime that he had not committed; later, they evolved to the point where he was afraid that he might actually commit a crime and confess to it. The checking rituals and avoidance of all places where such confessions might occur eventually led to his having to give up his career and his own apartment and move back in with his family.

At the time he presented for treatment, Mark's obsessions about harming others and confessing to crimes (whether or not he had committed them) were so severe that he had virtually confined himself to his room at his parents' house. Indeed, he could leave his room only if he had a tape recorder with him so that he would have a record of any crimes he confessed to out loud because he did not trust his own memory. The clinic was several hours' drive from his home; his mother usually had to drive because of his obsessions about causing accidents with pedestrians or moving vehicles and because the associated checking rituals could punctuate any trip with several very long stops. He also could not speak at all on the phone for fear of confessing some crime that he had (or had not) committed, and he could not mail a letter for the same reason. He also could not go into a store alone or into public bathrooms, where he feared he might write a confession on the wall and be caught and punished.

As we have noted, people with OCD feel compelled to perform acts repeatedly that often seem pointless and absurd even to them and that they in some sense do not want to perform. There are five primary types of compulsive rituals: cleaning

People who suffer from OCD often exhibit repetitive behaviors that are structured around rigid rules for performance. For example, this person turns the key in the lock a set number of times every time she leaves the house.

Howard Stern, a famous radio personality and author, as with other people who have suffered from OCD, found relief in a compulsive act or ritualized series of acts to bring about a feeling of reduced tension as well as a sense of control. In his book *Miss America*, Stern describes behaviors such as turning pages in magazines only with his pinky finger, walking through doors with the right side of his body leading, and flipping through television stations in a particular order before turning the set off.

(handwashing and showering), repeated checking, repeating, ordering or arranging, and counting (Antony et al., 1998; Mathews, 2009), and many people show multiple kinds of rituals. For a smaller number of people, the compulsions are to perform various everyday acts (such as eating or dressing) extremely slowly (primary obsessional slowness), and for others the compulsions are to have things exactly symmetrical or "evened up" (Mathews, 2009; Steketee & Barlow, 2002).

Washing or cleaning rituals vary from relatively mild ritual-like behavior such as spending 15 to 20 minutes washing one's hands after going to the bathroom, to more extreme behavior such as washing one's hands with disinfectants for hours every day to the point where the hands bleed. Checking rituals also vary in severity from relatively mild (such as checking all the lights, appliances, and locks two or three times before leaving the house) to very extreme (such as going back to an intersection where one thinks one may have run over a pedestrian and spending hours checking for any sign of the imagined accident, much as Mark does in the case study). Both cleaning and checking rituals are often performed a specific number of times and thus also involve repetitive counting. The performance of the compulsive act or the ritualized series of acts usually brings a feeling of reduced tension and satisfaction, as well as a sense of control, although this anxiety relief is typically fleeting. This is why the same rituals need to be repeated over and over (e.g., Purdon, 2009; Steketee & Barlow, 2002).

### Prevalence, Age of Onset, and Gender Differences

Obsessive-compulsive disorder is more prevalent than it was once thought to be. Specifically, the average 1-year prevalence rate of OCD in the National Comorbidity Survey-Replication

Many of us show some compulsive behavior, but people with obsessive-compulsive disorder feel compelled to perform repeatedly some action in response to an obsession, in order to reduce the anxiety or discomfort created by the obsession. Although the person may realize that the behavior is excessive or unreasonable, he or she does not feel able to control the urge. Obsessive-compulsive hand washers may spend hours a day washing and may even use abrasive cleansers to the point that their hands bleed.

study was 1.2 percent, and the average lifetime prevalence was 2.3 percent (Ruscio et al., 2010) although lifetime prevalence in other studies has been as high as 3 percent (Kessler et al., 2009). Over 90 percent of treatment-seeking people with OCD experience both obsessions and compulsions (Foa & Kozak, 1995; Franklin & Foa, 2007). When mental rituals and compulsions such as counting are included as compulsive behaviors, this figure jumps to 98 percent.

Divorced (or separated) and unemployed people are somewhat overrepresented among people with OCD (Karno et al., 1988; Torres et al., 2006). This is not surprising given the great difficulties this disorder creates for interpersonal and occupational functioning. Some studies showed little or no gender difference in adults, which would make OCD quite different from most of the rest of the anxiety disorders. However, one British epidemiological study found a gender ratio of 1.4 to 1 (women to men; Torres et al., 2006). Although the disorder generally begins in late adolescence or early adulthood and is most prevalent then (e.g., average age was 19.5 in the National Comorbidity Survey-Replication study), it is not uncommon in children, where its symptoms are strikingly similar to those of adults (Poulton et al., 2009; Torres et al., 2006). Childhood or early adolescent onset is more common in boys than in girls and is often associated with greater severity (Lomax et al., 2009) and greater heritability (Grisham et al., 2008, for a review). In most cases the disorder has a gradual onset, and once it becomes a serious condition, it tends to be chronic, although the severity of symptoms sometimes wax and wane over time (e.g., Mataix-Cols et al., 2002).

## Comorbidity with Other Disorders

Like the anxiety disorders, obsessive-compulsive disorder frequently co-occurs with other mood and anxiety disorders. Depression is especially common, and estimates are that at least 25 to 50 percent of people with OCD may experience major depression at some time in their lives and as many as 80 percent may experience significant depressive symptoms (Steketee & Barlow, 2002; Torres et al., 2006). Given the chronic and debilitating nature of this disorder, it may not be surprising that many develop depression at least partly in response to having OCD. The disorders with which OCD most often co-occurs include social phobia, panic disorder, GAD, and PTSD (Kessler, Chiu, Demler, et al., 2005c; Mathews, 2009). The personality disorders most commonly found in people with OCD are dependent and avoidant.

Another disorder that has been studied extensively only in the past 15 years—body dysmorphic disorder (BDD)—also co-occurs rather commonly with OCD. In one large study, 12 percent of patients with OCD also had body dysmorphic disorder. Many researchers believe BDD is closely related to OCD (e.g., Phillips, 2000, 2005; Phillips et al., 2007, 2010; Veale & Neziroglu, 2004). Recognizing this, in *DSM-5*, BDD is now grouped with OCD in the obsessive-compulsive and related disorders section of the manual.

## Psychological Causal Factors

**OCD AS LEARNED BEHAVIOR** The dominant behavioral or learning view of obsessive-compulsive disorder is derived from Mowrer's two-process theory of avoidance learning (1947). According to this theory, neutral stimuli become associated with frightening thoughts or experiences through classical conditioning and come to elicit anxiety. For example, touching a doorknob or shaking hands might become associated with the "scary" idea of contamination. Once having made this association, the person may discover that the anxiety produced by shaking hands or touching a doorknob can be reduced by hand washing. Washing his or her hands extensively reduces the anxiety, and so the washing response is reinforced, which makes it more likely to occur again in the future when other situations evoke anxiety about contamination (Rachman & Shafran, 1998). Once learned, such avoidance responses are extremely resistant to extinction (Mineka, 2004; Mineka & Zinbarg, 1996, 2006; Salkovskis & Kirk, 1997). Moreover, any stressors that raise anxiety levels can lead to a heightened frequency of avoidance responses in animals or compulsive rituals in humans (e.g., Cromer et al., 2007).

Several classic experiments conducted by Rachman and Hodgson (1980) supported this theory. They found that for most people with OCD, exposure to a situation that provoked

their obsession (e.g., a doorknob or toilet seat for someone with obsessions about contamination) did indeed produce distress, which would continue for a moderate amount of time and then gradually dissipate. If the person was allowed to engage in the compulsive ritual immediately after the provocation, however, her or his anxiety would generally decrease rapidly (although only temporarily) and therefore reinforce the compulsive ritual.

This model predicts, then, that exposure to feared objects or situations should be useful in treating OCD if the exposure is followed by prevention of the ritual, enabling the person to see that the anxiety will subside naturally in time without the ritual (see also Rachman & Shafran, 1998). This is indeed the core of the most effective form of behavior therapy for OCD, as discussed later. Thus the early behavioral model has been very useful in helping us understand what factors maintain obsessive-compulsive behavior, and it has also generated an effective form of treatment. However, it has not been so helpful in explaining why people with OCD develop obsessions in the first place and why some people never develop compulsive behaviors.

**OCD AND PREPAREDNESS** Just as the preparedness concept has us consider specific and social phobias in the evolutionary context of fears that may have been adaptive for our early ancestors, we have also enlarged our understanding of obsessive-compulsive disorder by looking at it in an evolutionary context (e.g., De Silva, Rachman, & Seligman, 1977; Rapoport, 1989). For example, thoughts about dirt and contamination associated with compulsive washing are so common as to make their occurrence seem non-random. The overall consensus seems to be that humans' obsessions about dirt and contamination and certain other potentially dangerous situations did not arise out of a vacuum but rather have deep evolutionary roots (Mineka & Zinbarg, 1996, 2006).

In addition, some theorists have argued that the displacement activities that many species of animals engage in under situations of conflict or high arousal resemble the compulsive rituals seen in obsessive-compulsive disorder (Craske, 1999; Mineka & Zinbarg, 1996; Rapoport, 1989; Winslow & Insel, 1991). Displacement activities often involve grooming (such as a bird preening its feathers) or nesting under conditions of high conflict or frustration. They may therefore be related to the distress-induced grooming (such as washing) or tidying rituals seen in people with OCD, which are often provoked by obsessive thoughts that elicit anxiety.

## COGNITIVE CAUSAL FACTORS

**The Effects of Attempting to Suppress Obsessive Thoughts** When normal people attempt to suppress unwanted thoughts (for example, "Don't think about white bears"), they may sometimes experience a paradoxical increase in those thoughts later (Abramowitz et al., 2001; Wegner, 1994). As already noted, people with normal and abnormal obsessions differ

primarily in the degree to which they resist their own thoughts and find them unacceptable. Thus, one factor contributing to the frequency of obsessive thoughts, and the negative moods with which they are often associated, may be these attempts to suppress them (similar to what was discussed earlier about the effects of attempts to control worry in people with GAD). For example, when people with OCD were asked to record intrusive thoughts in a diary, both on days when they were told to try to suppress those thoughts and on days without instructions to suppress, they reported approximately twice as many intrusive thoughts on the days when they were attempting to suppress them (Salkovskis & Kirk, 1997). In addition, some other research suggests that thought suppression leads to a more general increase in obsessive-compulsive symptoms beyond just the frequency of obsessions (Purdon, 2004). Finally, using a naturalistic diary study of people with OCD, investigators found that such individuals do indeed engage in frequent, strenuous, and time-consuming attempts to control the intrusive thoughts, although they are generally not effective in doing so (Purdon et al., 2007).

## Appraisals of Responsibility for Intrusive Thoughts

Salkovskis (e.g., 1989), Rachman (1997), and other cognitive theorists have distinguished between obsessive or intrusive thoughts per se and the negative automatic thoughts and catastrophic appraisals that people have about experiencing such thoughts. For example, people with OCD often seem to have an inflated sense of responsibility. In turn, in some vulnerable people, this inflated sense of responsibility can be associated with beliefs that simply having a thought about doing something (e.g., attacking a patient) is morally equivalent to actually having done it (e.g., having attacked a patient), or that thinking about committing a sin increases the chances of actually doing so. This is known as *thought-action fusion* (see Berle & Starcevic, 2005; Rachman et al., 2006; Shafran & Rachman, 2004, for reviews). This inflated sense of responsibility for the harm they may cause adds to the "perceived awfulness of any harmful consequences" (Salkovskis et al., 2000, p. 348) and also may motivate compulsive behaviors such as washing and checking to try to reduce the likelihood of anything harmful happening (Rachman et al., 2006). Thus, part of what differentiates normal people who have obsessions and can ordinarily dismiss them (without a perception of responsibility) from people with OCD is this sense of responsibility that makes the thought so "awful."

**Cognitive Biases and Distortions** Cognitive factors have also been implicated in obsessive-compulsive disorder. Research on people with OCD has shown that their attention is drawn to disturbing material relevant to their obsessive concerns, much as occurs in the other anxiety disorders (see McNally, 2000; Mineka et al., 2003, for reviews). People with OCD also seem to have difficulty blocking out negative, irrelevant input or distracting information, so they may attempt to suppress negative thoughts stimulated by this information (Enright & Beech,

1993a, 1993b; McNally, 2000). As we have noted, trying to suppress negative thoughts may paradoxically increase their frequency. These people also have low confidence in their memory ability (especially for situations they feel responsible for), which may contribute to their repeating their ritualistic behaviors over and over again (Cougle et al., 2007; Dar et al., 2000; McNally, 2000). An additional factor contributing to their repetitive behavior is that people with OCD have deficits in their ability to inhibit both motor responses (Morein-Zamir et al., 2010) and irrelevant information (Bannon et al., 2008).

## Biological Causal Factors

In the past 25 years there has been a large increase in research investigating the possible biological basis for obsessive-compulsive disorder, ranging from studies about its genetic basis to studies of abnormalities in brain function and neurotransmitter abnormalities. The evidence accumulating from all three kinds of studies suggests that biological causal factors are perhaps more strongly implicated in the causes of OCD than for the other disorders discussed in this chapter.

**GENETIC FACTORS** Most genetic studies have been twin studies or family studies. Evidence from twin studies reveals a moderately high concordance rate for monozygotic twins and a lower rate for dizygotic twins. One review of 14 published studies included 80 monozygotic pairs of twins, of whom 54 were concordant for the diagnosis of OCD, and 29 pairs of dizygotic twins, of whom 9 were concordant. This is consistent with a moderate genetic heritability, although it may be at least partially a nonspecific “neurotic” predisposition (Billett, Richter, & Kennedy, 1998; Hanna, 2000; see also van Grootenhuis et al., 2007). Consistent with twin studies, most family studies have found 3 to 12 times higher rates of OCD in first-degree relatives of OCD clients than would be expected from current estimates of the prevalence of OCD (Grabe et al., 2006; Hettema et al., 2001a). Finally, evidence also shows that early-onset OCD has a higher genetic loading than later-onset OCD (Grisham et al., 2008; Mundo et al., 2006).

Further compelling evidence of a genetic contribution to some forms of OCD concerns a type of OCD that often starts in childhood and is characterized by chronic motor tics (Lochner & Stein, 2003). This form of tic-related OCD is linked to Tourette’s syndrome, a disorder characterized by severe chronic motor and vocal tics that is known to have a substantial genetic basis (see Chapter 15). For example, one study found that 23 percent of first-degree relatives of people with Tourette’s syndrome had diagnosable OCD even though Tourette’s syndrome itself is very rare (Pauls et al., 1986, 1991, 1995).

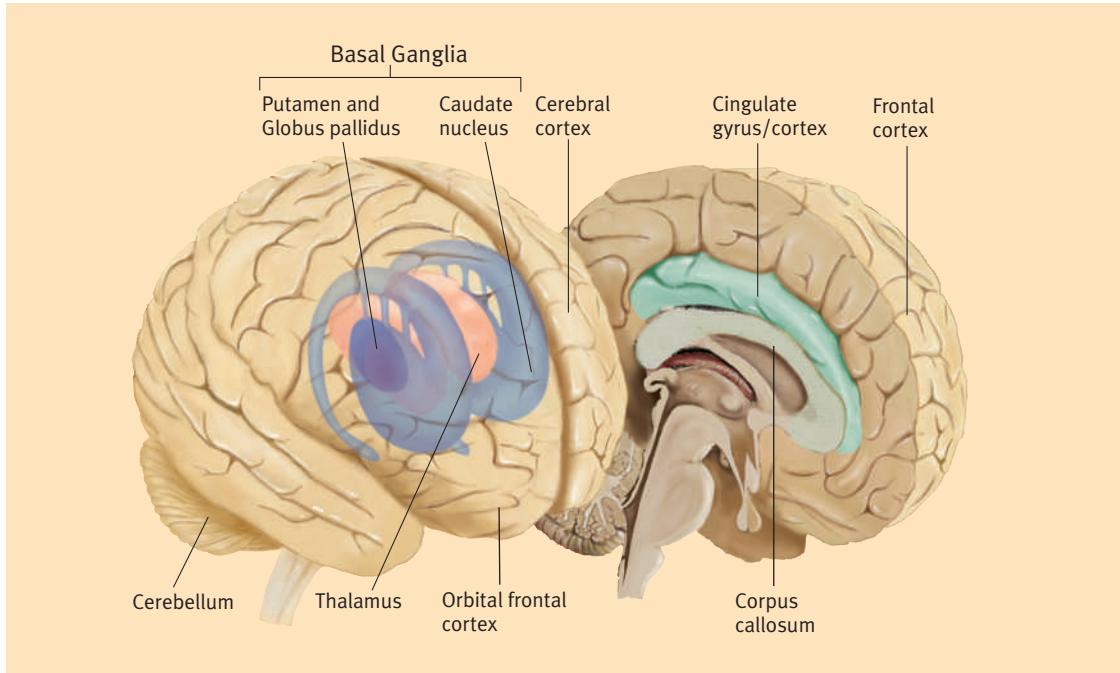

Finally, in recent years a number of molecular genetic studies have begun to examine the association of OCD with specific genetic polymorphisms (naturally occurring variations of genes;

e.g., Grisham et al., 2008; Mundo et al., 2006; Stewart et al., 2007). Preliminary findings suggest that different genetic polymorphisms are implicated in OCD with Tourette’s syndrome and in OCD without Tourette’s syndrome, suggesting that these two forms of OCD are at least partially distinguishable at a genetic level (Stewart et al., 2007).

**OCD AND THE BRAIN** The search for abnormalities in the brain for OCD has been intense in the past 30 years as advances have been made in brain-imaging techniques. Research has found that abnormalities occur primarily in certain cortical structures as well as in certain subcortical structures known as the *basal ganglia*. The basal ganglia are in turn linked at the amygdala to the limbic system, which controls emotional behaviors. Findings from a good number of studies using PET scans have shown that people with OCD have abnormally high levels of activity in two parts of the frontal cortex (the orbital frontal cortex and the cingulate cortex/gyrus), which are also linked to the limbic area. People with OCD also have abnormally high levels of activity in the subcortical caudate nucleus, which is part of the basal ganglia (see the three-dimensional depiction of the relevant brain parts in Figure 6.3 on p. 200). These primitive brain circuits are involved in executing primitive patterns of behavior such as those involved in sex, aggression, and hygiene concerns. Indeed, activity in some of these areas is further increased when symptoms are provoked by relevant stimuli that activate obsessive thoughts (e.g., dirt; see Evans, Lewis, & lobst, 2004; Rauch & Savage, 2000, for reviews). Some of these studies have also shown partial normalization of at least some of these abnormalities with successful treatment through either medication or behavior therapy (Baxter et al., 2000; Saxena et al., 2002; Saxena et al., 2009).

The orbital frontal cortex seems to be where primitive urges regarding sex, aggression, hygiene, and danger come from (the “stuff of obsessions”; Baxter et al., 1991, p. 116). These urges are ordinarily filtered by the caudate nucleus as they travel through the cortico-basal-ganglionic-thalamic circuit, allowing only the strongest to pass on to the thalamus. The caudate nucleus or corpus striatum (part of the set of structures called the basal ganglia, which are involved in the execution of voluntary, goal-directed movements) is part of an important neural circuit linking the orbital frontal cortex to the thalamus. The basal ganglia also include two other structures—the globus pallidus and the substantia nigra—that are also involved in this cortico-basal-ganglionic-thalamic circuit. The thalamus is an important relay station that receives nearly all sensory input and passes it back to the cerebral cortex.

This cortico-basal-ganglionic-thalamic circuit is normally involved in the preparation of complex sets of interrelated behavioral responses used in specific situations such as those involved in territorial or social concerns. Several theories have been proposed regarding what the sources of dysfunction in this circuit are. For example, Baxter and colleagues (1991, 2000) cite evidence that when this circuit is not functioning properly, inappropriate behavioral responses may occur, including repeated sets of

**FIGURE 6.3**

**Neurophysiological Mechanisms for Obsessive-Compulsive Disorder.** This three-dimensional view illustrates parts of the brain implicated in OCD. The overlying cerebral cortex has been made transparent so that the underlying areas can be seen. The orbital frontal cortex, cingulate cortex/gyrus, and basal ganglia (especially the caudate nucleus) are the brain structures most often implicated in OCD. Increased metabolic activity has been found in each of these three areas in people with OCD.

behaviors stemming from territorial and social concerns (e.g., checking and aggressive behavior) and from hygiene concerns (e.g., cleaning). Thus the overactivation of the orbital frontal cortex, which stimulates “the stuff of obsessions,” combined with a dysfunctional interaction among the orbital frontal cortex, the corpus striatum or caudate nucleus, and the thalamus (which is downstream from the corpus striatum) may be the central component of the brain dysfunction in OCD. According to Baxter’s theory, the dysfunctions in this circuit in turn prevent people with OCD from showing the normal inhibition of sensations, thoughts, and behaviors that would occur if the circuit were functioning properly. In this case, impulses toward aggression, sex, hygiene, and danger that most people keep under control with relative ease “leak through” as obsessions and distract people with OCD from ordinary goal-directed behavior. Evidence suggests that at least part of the reason that this circuit does not function properly may be due to abnormalities in white matter in some of these brain areas; white matter is involved in connectivity between various brain structures (Szeszko et al., 2004; Yoo et al., 2007).

Considering these problems, Baxter and colleagues proposed that we can begin to understand how the prolonged and repeated bouts of obsessive-compulsive behavior in people with OCD may occur (Baxter et al., 1991, 1992, 2000). Several other slightly different theories have also been proposed as to the exact nature or source of the dysfunctions, but there seems to be general agreement about most of the brain areas involved (e.g., Friedlander & Desrocher, 2006; Harrison et al., 2009; Saxena & Rauch, 2000).

**NEUROTRANSMITTER ABNORMALITIES** Pharmacological studies of causal factors in obsessive-compulsive disorder intensified with the discovery in the 1970s that a tricyclic drug

called Anafranil (clomipramine) is often effective in the treatment of OCD even though other tricyclic antidepressants are generally not very effective (Dougherty et al., 2007). Research shows that this is because clomipramine has greater effects on the neurotransmitter serotonin, which is now strongly implicated in OCD (Pogarell et al., 2003; Stewart et al., 2009). Moreover, several other antidepressant drugs from the SSRI category that also have relatively selective effects on serotonin, such as fluoxetine (Prozac), have also been shown to be about equally effective in the treatment of OCD (Dougherty, Rauch, et al., 2002, 2007).

The exact nature of the dysfunction in serotonergic systems in OCD is unclear (see Gross, et al., 1998; Lambert & Kinsley, 2005). Current evidence suggests that increased serotonin activity and increased sensitivity of some brain structures to serotonin are involved in OCD symptoms. Indeed, drugs that stimulate serotonergic systems lead to a worsening of symptoms. In this view, long-term administration of clomipramine (or fluoxetine) causes a down-regulation of certain serotonin receptors, further causing a functional decrease in availability of serotonin (Dolberg et al., 1996a, 1996b). That is, although the immediate short-term effects of clomipramine or fluoxetine may be to increase serotonin levels (and exacerbate OCD symptoms too), the long-term effects are quite different. This is consistent with the finding that these drugs must be taken for at least 6 to 12 weeks before significant improvement in OCD symptoms occurs (Baxter et al., 2000; Dougherty, Rauch, et al., 2002, 2007). However, it is also becoming clear that dysfunction in serotonergic systems cannot by itself fully explain this complex disorder. Other neurotransmitter systems (such as the dopaminergic, GABA, and glutamate systems) also seem to be involved, although their role is not yet well understood (Dougherty et al., 2007; Stewart et al., 2009).

In summary, there is now a substantial body of evidence implicating biological causal factors in OCD. This evidence comes from genetic studies, from studies of abnormalities in brain function, and from studies of neurotransmitter abnormalities. Although the exact nature of these factors and how they are interrelated is not yet fully understood, major research efforts that are currently under way are sure to enhance our understanding of this disorder, which is often very serious and disabling.

## Treatments

### BEHAVIORAL AND COGNITIVE-BEHAVIORAL

**TREATMENTS** A behavioral treatment that combines **exposure and response prevention** seems to be the most effective approach to treating obsessive-compulsive disorders (e.g., Franklin & Foa, 2002, 2007; Stein et al., 2009). This treatment involves having the OCD clients develop a hierarchy of upsetting stimuli and rate them on a 0 to 100 scale according to their capacity to evoke anxiety, distress, or disgust. Then the clients are asked to expose themselves repeatedly (either in guided fantasy or directly) to stimuli that will provoke their obsession (such as, for someone with compulsive washing rituals, touching the bottom of their shoe or a toilet seat in a public bathroom). Following each exposure, they are asked to not engage in the rituals that they ordinarily would engage in to reduce the anxiety or distress provoked by their obsession. Preventing the rituals is essential so that they can see that if they allow enough time to pass, the anxiety created by the obsession will dissipate naturally down to at least 40 to 50 on the 100-point scale, even if this takes several hours.

In intensive versions of this treatment, clients who, for example, are used to spending 2 to 3 hours a day showering and hand washing may be asked to not shower at all for 3 days at a time (and then only for 10 minutes). Later in treatment they are encouraged to shower for only 10 minutes a day, with no more than five 30-second hand washings at mealtimes, after bathroom use, and after touching clearly soiled objects. In addition to the exposures conducted during therapy sessions, "homework" is liberally assigned. For example, on one occasion well into treatment, a therapist drove a patient who was terrified of being contaminated by "dog dirt," bathroom germs, garbage, and dead animals in the road to a place where she had observed a dead cat on the roadside. The therapist insisted that the patient approach the "smelly" corpse, touch it with the sole of her shoe, and then touch her shoe. A pebble lying close by and a stick with which she had touched the cat were presented to the patient with the instruction that she keep them in her pocket and touch them frequently throughout the day. (See Franklin & Foa, 2008, pp. 192–205).

Although some people refuse such treatment or drop out early, it does help a majority of clients who stick with the treatment, most of whom show a 50 to 70 percent reduction in symptoms (Abramowitz et al., 2009; Steketee, 1993), as well

as improvement in quality of life (Diefenbach et al., 2007). About 50 percent are much improved or very much improved, and another 25 percent are moderately improved; about 76 percent maintain their gains at several-year follow-ups. These results are considered superior to those obtained with medication (Abramowitz et al., 2009; Franklin & Foa, 2008). There is also preliminary evidence that d-cycloserine (the drug known to facilitate extinction of fear) can decrease the number of sessions of exposure and response prevention that are needed, similar to results described earlier for specific phobias (Wilhelm et al., 2009). Finally, over the past 20 years a form of cognitive-behavioral therapy has also been developed by Salkovskis and colleagues (e.g., Abramowitz et al., 2009; Salkovskis & Wahl, 2003). Some of the goals were to determine whether it might help a higher percentage of people with OCD, or help increase the degree of symptom improvement, or decrease dropout rates. Current evidence suggests that this form of treatment can also be quite effective, but unfortunately it has not been shown to be superior to exposure and response prevention therapy in any of the predicted ways (see Abramowitz et al., 2009; D. A. Clark, 2005, for reviews). Moreover, some researchers have concluded that extinction and response-prevention treatment is probably enhanced by some cognitive therapy (Abramowitz et al., 2009). Given that OCD rarely remits completely, leaving the client with some residual obsessional problems or rituals (Abramowitz et al., 2009; Franklin & Foa, 2007), there is clearly a need to improve further the efficacy of these treatments.

The successful use of this exposure and response prevention treatment in the case of Mark, the young artist with severe OCD, is described here briefly.

→ **Mark's Treatment** Mark was initially treated with medication and with exposure and response prevention. He found the side effects of the medication (clomipramine) intolerable and gave it up within a few weeks. For the behavioral treatment, he was directed to get rid of the tape recorder and was given a series of exercises in which he exposed himself to feared situations where he might confess to a crime or cause harm to others, including making phone calls, mailing letters, and entering stores and public bathrooms (all things he had been unable to do). Checking rituals (including the tape recorder) were prevented. Although the initial round of treatment was not especially helpful, in part because of difficulty in getting to treatment, he did eventually make a commitment to more intensive treatment by moving to a small apartment closer to the clinic. Thereafter, he did quite well.

**MEDICATIONS** To date, medications that affect the neurotransmitter serotonin seem to be the primary class of medication that has mild to moderate effects in treating persons with

OCD. The other anxiety and mood disorders respond to a wider range of drugs (Bartz & Hollander, 2007; Dougherty, Baer, et al., 2002; Dougherty, et al., 2007). These medications, such as clomipramine (Anafranil) and fluoxetine (Prozac), which alter functioning of the serotonin system, appear to reduce the intensity of the symptoms of this disorder; approximately 40 to 60 percent of OCD clients show at least a 25 to 35 percent reduction in symptoms (relative to 4 to 5 percent on placebo; Dougherty, et al., 2007; Iancu et al., 2000). Some clients may show greater improvement than this, but about 30 to 50 percent do not show any clinically significant improvement (e.g., Mancebo et al., 2006). In approximately one-third of people who fail to respond to these serotonergic medications, small doses of certain antipsychotic medications may produce significantly greater improvement (Bloch et al., 2006).

A major disadvantage of medication treatment for OCD, as for other anxiety disorders, is that when the medication is discontinued relapse rates are generally very high (as high as 50 to 90 percent; Dougherty et al., 2007; Simpson & Liebowitz, 2006). Thus, many people who do not seek alternative forms of behavior therapy that have more long-lasting benefits may have to stay on these medications indefinitely. Studies in adults have generally found that combining medication with exposure and response prevention is much more effective than behavior therapy alone (Foa et al., 2005; Franklin & Foa, 2002, 2007), although one large study showed that a combination treatment was superior in the treatment of children and adolescents with OCD (March & Franklin, 2006; Pediatric OCD Treatment Study, 2004).

Finally, because OCD in its most severe form is such a crippling and disabling disorder, psychiatrists have begun to reexamine the usefulness of certain neurosurgical techniques for the treatment of severe, intractable OCD (which may afflict as many as 10 percent of people diagnosed with OCD; Mindus, Rasmussen, & Lindquist, 1994).

Before such surgery is even contemplated, the person must have had severe OCD for at least 5 years and must not have responded to any of the known treatments discussed so far (medication or behavior therapy). Several studies have shown that approximately 35 to 45 percent of these intractable cases respond quite well (at least a one-third reduction in symptoms) to neurosurgery designed to destroy brain tissue in one of the areas implicated in this condition (Dougherty, Baer, et al., 2002; Jenike, 2000; Rück et al., 2008). However, a significant number of these have adverse side effects. The results of these techniques will be discussed in greater detail in Chapter 16.

## Body Dysmorphic Disorder

**Body dysmorphic disorder (BDD)** was classified as a somatoform disorder in *DSM-IV-TR* because it involves preoccupation with certain aspects of the body. However, because of its very strong similarities with OCD, it was moved out of the somatoform category and into the OCD and related disorders category in *DSM-5*.

People with BDD are obsessed with some *perceived* or *imagined flaw* or flaws in their appearance to the point they firmly believe they are disfigured or ugly (see p. 204 for *DSM-5* criteria). This preoccupation is so intense that it causes clinically significant distress and impairment in social or occupational functioning. Although it is not considered necessary for the diagnosis, most people with BDD have compulsive checking behaviors (such as checking their appearance in the mirror excessively or hiding or repairing a perceived flaw). Another very common symptom is avoidance of usual activities because of fear that other people will see the imaginary defect and be repulsed. In severe cases, they may become so isolated that they lock themselves up in their houses and never go out, even to work, with the average employment rate estimated at only about 50 percent (Neziroglu et al., 2004). Not surprisingly, their average quality of life is quite poor (IsHak et al. 2012). Table 6.4 illustrates the range of activities that BDD interferes with.

People with BDD may focus on almost any body part: their skin has blemishes, their breasts are too small, their face is too thin (or too fat) or disfigured by visible blood vessels that others find repulsive, and so on. One large study found that some of the more common locations for perceived defects include skin (73 percent), hair (56 percent), nose (37 percent), eyes (20 percent), breasts/chest/nipples (21 percent), stomach (22 percent), and face size/shape (12 percent) (Phillips, 2005). Many sufferers have perceived defects in more than one body part. It is very important to remember that these are not the ordinary concerns that most of us have about our appearance; they are far more extreme, leading in many cases to complete preoccupation and significant emotional pain. Some researchers estimate that about half the people with BDD have concerns about their appearance that are of delusional intensity (e.g., Allen & Hollander, 2004). It is important to

People with body dysmorphic disorder are preoccupied with perceived defects in certain aspects of their body and frequently spend an inordinate amount of time obsessively checking their appearance in the mirror.

**TABLE 6.4**  
**BDD Interference in Functioning**

Problem	Percent of People with BDD Who Experienced the Problem
Interference with social functioning (e.g., with friends, family, or intimate relationships) due to BDD	99
Periods of avoidance of nearly all social interactions because of BDD	95
Ever felt depressed because of BDD	94
Interference with work or academic functioning because of BDD	90
Ever thought about suicide because of BDD*	63
Completely housebound for at least 1 week because of BDD	29
Psychiatrically hospitalized at least once because of BDD	26
Ever attempted suicide	25
Ever attempted suicide because of BDD	14
Average Number of Days Missed	
Days of work missed because of BDD*	52 days
Days of school missed because of BDD*	49 days

\*Since BDD began.

remember that others do not even see the defects that the person with BDD believes she or he has, or if they do, they see only a very minor defect within the normal range.

Another common feature of BDD is that people with this condition frequently seek reassurance from friends and family about their defects, but the reassurances almost never provide more than very temporary relief. They also frequently seek reassurance for themselves by checking their appearance in the mirror countless times in a day (although some avoid mirrors completely). They are usually driven by the hope that they will look different, and sometimes they may think their perceived defect does not look as bad as it has at other times. However, much more commonly they feel worse after mirror gazing (Veale & Riley, 2001). They frequently engage in excessive grooming behavior, often trying to camouflage their perceived defect through their hairstyle, clothing, or makeup (Sarwer et al., 2004).

The case below illustrates the primary features of this disorder.

**→ The Elephant Man** Chris is a shy, anxious-looking, 31-year-old carpenter who has been hospitalized after making a suicide attempt.... He asks to meet with the psychiatrist in a darkened room. He is wearing a baseball cap pulled down over his forehead. Looking down at the floor, Chris says he has no friends, has just been fired from his job, and was recently rejected by his girlfriend. "It's my nose... these huge pockmarks on my nose. They're grotesque! I look like a monster. I'm as ugly as the Elephant Man! These marks on my nose are all that I can think

about. I've thought about them every day for the past 15 years, and I think that everyone can see them and that they laugh at me because of them. That's why I wear this hat all the time. And that's why I couldn't talk to you in a bright room... you'd see how ugly I am."

The psychiatrist couldn't see the huge pockmarks that Chris was referring to, even in a brightly lit room. Chris is, in fact, a handsome man with normal-appearing facial pores. [Later Chris says,] "I've pretty much kept this preoccupation a secret because it's so embarrassing. I'm afraid people will think I'm vain. But I've told a few people about it, and they've tried to convince me that the pores really aren't visible.... This problem has ruined my life. All I can think about is my face. I spend hours a day looking at the marks in the mirror.... I started missing more and more work, and I stopped going out with my friends and my girlfriend... staying in the house most of the time...."

Chris... had seen a dermatologist to request dermabrasion, but was refused the procedure because "there was nothing there." He finally convinced another dermatologist to do the procedure but thought it did not help. Eventually he felt so desperate that he made two suicide attempts. His most recent attempt occurred after he looked in the mirror and was horrified by what he saw... "I saw how awful I looked, and I thought, I'm not sure it's worth it to go on living if I have to look like this and think about this all the time."

- A. Preoccupation with one or more perceived defects or flaws in physical appearance that are not observable or appear slight to others.
- B. At some point during the course of the disorder, the individual has performed repetitive behaviors (e.g., mirror checking, excessive grooming, skin picking, reassurance seeking) or mental acts (e.g., comparing his or her appearance with that of others) in response to the appearance concerns.

- C. The preoccupation causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- D. The appearance preoccupation is not better explained by concerns with body fat or weight in an individual whose symptoms meet diagnostic criteria for an eating disorder.

### PREVALENCE, AGE OF ONSET, AND GENDER DIFFERENCES

**Good estimates of the prevalence of BDD are difficult to obtain because of the great secrecy that usually surrounds this disorder.** Some leading researchers estimate that it is not a rare disorder, affecting perhaps 1 to 2 percent of the general population and up to 8 percent of people with depression (e.g., Phillips, 2005; Rief et al., 2006; Buhlmann et al., 2010). The prevalence seems to be approximately equal in men and women, although the primary body parts that are focused on tend to differ in men and women (Phillips, 2005; Phillips & Diaz, 1997). Men are more likely to obsess about their genitals, body build, and balding, whereas women tend to obsess more about their skin, stomach, breasts, buttocks, hips, and legs (Phillips, Menard, & Fay, 2006). The age of onset is usually in adolescence, when many people start to become preoccupied with their appearance. People with BDD very commonly also have a depressive diagnosis (with most estimates being over 50 percent; Allen & Hollander, 2004), and, as in Chris's case, it often leads to suicide attempts or completed suicide (Neziroglu et al., 2004; Phillips & Menard, 2006). Indeed, of nearly 200 patients with BDD, Phillips and Menard (2006) found that 80 percent reported a history of suicidal ideation, and 28 percent had a history of a suicide attempt. Rates of comorbid social phobia and obsessive-compulsive disorder are also quite substantial, although not as high as for depression (Allen & Hollander, 2004; Coles et al., 2006). Not surprisingly, BDD, like OCD, is often associated with a poor quality of life (IsHak et al., 2012).

Sufferers of BDD like Chris commonly make their way into the office of a dermatologist or plastic surgeon, one estimate being that over 75 percent seek nonpsychiatric treatment (Phillips et al., 2001). One study found that 8 percent of those seeking cosmetic medical treatments met criteria for BDD (Crerand et al., 2004), although other studies have estimated this to be as high as 20 percent (Phillips, 2005). An astute doctor will not do the requested procedures and may instead make a referral to a psychologist or psychiatrist. All too often, though, the patient, like Chris, does get what he or she requests—and unfortunately is almost never satisfied with the outcome. Even if they are satisfied with the outcome, such

patients still tend to retain their diagnosis of BDD (Tignol et al., 2007).

**RELATIONSHIP TO OCD AND EATING DISORDERS** At this point, the similarities to OCD should be fairly obvious. Like people with OCD, those with BDD have prominent obsessions, and they engage in a variety of ritualistic behaviors such as reassurance seeking, mirror checking, comparing themselves to others, and camouflage. Moreover, they are even more convinced that their obsessive beliefs are accurate than are people with OCD (Eisen et al., 2003). But in addition to these similarities in symptoms, research is also increasingly suggesting an overlap in causes. For example, the same neurotransmitter (serotonin) and the same sets of brain structures are implicated in the two disorders (Rauch et al., 2003; Saxena & Feusner, 2006), and, as we will discuss later, the same kinds of treatments that work for OCD are also the treatments of choice for BDD (Phillips, 2005).

Other researchers have also noted significant overlapping features between BDD and eating disorders (especially anorexia nervosa), the most striking similarity being the body image distortion in both kinds of conditions. Specifically, excessive concerns and preoccupation about physical appearance, dissatisfaction with one's body, and a distorted image of certain features of one's body are central to the diagnostic criteria for each (Allen & Hollander, 2004; Cororve & Gleaves, 2001). Nevertheless, it is important to remember that people with BDD look normal and yet are terribly obsessed and distressed about some aspect of their appearance. By contrast, people with anorexia are emaciated and generally satisfied with this aspect of their appearance (Phillips, 2005).

**WHY NOW?** BDD has clearly existed for centuries. It also seems to be a universal disorder, occurring in all European countries, the Middle East, China, Japan, and Africa (Phillips, 2005). Why, then, did its examination in the literature begin only recently? One possible reason is that its prevalence may actually have increased in recent years as contemporary Western

culture has become increasingly focused on “looks as everything,” with billions of dollars spent each year on enhancing appearance through makeup, clothes, plastic surgery, and other means (Fawcett, 2004). A second reason BDD has been understudied is that most people with this condition never seek psychological or psychiatric treatment. Rather, they suffer silently or go to dermatologists or plastic surgeons (Crerand et al., 2004; Phillips, 1996, 2001; Tignol et al., 2007). Reasons for this secrecy and shame include worries that others will think they are superficial, silly, or vain and that if they mention their perceived defect, others will notice it and focus more on it. Part of the reason why more people are now seeking treatment is that starting in the past 15 years the disorder has received a good deal of media attention. It has even been discussed on some daily talk shows, where it is sometimes called “imaginary defect disorder.” As increasing attention is focused on this disorder, the secrecy and shame often surrounding it should decrease, and more people will seek treatment.

### CAUSAL FACTORS: A BIOPSYCHOSOCIAL APPROACH

**TO BDD** Our understanding of what causes BDD is still at a preliminary stage, but recent research seems to suggest that a biopsychosocial approach offers some reasonable hypotheses. First, one recent twin study found that over-concern with a perceived or slight defect in physical appearance is a moderately heritable trait (Monzani et al., 2012). Second, BDD seems to be occurring, at least today, in a sociocultural context that places great value on attractiveness and beauty, and people who develop BDD often hold attractiveness as their primary value. This means that their self-schemas are heavily focused around such ideas as, “If my appearance is defective, then I am worthless” (endorsed by 60 percent in one study) (Buhlmann & Wilhelm, 2004, p. 924). One possibility why this occurs is that, in many cases, these people were reinforced as children for their overall appearance more than for their behavior (Neziroglu et al., 2004). Another possibility is that they were teased or criticized for their appearance, which caused conditioning of disgust, shame, or anxiety to their own image of some part of their body. For example, one study of individuals with BDD found that 56 to 68 percent reported a history of emotional neglect or emotional abuse, and approximately 30 percent reported a history of physical or sexual abuse or physical neglect (Didie et al., 2006).

In addition, substantial empirical evidence now demonstrates that people with BDD show biased attention and interpretation of information relating to attractiveness (e.g., Buhlmann & Wilhelm, 2004). They selectively attend to positive or negative words such as *ugly* or *beautiful* more than to other emotional words not related to appearance, and they tend to interpret ambiguous facial expressions as contemptuous or angry more than do controls. When they are shown pictures of

their own face that have been manipulated to be more or less symmetrical than in reality, they show a greater discrepancy than controls between judgments of their “actual” face and their “ideal” face. Asked to choose the pictures that best matched their faces, controls’ choices were more symmetrical than their real faces, while patients with BDD lacked this bias (Lambrou et al., 2011). Moreover, several studies that used fMRI technology found that patients with BDD showed fundamental differences in visually processing other people’s faces relative to controls. Specifically, they showed a bias for extracting local, detailed features rather than the more global or holistic processing of faces seen in controls (Feusner et al., 2007). A second study showed that when patients with BDD are shown a picture of their own face, they demonstrate greater activation than do healthy controls in brain regions associated with inhibitory processes and the rigidity of behavior and thinking (the orbitofrontal cortex and the caudate) (Feusner et al., 2010, 2011). Similarly, compared to controls, patients with BDD demonstrate performance deficits on tasks that measure executive functioning (e.g., manipulating information, planning, and organization), which is thought to be guided by prefrontal brain regions (Dunai et al., 2010). Whether or not these factors play a causal role is not yet known, but certainly having such biases and deficits in processing information would, at a minimum, serve to perpetuate the disorder once it has developed.

**TREATMENT OF BODY DYSMORPHIC DISORDER** As we have already noted, the treatments that are effective for BDD are closely related to those used in the effective treatment of obsessive-compulsive disorder. There is some evidence that antidepressant medications from the SSRI category often produce moderate improvement in patients with BDD, but many are not helped or show only a modest improvement (Phillips, 2004, 2005; Phillips, Pagano, & Menard, 2006). However, in some cases showing only limited improvement, it is possible that inadequate doses of the medication were used, thus leading to an underestimation of their true potential effects. In general, it seems that higher doses of these medications are needed to effectively treat BDD relative to OCD (Hadley et al., 2006). In addition, a form of cognitive-behavioral treatment emphasizing exposure and response prevention has been shown to produce marked improvement in 50 to 80 percent of treated patients (Sarwer et al., 2004; Simon, 2002; Williams et al., 2006). These treatment approaches focus on getting the patient to identify and change distorted perceptions of his or her body during exposure to anxiety-provoking situations (e.g., when wearing something that highlights rather than disguises the “defect”) and on prevention of checking responses (e.g., mirror checking, reassurance seeking, and repeated examining of the imaginary defect). The treatment gains are generally well maintained at follow-up (Looper & Kirmayer, 2002; Sarwer et al., 2004).

## Hoarding Disorder

Compulsive hoarding is a fascinating condition that had received very little research attention until the past 15–20 years. However, it has been brought into public awareness recently through several TV series such as A&E's *Hoarders* or TLC's *Hoarding: Buried Alive*. Traditionally, hoarding was thought of as one particular symptom of OCD, but this categorization began to be seriously questioned (e.g., Mataix-Cols et al., 2010). Reflecting this evolution of thinking, hoarding has now been added as a new disorder in *DSM-5*. Compulsive hoarding (as a symptom) occurs in approximately 10 to 40 percent of people diagnosed with OCD (Mataix-Cols, 2010; Steketee & Frost, 2004). However, as many as 4 out of 5 people show only compulsive hoarding (Tolin et al., 2008), and some studies have estimated its prevalence at 3 to 5 percent of the adult population. Such individuals both acquire and fail to discard many possessions that seem useless or of very limited value, in part because of the emotional attachment they develop to their possessions. In addition, their living spaces are extremely cluttered and disorganized to the point of interfering with normal activities that would otherwise occur in those spaces, such as cleaning, cooking, and walking through the house. In severe cases people have literally been buried alive in their own home by their hoarded possessions.

Part of the reason compulsive hoarding has become a focus of significant research attention stems from the realization that, on average, compulsive hoarders are significantly more disabled (both occupationally and socially) than people with OCD but without compulsive hoarding symptoms (Mataix-Cols et al., 2010; Pertusa et al., 2010). They are also at high risk for fire, falling, poor sanitation, and serious health problems (Saxena et al., 2011; Steketee & Frost, 2004). In addition, these individuals have a poorer prognosis for treatment than do people without hoarding symptoms. Early studies found that the medications typically used to treat OCD were generally not effective in treating people with compulsive hoarding symptoms, although some studies have suggested that one antidepressant can be somewhat effective (Saxena, 2007). Traditional behavioral therapy using exposure and response prevention is also less effective than for traditional OCD (Saxena, 2007), although there are some promising, new intensive and prolonged behavioral treatments that include home visits, which seem to be more effective (e.g., Tolin et al., 2007, 2008).

Recent neuroimaging research has found that people diagnosed with OCD who have compulsive hoarding symptoms also show patterns of activation in certain brain areas when their symptoms are provoked. These brain activation patterns are different from those of people diagnosed with OCD who do not have hoarding symptoms (Mataix-Cols et al., 2004, 2010; Pertusa et al., 2010). This has led some to suggest that people with compulsive hoarding may be neurologically

distinct from people with OCD (Mataix-Cols et al., 2010; Saxena, 2008). This conclusion would also be consistent with some findings of a relative lack of responsiveness to the same medications that are often successful in reducing the severity of other forms of OCD and with recent findings that different genes seem to be implicated in OCD without hoarding versus OCD with hoarding (Pertusa et al., 2010; Samuels, Shugart, et al., 2007).

## Trichotillomania

**Trichotillomania** (also known as compulsive hair pulling) has as its primary symptom the urge to pull out one's hair from anywhere on the body (most often the scalp, eyebrows, or arms), resulting in noticeable hair loss. In earlier editions of the *DSM*, trichotillomania was categorized as an impulse-control disorder. However, reflecting its relationship to OCD, in *DSM-5* it is now placed in the obsessive-compulsive and related disorders category. The hair pulling is usually preceded by an increasing sense of tension, followed by pleasure, gratification or relief when the hair is pulled out. The symptoms must cause clinically significant distress or impairment in some important areas of functioning. It usually occurs when the person is alone (or with immediate family members) and the person often examines the hair root, twirls it off and sometimes pulls the strand between their teeth and/or eats it. The onset can be in childhood or later, with onset post-puberty being associated with a more severe course (Odlaug et al. 2012). Research on trichotillomania is in very early stages and much remains to be learned about this condition (see Grant et al., 2012).

## in review

- Summarize the major symptoms of obsessive-compulsive disorder.
- How have conditioning and cognitive factors been implicated in OCD?
- What are the major biological causal factors for OCD?
- What are the primary symptoms of body dysmorphic disorder, and how are they related to obsessive-compulsive disorder?
- What are the primary symptoms of hoarding disorder and why is it often so debilitating?
- What are the primary symptoms of trichotillomania?

## Cultural Perspectives

Cross-cultural research suggests that although anxiety is a universal emotion, and anxiety disorders probably exist in all human societies, there are some differences in prevalence and in the form in which the different disorders are expressed in different

cultures (Barlow, 2002; Good & Kleinman, 1985; Kirmayer et al., 1995). Within the United States, lifetime prevalence rates of several anxiety disorders vary in somewhat surprising ways across different racial and ethnic groups, including non-Hispanic whites, African Americans, and Hispanic Americans (Breslau et al., 2006). Specifically, results from the National Comorbidity Survey-Replication study showed that lifetime risk for social phobia, generalized anxiety disorder, and panic disorder is somewhat lower among the two minority groups than among the non-Hispanic whites. These differences were slightly larger for people under age 45 and from lower socioeconomic classes. However, once a disorder has developed, the disorders are equally persistent across the three groups.

Latin Americans from the Caribbean (especially those from Puerto Rico), and other people from the Caribbean, do show higher rates of a variant of panic disorder called *ataque de nervios* (Guarnaccia et al., 2010; Hinton et al., 2008; Hinton, Lewis-Fernandez, Pollack, et al., 2009) than do other groups. Most of the symptoms of *ataque de nervios* are the same as in a panic attack, but they may also include bursting into tears, anger, and uncontrollable shouting. Other symptoms can include shakiness, verbal or physical aggression, dissociative experiences, and seizure-like or fainting episodes. Such attacks are often associated with a stressful event relating to the family (e.g., news of a death), and the person may have amnesia for the episode. At least in Puerto Rico this disorder is quite common in children and adolescents as well, affecting about 9 percent (Guarnaccia et al., 2005). Individuals who experience *ataque de nervios* also seem to be vulnerable to a wider range of other anxiety and mood disorders (Guarnaccia et al., 2010).

Looking at anxiety disorders from a cross-national perspective, one very large study of over 60,000 people across 14 countries (8 developed and 6 less developed) by the World Health Organization (WHO World Mental Health Survey Consortium, 2004) showed that anxiety disorders were the most common category of disorder reported in all but one country (Ukraine). However, reported prevalence rates for all the anxiety disorders combined varied from 2.4 percent (Shanghai, China) to 18.2 percent (United States). Other countries with moderately high rates of reported anxiety disorders were Colombia, France, and Lebanon, and other countries with moderately low rates were China, Japan, Nigeria, and Spain. We now turn to several examples of cultural variants on anxiety disorders that illustrate the range of expressions of anxiety that are exhibited worldwide.

### Cultural Differences in Sources of Worry

In the Yoruba culture of Nigeria, there are three primary clusters of symptoms associated with generalized anxiety: worry, dreams, and bodily complaints. However, the sources of worry are very different than those in Western society; they focus on creating and maintaining a large family and on fertility. Dreams are a

major source of anxiety because they are thought to indicate that one may be bewitched. The common somatic complaints are also unusual from a Western standpoint: “I have the feeling of something like water in my brain,” “Things like ants keep on creeping in various parts of my brain,” and “I am convinced some types of worms are in my head” (Ebigbo, 1982; Good & Kleinman, 1985). Nigerians with this syndrome often have paranoid fears of malevolent attack by witchcraft (Kirmayer et al., 1995). In India also there are many more worries about being possessed by spirits and about sexual inadequacy than are seen in generalized anxiety in Western cultures (Carstairs & Kapur, 1976; Good & Kleinman, 1985).

Another culture-related syndrome that occurs in places like China and other Southeast Asian countries is *Koro*, which for men involves intense, acute fear that the penis is retracting into the body and that when this process is complete the sufferer will die. *Koro* occurs less frequently in women, for whom the fear is that their nipples are retracting and their breasts shrinking. *Koro* tends to occur in epidemics (sometimes referred to as a form of mass hysteria; Sinha, 2011)—especially in cultural minority groups when their survival is threatened—and it is often attributed to either malicious spirits or contaminated food. A variant on this syndrome also occurs in West African nations, where afflicted individuals report shrinking of the penis or breasts (but not retraction), which they fear will lead to loss of sexual functioning and reproductive capacity (but not death). Frequently, another person who was present at the time is blamed and often severely beaten or otherwise punished (Dzokoto & Adams, 2005). They both occur in a cultural context where there are serious concerns about male sexual potency (Barlow, 2002; Kirmayer et al., 1995).

### Taijin Kyofusho

There is also some evidence that the form that certain anxiety disorders take has actually evolved to fit certain cultural patterns (e.g., Hinton et al., 2009). A good example is the Japanese disorder *taijin kyofusho*, which is related to the Western diagnosis of social phobia. Like social phobia, it is a fear of interpersonal relations or of social situations (Kim et al., 2008; Kirmayer, 1991; Kleinknecht et al., 1997). However, Westerners with social phobia are afraid of social situations where they may be the object of scrutiny or criticism. By contrast, most people with *taijin kyofusho* are concerned about doing something that will embarrass or offend others (Kim et al., 2008). For example, they may fear offending others by blushing, emitting an offensive odor, staring inappropriately into the eyes of another person, or through their perceived physical defects or imagined deformities (which can reach delusional levels; (Kim et al., 2008)). This fear of bringing shame on others or offending them is what leads to social avoidance (Kleinknecht et al., 1997). Body dysmorphic disorder, described earlier, also commonly occurs

in sufferers of taijin kyofusho (Nagata, van Vliet, et al., 2006).

Kirmayer (1991) and colleagues (1995) have argued that the pattern of symptoms that occurs in taijin kyofusho has clearly been shaped by cultural factors. Japanese children are raised to be highly dependent on their mothers and to have a fear of the outside world, especially strangers. As babies and young children, they are praised for being obedient and docile. There is also a great deal of emphasis on implicit communication—being able to guess another's thoughts and feelings and being sensitive to them. People who make too much eye contact are likely to be considered aggressive and insensitive, and children are taught to look at the throat of people with whom they are conversing rather than into their eyes. The society is also very hierarchical and structured, and many subtleties in language and facial communication are used to communicate one's response to social status.

At a more general level, cross-cultural researchers have noted that recognition of the cognitive component of most anxiety disorders leads one to expect many cross-cultural variations in the form that different anxiety disorders take. Anxiety disorders can be considered, at least in part, disorders of the interpretive process. Because cultures influence the categories and schemas that we use to interpret our symptoms of distress, there are bound to be significant differences in the form that anxiety disorders take in different cultures (e.g., Barlow, 2002; Good & Kleinman, 1985; Kirmayer et al., 1995).

- What are some examples of cultural differences in sources of worry?
- How is taijin kyofusho related to social phobia, and what kinds of cultural forces seem to have shaped it?

## UNRESOLVED issues

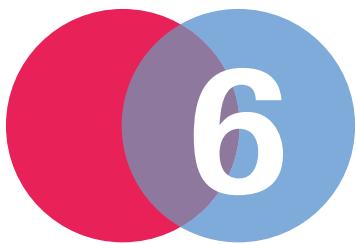

### The Choice of Treatments: Medications or Cognitive-Behavior Therapy?

Many people with anxiety or obsessive-compulsive disorders are unaware of the treatment options that are available to them. They also know little about the pros and cons of different types of treatment. Many mental health professionals are similarly uninformed or lack the training to conduct some of the more specialized treatments. For these reasons they may not recommend referral to what could be a more effective form of treatment. For example, in the United States specialized training in exposure and response prevention treatment for OCD is often not given to therapists in training. Many graduate programs in clinical psychology are also not very scientifically based (see Baker et al., 2008).

Some people prefer treatment with medications because they believe it is easier to take pills than to engage in cognitive-behavior therapy (which might be more costly or involve homework assignments). On the other hand, therapy (unlike medications) does not typically lead to unpleasant

side effects other than briefly elicited fear or anxiety. Over the longer-term, therapy can also be more cost-effective because people treated with medications routinely stay on them indefinitely but therapy usually has very long-lasting effects that do not wear off with time. Medications sometimes also have limited effectiveness relative to the treatment effects that are seen with properly-administered cognitive-behavior therapy.

But finding a well trained cognitive behavior therapist is far from easy. And even trained therapists are frequently limited in the range of disorders they have been trained to treat. One solution is to provide therapists in training with proficiency in treating a broader range of disorders. The Association for Psychological Science (APS) is trying to improve this situation by developing a new system for accrediting clinical training programs that teach their students well-validated forms of effective treatments. Although progress is being made, the pace of change is much slower than would be desirable.

# 6 summary

## 6.1 What are the essential features of anxiety disorders?

- The anxiety disorders have anxiety or panic or both at their core. They were initially considered a subset of the neuroses, but this term was largely abandoned after *DSM-III*.
- Fear or panic is a basic emotion that involves activation of the fight-or-flight response of the autonomic nervous system; it occurs in response to imminent danger.
- Anxiety is a more diffuse blend of emotions that includes high levels of negative affect, worry about possible threat or danger, and the sense of being unable to predict threat or to control it if it occurs.

## 6.2 What are the different types of phobias?

- With *specific phobias*, there is an intense and irrational fear of specific objects or situations that leads to a great deal of avoidance behavior; when confronted with a feared object, the phobic person often shows activation of the fight-or-flight response, which is also associated with panic.
- In *social phobia*, a person has disabling fears of one or more social situations, usually because of fears of negative evaluation by others or of acting in an embarrassing or humiliating manner; in some cases a person with social phobia may actually experience panic attacks in social situations.
- People with social phobia also have prominent perceptions of unpredictability and uncontrollability and are preoccupied with negative self-evaluative thoughts that tend to interfere with their ability to interact in a socially skillful fashion.

## 6.3 Why do anxiety disorders develop?

- Many sources of fear and anxiety are believed to be acquired through conditioning or other learning mechanisms. However, some people (because of either temperamental or experiential factors) are more vulnerable than others to acquiring such responses.
- We seem to have an evolutionarily based preparedness to acquire readily fears of objects or situations that posed a threat to our early ancestors.

## 6.4 What are the clinical features of Panic Disorder?

- In *panic disorder*, a person experiences recurrent, unexpected panic attacks that often create a sense of stark terror and numerous other physical symptoms of the fight-or-flight response; panic attacks usually subside in a matter of minutes.
- Many people who experience panic attacks develop anxious apprehension about experiencing another attack; this apprehension is required for a diagnosis of panic disorder.
- Many people with panic disorder also develop agoraphobic avoidance of situations in which they fear that they might have an attack.

## 6.5 What factors are implicated in the development of panic disorder?

- Biological theories of panic disorder emphasize that the disorder may result from biochemical abnormalities in the brain as well as abnormal activity of the neurotransmitters norepinephrine and serotonin.
- Panic attacks may arise primarily from the brain area called the amygdala, although many other areas are also involved in panic disorder.
- The learning theory of panic disorder proposes that panic attacks cause the conditioning of anxiety primarily to external cues associated with the attacks and conditioning of panic itself primarily to interoceptive cues associated with the early stages of the attacks.
- The cognitive theory of panic disorder holds that this condition may develop in people who are prone to making catastrophic misinterpretations of their bodily sensations, a tendency that may be related to preexisting high levels of anxiety sensitivity.

## 6.6 Describe the clinical aspects of Generalized Anxiety Disorder.

- In *generalized anxiety disorder*, a person has chronic and excessively high levels of worry about a number of events or activities and responds to stress with high levels of psychic and muscle tension.
- Generalized anxiety disorder may occur in people who have had extensive experience with unpredictable or uncontrollable life events.
- People with generalized anxiety seem to have danger schemas about their inability to cope with strange and dangerous situations that promote worries focused on possible future threats.
- The neurobiological factor most implicated in generalized anxiety is a functional deficiency in the neurotransmitter GABA, which is involved in inhibiting anxiety in stressful situations; the limbic system is the brain area most involved.

## 6.7 How are anxiety disorders treated?

- Once a person has an anxiety disorder, mood-congruent information processing, such as attentional and interpretive biases, seems to help maintain it. This explains why, without treatment, anxiety disorders are often chronic conditions.
- Many people with anxiety disorders are treated by physicians, often with medications designed to allay anxiety or with antidepressant medications that also have antianxiety effects when taken for at least 3 to 4 weeks. Such treatment focuses on suppressing the symptoms, and some anxiolytic medications have the potential to cause physiological dependence. Once the medications are discontinued, relapse rates tend to be high.
- Behavioral and cognitive therapies have a very good track record with regard to treatment of the anxiety disorders. A key ingredient of effective treatment is prolonged exposure to feared situations.
- Cognitive therapies focus on helping clients understand their underlying automatic thoughts, which often involve cognitive distortions such as unrealistic predictions of catastrophes that in reality are very unlikely to occur. Then they learn to change

these inner thoughts and beliefs through a process of logical reanalysis known as cognitive restructuring.

### 6.8 What are the clinical features of obsessive-compulsive disorder and how is this disorder treated?

- In *obsessive-compulsive disorder*, a person experiences unwanted and intrusive distressing thoughts or images that are usually accompanied by compulsive behaviors performed to neutralize those thoughts or images. Checking and cleaning rituals are most common.
- Biological causal factors are also involved in obsessive-compulsive disorder, with evidence coming from genetic studies, studies of brain functioning, and psychopharmacological studies.
- Once this disorder begins, the anxiety-reducing qualities of the compulsive behaviors may help to maintain the disorder.
- Behavior therapies that involve exposure are effective in the treatment of OCD. Rituals must also be prevented following exposure to the feared situations.

### 6.9 Describe three obsessive-compulsive related disorders.

- People with *BDD* are obsessed with some *perceived* or *imagined flaw* or flaws in their appearance to the point they firmly believe they are disfigured or ugly. This preoccupation is so intense that it causes clinically significant distress and impairment in social or occupational functioning.
- Compulsive hoarders acquire and fail to discard many possessions that seem useless or of very limited value, in part because of the emotional attachment they develop to their possessions. Compulsive hoarders are significantly more disabled than people with OCD without compulsive hoarding symptoms.
- Trichotillomania (also known as compulsive hair pulling) has as its primary symptom the urge to pull out one's hair from anywhere on the body (most often the scalp, eyebrows, or arms), resulting in noticeable hair loss.

## learning objectives

### 7.1

What are mood disorders?

### 7.2

What symptoms are characteristic of depressive disorders?

### 7.3

What are the causal factors in unipolar mood disorders?

### 7.4

What are bipolar disorders?

### 7.5

What are the causal factors in bipolar disorder?

### 7.6

What are the treatments and outcomes for mood disorders?

### 7.7

What is the clinical picture and the causal pattern of suicide?

### 7.8

What role does ambivalence play in thoughts of suicide?

### 7.9

How can suicide be prevented?

→ **A Successful “Total Failure”** Margaret, a prominent businesswoman in her late 40s noted for her energy and productivity, was unexpectedly deserted by her husband for a younger woman. Following her initial shock and rage, she began to have uncontrollable weeping spells and doubts about her business acumen. Decision making became an ordeal. Her spirits rapidly sank, and she began to spend more and more time in bed, refusing to deal with anyone. Her alcohol consumption increased to the point where she was seldom entirely sober. Within a period of weeks, she had suffered serious financial losses owing to her inability, or refusal, to keep her affairs in order. She felt she was a “total failure,” even when reminded of her considerable personal and professional achievements; indeed, her self-criticism gradually spread to all aspects of her life and her personal history. Finally, alarmed members of her family essentially forced her to accept an appointment with a clinical psychologist.

Was something “wrong” with Margaret, or was she merely experiencing normal human emotions because of her husband having deserted her? The psychologist concluded that she

was suffering from a serious mood disorder and initiated treatment. The diagnosis, based on the severity of the symptoms and the degree of impairment, was major depressive disorder. Secondarily, she had also developed a serious drinking problem—a condition that frequently co-occurs with major depressive disorder.

Most of us feel depressed from time to time. Failing an exam, arguing with a friend, not being accepted into one’s first choice of college or graduate school, and breaking up with a romantic partner are all examples of events that can precipitate a depressed mood in many people. However, **mood disorders** involve much more severe alterations in mood for much longer periods of time. In such cases the disturbances of mood are intense and persistent enough to be clearly maladaptive and often lead to serious problems in relationships and work performance.

Mood disorders are diverse in nature, as is illustrated by the many types of depression recognized in the *DSM-5* that we will discuss. Nevertheless, in all mood disorders (formerly called *affective disorders*), extremes of emotion or *affect*—soaring elation or deep depression—dominate the clinical picture. Other symptoms are also present, but the abnormal mood is the defining feature.

## Mood Disorders: An Overview

The two key moods involved in mood disorders are **mania**, often characterized by intense and unrealistic feelings of excitement and euphoria, and **depression**, which usually involves feelings of extraordinary sadness and dejection. Some people with mood disorders experience only time periods or episodes characterized by depressed moods. However, other people experience manic episodes at certain time points and depressive episodes at other time points. Normal mood states can occur between both types of episodes. Manic and depressive mood states are often conceived to be at opposite ends of a mood continuum, with normal mood in the middle. Although this concept is accurate to a degree, sometimes an individual may have symptoms of mania and depression during the same time period. In these *mixed-episode* cases, the person experiences rapidly alternating moods such as sadness, euphoria, and irritability, all within the same episode of illness.

## Types of Mood Disorders

We will first discuss the **unipolar depressive disorders**, in which the person experiences only depressive episodes, and then discuss the **bipolar and related disorders**, in which the person experiences both manic and depressive episodes.

The most common form of mood disturbance involves depression. To be diagnosed with major depressive disorder, a person must be markedly depressed or lose interest in formerly pleasurable activities (or both) for at least two weeks. Other symptoms such as changes in sleep or appetite, or feelings of

worthlessness must also be present (see the *DSM-5* box for diagnostic criteria).

The other primary kind of mood episode is a **manic episode**, in which the person shows a markedly elevated, euphoric, or expansive mood, often interrupted by occasional outbursts of intense irritability or even violence—particularly when others refuse to go along with the manic person's wishes and schemes. These extreme moods must persist for at least a week for this diagnosis to be made. In addition, three or more additional symptoms must occur in the same time period, ranging from behavioral symptoms (such as a notable increase in goal-directed activity), to mental symptoms where self-esteem becomes grossly inflated and mental activity may speed up (such as a "flight of

ideas" or "racing thoughts"), to physical symptoms (such as a decreased need for sleep or psychomotor agitation). (See the *DSM-5* box "Criteria for Manic Episode.")

In milder forms, similar kinds of symptoms can lead to a diagnosis of **hypomanic episode**, in which a person experiences abnormally elevated, expansive, or irritable mood for at least 4 days. In addition, the person must have at least three other symptoms similar to those involved in mania but to a lesser degree (e.g., inflated self-esteem, decreased need for sleep, flights of ideas, pressured speech, etc.). Although the symptoms listed are the same for manic and hypomanic episodes, there is much less impairment in social and occupational functioning in hypomania, and hospitalization is not required.

## criteria for Major Depressive Disorder

DSM-5

- A. Five (or more) of the following symptoms have been present during the same 2-week period and represent a change from previous functioning; at least one of the symptoms is either (1) depressed mood or (2) loss of interest or pleasure.

**Note:** Do not include symptoms that are clearly attributable to another medical condition.

1. Depressed mood most of the day, nearly every day, as indicated by either subjective report (e.g., feels sad, empty, or hopeless) or observation made by others (e.g., appears tearful). (**Note:** In children and adolescents, can be irritable mood.)
2. Markedly diminished interest or pleasure in all, or almost all, activities most of the day, nearly every day (as indicated by either subjective account or observation).
3. Significant weight loss when not dieting or weight gain (e.g., a change of more than 5% of body weight in a month), or decrease or increase in appetite nearly every day. (**Note:** In children, consider failure to make expected weight gain.)
4. Insomnia or hypersomnia nearly every day.
5. Psychomotor agitation or retardation nearly every day (observable by others; not merely subjective feelings of restlessness or being slowed down).
6. Fatigue or loss of energy nearly every day.
7. Feelings of worthlessness or excessive or inappropriate guilt (which may be delusional) nearly every day (not merely self-reproach or guilt about being sick).
8. Diminished ability to think or concentrate, or indecisiveness, nearly every day (either by subjective account or as observed by others).
9. Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan, or a suicide attempt or a specific plan for committing suicide.

- B. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

- C. The episode is not attributable to the physiological effects of a substance or another medical condition.

**Note:** Criteria A–C constitute a major depressive episode. Major depressive episodes are common in bipolar I disorder but are not required for the diagnosis of bipolar I disorder.

**Note:** Responses to a significant loss (e.g., bereavement, financial ruin, losses from a natural disaster, a serious medical illness or disability) may include the feelings of intense sadness, rumination about the loss, insomnia, poor appetite, and weight loss noted in Criterion A, which may resemble a depressive episode. Although such symptoms may be understandable or considered appropriate to the loss, the presence of a major depressive episode in addition to the normal response to a significant loss should also be carefully considered. This decision inevitably requires the exercise of clinical judgment based on the individual's history and the cultural norms for the expression of distress in the context of loss.

- D. The occurrence of the major depressive episode is not better explained by schizoaffective disorder, schizophrenia, schizophasic disorder, delusional disorder, or other specified and unspecified schizophrenia spectrum and other psychotic disorders.

- E. There has never been a manic episode or a hypomanic episode.

**Note:** This exclusion does not apply if all of the manic-like or hypomanic-like episodes are substance-induced or are attributable to the physiological effects of another medical condition.

Source: Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, (Copyright 2013). American Psychiatric Association.

- A. A distinct period of abnormally and persistently elevated, expansive, or irritable mood and abnormally and persistently increased goal-directed activity or energy, lasting at least 1 week and present most of the day, nearly every day (or any duration if hospitalization is necessary).
- B. During the period of mood disturbance and increased energy or activity, three (or more) of the following symptoms (four if the mood is only irritable) are present to a significant degree and represent a noticeable change from usual behavior:
1. Inflated self-esteem or grandiosity.
  2. Decreased need for sleep (e.g., feels rested after only 3 hours of sleep).
  3. More talkative than usual or pressure to keep talking.
  4. Flight of ideas or subjective experience that thoughts are racing.
  5. Distractibility (i.e., attention too easily drawn to unimportant or irrelevant external stimuli), as reported or observed.
  6. Increase in goal-directed activity (either socially, at work or school, or sexually) or psychomotor agitation (i.e., purposeless non-goal-directed activity).

- C. The mood disturbance is sufficiently severe to cause marked impairment in social or occupational functioning or to necessitate hospitalization to prevent harm to self or others, or there are psychotic features.
- D. The episode is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication, other treatment) or to another medical condition.

**Note:** A full manic episode that emerges during antidepressant treatment (e.g., medication, electroconvulsive therapy) but persists at a fully syndromal level beyond the physiological effect of that treatment is sufficient evidence for a manic episode and, therefore, a bipolar I diagnosis.

**Note:** Criteria A–D constitute a manic episode. At least one lifetime manic episode is required for the diagnosis of bipolar I disorder.

## The Prevalence of Mood Disorders

Major mood disorders occur with alarming frequency—at least 15 to 20 times more frequently than schizophrenia, for example, and at almost the same rate as all the anxiety disorders taken together. Of the two types of serious mood disorders, *major depressive disorder* (MDD), in which only **major depressive episodes** occur (also known as *unipolar* major depression), is the most common, and its occurrence has apparently increased in recent decades (Kaelber et al., 1995; Kessler et al., 2003). The most recent epidemiological results from the National Comorbidity Survey-Replication (NCS-R) found lifetime prevalence rates of unipolar major depression at nearly 17 percent (12-month prevalence rates were nearly 7 percent; Kessler, Chiu et al., 2005).

Moreover, rates for unipolar major depression are always much higher for women than for men (usually about 2:1), similar to the sex differences for most anxiety disorders (see Chapter 6) (Hasin et al., 2005; Nolen-Hoeksema & Hilt, 2009; Nolen-Hoeksema, 2012). These differences occur in most countries around the world; the few exceptions are developing and rural countries such as Nigeria and Iran. In the United States, this sex difference starts in adolescence and continues until about age 65, when it seems to disappear. Yet among school children, boys are equally likely or slightly more likely to be diagnosed with depression.

The other type of major mood disorder, *bipolar disorder* (in which both manic and depressive episodes occur), is much less common. The NCS-R estimated that the lifetime risk of developing the classic form of this disorder is about 1 percent (see also Goodwin & Jamison, 2007), and there is no discernible difference in the prevalence rates between the sexes.

### in review

- What are the primary distinctions between depressive disorders and bipolar disorders?
- How prevalent are the two types of mood disorders?
- How do the prevalence rates of depressive and bipolar disorders differ between the sexes?

## Unipolar Depressive Disorders

Sadness, discouragement, pessimism, and hopelessness about matters improving are familiar feelings to most people. Feelings of depression are unpleasant when we are experiencing them, but they usually do not last long, dissipating on their own after a period of days or weeks or after they have reached a certain intensity level. Indeed, mild and brief depression may actually be “normal” and adaptive in the long run. By slowing us down, mild depression sometimes saves us from wasting a lot of energy

in the futile pursuit of unobtainable goals (Keller & Nesse, 2005; Nesse, 2000). Usually, normal depressions would be expected to occur in people undergoing painful but common life events such as significant personal, interpersonal, or economic losses.

## Other Forms of Depression

Depressions are nearly always the result of recent stress. In the next sections we consider routine life situations that are commonly associated with depressive symptoms. Not all of these depressions will be severe enough to be considered as mood disorders. In most cases, symptoms are short-term and time limited. However, when severe symptoms are experienced for an extended period of time, the diagnosis will be one of mood disorder.

**LOSS AND THE GRIEVING PROCESS** We usually think of grief as the psychological process one goes through following the death of a loved one—a process that appears to be more difficult for men than for women (Bonanno & Kaltman, 1999). Grief often has certain characteristic qualities. Indeed, Bowlby's (1980) classic observations revealed that there are usually four phases of *normal response* to the loss of a spouse or close family member: (1) numbing and disbelief, (2) yearning

and searching for the dead person, (3) disorganization and despair that sets in when the person accepts the loss as permanent, and (4) some reorganization as the person gradually begins to rebuild his or her life.

For decades this was generally considered as a normal pattern, and in 2007 a careful study of over 200 individuals who had lost a loved one due to natural causes documented that this is indeed the typical sequence (Maciejewski et al., 2007). The normal nature of exhibiting a certain number of grief symptoms led *DSM-IV-TR* to suggest that a major depressive disorder usually should not be diagnosed for the first 2 months following the loss, even if all the symptom criteria are met. However, in a very controversial move, this 2-month bereavement exclusion has now been dropped in *DSM-5* (see “Thinking Critically About *DSM-5*” box). Another controversial change is described in “Developments in Thinking” box on page 216.

It is easy to think of uncomplicated grief as having an adaptive function (Bowlby, 1980). Traditionally, failing to exhibit grief under conditions in which it seems warranted has been a cause of concern because it was thought to suggest that the person was not fully processing the loss, at least at a psychological level. However, recent studies of bereaved individuals following

## THINKING CRITICALLY about *DSM-5*

### Was It Wise to Drop the Bereavement Exclusion for Major Depression?

**DSM-5**

**O**ne feature of *DSM-IV* was that it contained a bereavement exclusion criterion for major depression. This stipulated that people who had recently been bereaved, but who otherwise meet diagnostic criteria for a major depressive episode, could be excluded from being diagnosed with clinical depression for up to 2 months post-loss. This criterion was designed to distinguish true disorder from normal sadness, thus reducing diagnostic false-positives, unnecessary treatment, potential stigmatization, and inflated prevalence rates (Wakefield, Schmitz, First, & Horwitz, 2007).

However, no exclusion was made for other types of loss. This raised the issue of whether it was justifiable to consider depression in response to the loss of a loved one as normal, and depression in response to other losses as a form of mental disorder. In an examination of this Wakefield and colleagues (2007) found that bereavement-triggered depression and depression triggered by other forms of loss were very similar on eight of nine symptoms of depression (the exception being that bereaved individuals, not surprisingly, thought about death more). There was therefore no evidence to support granting bereavement special status.

In *DSM-5*, many people expected that the specific bereavement exclusion would be dropped and replaced by an

expanded exclusion that included other types of loss (loss of a job, divorce) as well as death of a loved one. However, in a controversial decision, the bereavement exclusion has not only not been expanded, but it has been removed completely from *DSM-5*.

What are the issues here? Dropping the bereavement exclusion may now create the risk that a normal grief reaction becomes misdiagnosed as a major depressive episode leading to unnecessary treatment, stigmatization, or other negative consequences. On the other hand, the assumption that any depressive response to the loss of a love one is “normal” could lead to delays in receiving needed treatment. One finding in support of keeping the bereavement criterion as it was in *DSM-IV* is that people who experience symptoms of major depression following death of a loved one are not at elevated risk for a recurrence of later major depression the way people who have major depressive episodes under other conditions are. So they may indeed be a special group. What do you think? Is grief normal? How is grief different from depression? Does the removal of the bereavement criterion in *DSM-5* now pathologize grief? Going forward, what do you think some of the consequences of this change in *DSM-5* might be?

the loss of a spouse, life partner, or parent have found that about 50 percent exhibit genuine resilience in the face of loss, with minimal, very short-lived symptoms of depression or bereavement. Also, in contrast to what was previously thought, these resilient individuals are not emotionally maladjusted or unattached to their spouses (e.g., Bonanno et al., 2004; Bonanno et al., 2005).

**POSTPARTUM "BLUES"** Even though the birth of a child would usually seem to be a happy event, postpartum depression sometimes occurs in new mothers (and occasionally fathers) and it is known to have adverse effects on child outcomes (e.g., Ramchandani et al., 2005). In the past it was believed that postpartum major depression in mothers was relatively common, but more recent evidence suggests that only "postpartum blues" are very common. The symptoms of postpartum blues typically include changeable mood, crying easily, sadness, and irritability, often liberally intermixed with happy feelings (Miller, 2002; O'Hara et al., 1990, 1991; Reck et al., 2009). Such symptoms occur in as many as 50 to 70 percent of women within 10 days of the birth of their child and usually subside on their own (Miller, 2002; Nolen-Hoeksema & Hilt, 2009). New findings show that hypomanic symptoms are also frequently observed, intermixed with the more depression-like symptoms (Sharma et al., 2009).

It appears that major depression in women occurs no more frequently in the postpartum period than would be expected in women of the same age and socioeconomic status who have not just given birth (Hobfoll et al., 1995; O'Hara & Swain, 1996). Especially rare are instances in which the major depression is accompanied by psychotic features. Thus the once firmly held notion that women are at especially high risk for major depression in the postpartum period has not been upheld. There is, however, a greater likelihood of developing major depression after the postpartum blues—especially if they are severe (Henshaw et al., 2004; Reck et al., 2009).

This new mother is experiencing postpartum blues; her mood is very labile and she cries easily.

Hormonal readjustments (Miller, 2002; O'Hara et al., 1991) and alterations in serotonergic and noradrenergic functioning (Doornbos et al., 2008) may play a role in postpartum blues and depression, although the evidence on this issue is mixed. It is obvious that a psychological component is present as well. Postpartum blues or depression may be especially likely to occur if the new mother has lack of social support or has difficulty in adjusting to her new identity and responsibilities, or if the woman has a personal or family history of depression that leads to heightened sensitivity to the stress of childbirth (Collins et al., 2004; Miller, 2002; O'Hara & Gorman, 2004).

### Dysthymic Disorder (Persistent Depressive Disorder)

DSM-5 has introduced a new category of disorder called persistent depressive disorder. This was formerly known as dysthymia and is described below. **Dysthymic disorder** is generally

## developments in THINKING

### A New DSM-5 Diagnosis: Premenstrual Dysphoric Disorder

**A**fter years of study, surrounded by some controversy, a new disorder called Premenstrual Dysphoric Disorder, has been added to the Depressive Disorders category in DSM-5. This disorder is diagnosed if a woman has had a certain set of symptoms in the majority of her menstrual cycles for the past year. In particular she must have at least one of the following four symptoms in the final week before the onset of menses; these symptoms must start to improve within a few days after the onset of menses, and become minimal or absent in the week post-menses. The four symptoms of which one must occur include (1) marked affective lability such as mood swings, (2) marked irritability or anger or increased interpersonal conflicts,

(3) marked depressed mood, or feelings of hopelessness or self-deprecating thoughts, or (4) marked anxiety, tension or feelings of being "keyed up" or "on edge." There are seven other symptoms that are listed and a total of five symptoms must be experienced. These other symptoms include (1) decrease interest in usual activities, (2) subjective sense of difficulties in concentration; (3) lethargy, easy fatigability, or lack of energy, (4) marked changes in appetite or overeating, (5) hypersomnia or insomnia, (6) a sense of being overwhelmed or out of control, and (7) physical symptoms such as breast tenderness or swelling, a sense of bloating, weight gain, etc. This is one form of depression where hormones clearly play an important role.

**criteria for**  
**Persistent Depressive Disorder (Dysthymia)**

**DSM-5**

This disorder represents a consolidation of DSM-IV-defined chronic major depressive disorder and dysthymic disorder.

- A. Depressed mood for most of the day, for more days than not, as indicated by either subjective account or observation by others, for at least 2 years.  
**Note:** In children and adolescents, mood can be irritable and duration must be at least 1 year.
- B. Presence, while depressed, of two (or more) of the following:
  1. Poor appetite or overeating.
  2. Insomnia or hypersomnia.
  3. Low energy or fatigue.
  4. Low self-esteem.
  5. Poor concentration or difficulty making decisions.
  6. Feelings of hopelessness.
- C. During the 2-year period (1 year for children or adolescents) of the disturbance, the individual has never been without the symptoms in Criteria A and B for more than 2 months at a time.
- D. Criteria for a major depressive disorder may be continuously present for 2 years.
- E. There has never been a manic episode or a hypomanic episode, and criteria have never been met for cyclothymic disorder.

- F. The disturbance is not better explained by a persistent schizoaffective disorder, schizophrenia, delusional disorder, or other specified or unspecified schizophrenia spectrum and other psychotic disorder.
- G. The symptoms are not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or another medical condition (e.g. hypothyroidism).
- H. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

**Note:** Because the criteria for a major depressive episode include four symptoms that are absent from the symptom list for persistent depressive disorder (dysthymia), a very limited number of individuals will have depressive symptoms that have persisted longer than 2 years but will not meet criteria for persistent depressive disorder. If full criteria for a major depressive episode have been met at some point during the current episode of illness, they should be given a diagnosis of major depressive disorder. Otherwise, a diagnosis of other specified depressive disorder or unspecified depressive disorder is warranted.

Source: Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, (Copyright 2013). American Psychiatric Association.

considered to be of mild to moderate intensity, but its primary hallmark is its chronicity. To qualify for a diagnosis of **persistent depressive disorder** (dysthymia), a person must have a persistently depressed mood most of the day, for more days than not, for at least 2 years (1 year for children and adolescents). In addition, individuals must have at least two of six additional symptoms when depressed (see the *DSM-5* box for diagnostic criteria). Periods of normal mood may occur briefly, but they usually last for only a few days to a few weeks (and for a maximum of 2 months). These intermittently normal moods are one of the most important characteristics distinguishing dysthymic disorder from major depressive disorder. Nevertheless, in spite of the intermittently normal moods, because of its chronic course people with dysthymia show poorer outcomes and as much impairment as those with major depression (Klein, 2008, 2010).

Dysthymia is quite common, with a lifetime prevalence estimated at between 2.5 and 6 percent (Kessler et al., 1994; Kessler, Berglund, Demler et al., 2005). The average duration of dysthymia is 4 to 5 years, but it can persist for 20 years or more (Keller et al., 1997; Klein et al., 2006). Chronic stress has been shown to increase the severity of symptoms over a 7.5-year follow-up period (Dougherty et al., 2004). Dysthymia often begins during the teenage years, and over 50 percent of those who present for treatment have an onset before age 21. One 10-year prospective

study of 97 individuals with early-onset dysthymia found that 74 percent recovered within 10 years but that, among those who recovered, 71 percent relapsed, with most relapses occurring within approximately 3 years of follow-up (Klein et al., 2006; see also Klein, 2010).

The following case is typical of this disorder.

→ **A Dysthymic Executive** A 28-year-old junior executive . . . complained of being "depressed" about everything: her job, her husband, and her prospects for the future. . . . Her complaints were of persistent feelings of depressed mood, inferiority, and pessimism, which she claims to have had since she was 16 or 17 years old. Although she did reasonably well in college, she constantly ruminated about those students who were "genuinely intelligent." She dated during college and graduate school but claimed that she would never go after a guy she thought was "special," always feeling inferior and intimidated. . . .

Just after graduation, she had married the man she was going out with at the time. She thought of him as reasonably desirable, though not "special," and married him primarily because she felt she "needed a husband" for companionship. Shortly after their marriage, the couple started to bicker. She was very critical of his clothes, his job, and his parents; and he, in

turn, found her rejecting, controlling, and moody. She began to feel that she had made a mistake in marrying him.

Recently she has also been having difficulties at work. She is assigned the most menial tasks at the firm and is never given an assignment of importance or responsibility. She admits that she frequently does a "slipshod" job of what is given her, never does more than is required, and never demonstrates any assertiveness or initiative. . . . She feels that she will never go very far in her profession because she does not have the right "connections" and neither does her husband, yet she dreams of money, status, and power. Her social life with her husband involves several other couples. The man in these couples is usually a friend of her husband. She is sure that the women find her uninteresting and unimpressive and that the people who seem to like her are probably no better off than she.

Under the burden of her dissatisfaction with her marriage, her job, and her social life, feeling tired and uninterested in "life," she now enters treatment for the third time.

Source: Adapted with permission from *DSM-IV-TR Casebook: A Learning Companion to the Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision (Copyright © 2002). American Psychiatric Association.

A person with major depressive disorder may experience a loss of energy, too much or too little sleep, decreased appetite and weight loss, an increase or slowdown in mental and physical activity, difficulty concentrating, irrational guilt, and recurrent thoughts of death or suicide.

The following account illustrates a moderately severe case of major depressive disorder.

→ **Connie** Connie, a 33-year-old homemaker and mother of a 4-year-old son, Robert, is referred . . . to a psychiatric outpatient program because . . . she has been depressed and unable to concentrate ever since she separated from her husband 3 months previously. Connie left her husband, Donald, after a 5-year marriage. Violent arguments between them, during which Connie was beaten by her husband, had occurred for the last 4 years of their marriage, beginning when she became pregnant with Robert. There were daily arguments during which Donald hit her hard enough to leave bruises on her face and arms. . . .

Before her marriage . . . she was close to her parents [and] had many friends who she also saw regularly . . . In high school she had been a popular cheerleader and a good student. . . . She had no personal history of depression, and there was no family history . . . mental illness.

During the first year of marriage, Donald became increasingly irritable and critical of Connie. He began to request that Connie stop calling and seeing her friends after work, and refused to allow them or his in-laws to visit their apartment. . . . Despite her misgivings about Donald's behavior toward her, Connie decided to become pregnant. During the seventh month of the pregnancy . . . Donald began complaining [and] began hitting her with his fists. She left him and went to live with her parents for a week. He expressed remorse . . . and . . . Connie returned to her apartment. No further violence occurred until after Robert's birth. At that time, Donald began using cocaine every weekend and often became violent when he was high.

In the 3 months since she left Donald, Connie has become increasingly depressed. Her appetite has been poor and she has lost 10 pounds. She cries a lot and often wakes up at 5:00 A.M. and is unable to get back to sleep. . . . Connie is pale and thin. . . . She speaks slowly, describing her depressed mood and lack of energy. She says that her only pleasure is in being with her son. She is able to take care of him physically but feels guilty because her preoccupation with her own bad feelings prevents

## Major Depressive Disorder

The diagnostic criteria for **major depressive disorder** (also known as major depression) require that the person exhibit more symptoms than are required for dysthymia and that the symptoms be more persistent (not interwoven with periods of normal mood). To receive a diagnosis of major depressive disorder, a person must be in a *major depressive episode* and never have had a manic, hypomanic, or mixed episode. An affected person must experience either markedly depressed moods or marked loss of interest in pleasurable activities most of every day, nearly every day, for at least two consecutive weeks. In addition to showing one or both of these symptoms, the person must experience additional symptoms during the same period (for a total of at least five symptoms; see the *DSM-5* box on p. 213).

Watch the Video *Martha: Major Depressive Disorder (MDD)* on [MyPsychLab](#).

It should be noted that few if any depressions—including milder ones—occur in the absence of significant anxiety (e.g., Merikangas et al., 2003; Mineka et al., 1998; Watson, 2005). Indeed, there is a high degree of overlap between measures of depressive and anxious symptoms in self-reports and in clinician ratings. At the diagnostic level, there are very high levels of comorbidity between depressive and anxiety disorders (e.g., Kessler, Merikangas, & Wang, 2007; Watson, 2005). The issues surrounding the co-occurrence of depression and anxiety, which have received a great deal of attention in recent years, are very complex.

her from being able to play with him. She now has no contacts other than with her parents and her son. She feels worthless and blames herself for her marital problems, saying that if she had been a better wife, maybe Donald would have been able to give up the cocaine. . . .

Connie's case clearly illustrates that a person with major depressive disorder shows not only mood symptoms of sadness but also a variety of symptoms that are more severe than those in milder forms of depression. Connie shows various cognitive distortions, including feeling worthless and guilty. She complains of a lack of energy and inability to play with her child. Her physical symptoms include loss of appetite and early morning awakening. The loss of contact with friends also occurs commonly with major depression, in part because the person is unmotivated to seek contact. Connie's case also illustrates the multiple complex, interacting factors that may be involved in the etiology of depression. Although she does not have a personal or a family history of depression, the experiences from 5 years of a very difficult marriage to a violent and abusive husband were sufficient to finally precipitate her major depressive episode.

**DEPRESSION AS A RECURRENT DISORDER** When a diagnosis of major depressive disorder is made, it is usually also specified whether this is a first, and therefore *single* (initial), episode or a *recurrent* episode (preceded by one or more previous episodes). This reflects the fact that depressive episodes are usually time limited; the average duration of an untreated episode is about 6 to 9 months. In a large untreated sample of women with depression, certain predictors pointed to a longer time to spontaneous remission of symptoms: having financial difficulties, severe stressful life events, and high genetic risk (Kendler, Walters, & Kessler, 1997). In approximately 10 to 20 percent of people with major depression, the symptoms do not remit for over 2 years, in which case persistent depressive disorder is diagnosed (Boland & Keller, 2009; Gilmer et al., 2005). Chronic major depression has been associated with serious childhood family problems and an anxious personality in childhood (Angst et al., 2011).

Although most depressive episodes remit (which is not said to occur until symptoms have largely been gone for at least 2 months), depressive episodes often recur at some future point. In recent years, **recurrence** has been distinguished from **relapse**. Relapse refers to the return of symptoms within a fairly short period of time, a situation that probably reflects the fact that the underlying episode of depression has not yet run its course (Boland & Keller, 2002; Frank et al., 1991). For example, relapse may commonly occur when pharmacotherapy is terminated prematurely—after symptoms have remitted but before the underlying episode is really over (Hollon & Dimidjian, 2009).

Until very recently the proportion of patients who will exhibit a recurrence (i.e., a new episode of depression) of major depression has been estimated as 60 percent, although the time period before a recurrence occurs is highly variable. However, a careful review of the studies leading to the 60-percent estimate has shown that there were methodological flaws in the way these estimates were calculated and that a more accurate estimate is that 40 or 50 percent will have a recurrence at some point (Monroe & Harkness, 2011). There is also evidence that the probability of recurrence increases with the number of prior episodes and also when the person has comorbid disorders. Unfortunately very little is known about what the differences are between people who will only suffer a single depressive episode and those who will go on to develop more (Monroe & Harkness, 2011).

The traditional view is that between episodes a person suffering from a recurrent major mood disorder is essentially symptom free. However, as more research data on the course of depression became available (e.g., Coryell & Winokur, 1992; Judd et al., 1998), it became clear that this is frequently not the case. For example, in a large five-site study with over 400 patients, Judd and colleagues (1998) found that patients experiencing their first episode of depression at the time of the study were only symptom free for about 54 percent of the weeks of the 12-year follow-up period. Patients who had had more than one episode of depression at the start of the study fared even worse. Those in this group were symptom free for only 37 percent of weeks during the follow-up. Moreover, people with some residual symptoms, or with significant psychosocial impairment, following an episode are even more likely to have recurrences than those whose symptoms remit completely (Judd et al., 1999; Solomon et al., 2004).

**DEPRESSION THROUGHOUT THE LIFE CYCLE** Although the onset of unipolar depressive disorders most often occurs during late adolescence up to middle adulthood, such reactions may begin at any time from early childhood to old age. Depression was once thought not to occur in childhood, but more recent research has estimated that about 1 to 3 percent of school-age children meet the criteria for some form of unipolar depressive disorder, with a smaller percentage exhibiting dysthymic disorder than major depression (see Avenevoli et al., 2008; Garber et al., 2009). As in adults, recurrence rates are high in children. Even infants may experience a form of depression (formerly known as *anaclitic depression* or despair) if they are separated for a prolonged period from their attachment figure (usually their mother; Bowlby, 1973, 1980; Speier et al., 1995), although current thinking suggests this may not happen until at least 18 months of age (Guedeney, 2007).

The incidence of depression rises sharply during adolescence—a period of great turmoil for many people. Indeed, one review estimated that approximately 15 to 20 percent of adolescents experience major depressive disorder at some point and subclinical levels of depression affect a further 10 to 20 percent (Avenevoli et al., 2008; Lewinsohn & Essau, 2002). It is during this time period

that sex differences in rates of depression first emerge (e.g., Essau, Lewinsohn, Seeley, & Sasagawa, 2010; Hankin et al., 2008; Nolen-Hoeksema, 2012; Nolen-Hoeksema & Hilt, 2009). The Developments in Research box on page 235 provides some insights into why this might be. The long-term effects of major depressive disorder in adolescence can last at least through young adulthood, when such individuals show small but significant psychosocial impairments in many domains, including their occupational lives, interpersonal relationships, and general quality of life (e.g., Lewinsohn et al., 2003; Rudolph, 2009). Moreover, major depression that occurs in adolescence is very likely to recur in adulthood (Avenevoli et al., 2008; Rudolph, 2009).

The occurrence of major depression continues into later life. Although the 1-year prevalence of major depression is significantly lower in people over age 65 than in younger adults (Kessler et al., 2010), major depression and dysthymia in older adults are still considered a major public health problem today (Blazer & Hybels, 2009; Kessler, Berglund, Demler et al., 2005). Moreover, research suggests that rates of depression among physically ill residents of nursing homes or residential care facilities are substantially higher than among older adults living at home (see Davison et al., 2007; Powers et al., 2002). Unfortunately, depression in later life can be difficult to diagnose because many of the symptoms overlap with those of several medical illnesses and dementia (Alexopoulos et al., 2002; Harvey et al., 2006). Yet it is very important to try and diagnose it reliably because depression in later life has many adverse consequences for a person's health, including doubling the risk of death in people who have had a heart attack or stroke (e.g., Davidson et al., 2010; Schulz et al., 2002).

**SPECIFIERS FOR MAJOR DEPRESSIVE EPISODES** Some individuals who meet the basic criteria for diagnosis of a major depressive episode also have additional patterns of symptoms or features that are important to note when making a diagnosis because these patterns have implications for understanding more about the course of the disorder and its most effective treatment. These different patterns of symptoms or features are called **specifiers** in *DSM-5* (see Table 7.1 for a summary of the major specifiers). One such specifier is **major depressive episode with melancholic features**. This designation is applied when, in addition to meeting the criteria for a major depressive episode, a patient either has lost interest or pleasure in almost all activities or does not react to usually pleasurable stimuli or desired events. This severe subtype of depression is more heritable than most other forms of depression and is more often associated with a history of childhood trauma (Harkness & Monroe, 2002; Kendler, 1997). People with this subtype of depression also show greater cognitive impairment than with most other subtypes of depression (Withall et al., 2010).

Psychotic symptoms, characterized by loss of contact with reality and delusions (false beliefs) or hallucinations (false sensory perceptions), may sometimes accompany other symptoms of major depression. In such cases the diagnosis is **severe major depressive episode with psychotic features**. Ordinarily, any

**TABLE 7.1**  
**Specifiers of Major Depressive Episodes**

Specifier	Characteristic Symptoms
<b>With Melancholic Features</b>	Three of the following: Early morning awakening, depression worse in the morning, marked psychomotor agitation or retardation, loss of appetite or weight, excessive guilt, qualitatively different depressed mood.
<b>With Psychotic Features</b>	Delusions or hallucinations (usually mood congruent); feelings of guilt and worthlessness common.
<b>With Atypical Features</b>	Mood reactivity—brightens to positive events; two of the four following symptoms: weight gain or increase in appetite, hypersomnia, leaden paralysis (arms and legs feel as heavy as lead), being acutely sensitive to interpersonal rejection.
<b>With Catatonic Features</b>	A range of psychomotor symptoms from motoric immobility to extensive psychomotor activity, as well as mutism and rigidity.
<b>With Seasonal Pattern</b>	At least two or more episodes in past 2 years that have occurred at the same time (usually fall or winter), and full remission at the same time (usually spring). No other nonseasonal episodes in the same 2-year period.

delusions or hallucinations present are **mood congruent**—that is, they seem in some sense appropriate to serious depression because the content is negative in tone, such as themes of personal inadequacy, guilt, deserved punishment, death, or disease. For example, the delusional idea that one's internal organs have totally deteriorated—an idea sometimes held by people with severe depression—ties in with the mood of a person who is despondent. Feelings of guilt and worthlessness are also commonly part of the clinical picture (Keller et al., 2007; Ohayon & Schatzberg, 2002). Individuals who are psychotically depressed are likely to have longer episodes, more cognitive impairment, and a poorer long-term prognosis than those suffering from depression without psychotic features (Bora et al., 2010; Flores & Schatzberg, 2006), and any recurrent episodes are also likely to be characterized by psychotic symptoms (Fleming et al., 2004). Treatment generally involves an antipsychotic medication as well as an antidepressant (Keller et al., 2007).

A third important specifier is used when the individual shows “atypical features.” **Major depressive episode with atypical features** includes a pattern of symptoms characterized by mood reactivity; that is, the person's mood brightens in response to potential positive events. In addition, the person must show two or more of the four symptoms listed in Table 7.1. A disproportionate number of individuals who have atypical features are females, who have an earlier-than-average age of onset and who are more likely to show suicidal thoughts (Matza et al., 2003). Research has also shown that atypical depression is linked to a mild form of bipolar disorder that is associated with hypomanic rather than manic episodes (Akiskal & Benazzi, 2005). This is also an important specifier because there are indications that

individuals with atypical features may preferentially respond to a different class of antidepressants—the monoamine oxidase inhibitors—than do most other individuals with depression.

A fourth specifier is used when the individual shows marked psychomotor disturbances. **Major depressive episode with catatonic features** includes a range of psychomotor symptoms, from motoric immobility (*catalepsy*—a stuporous state) to extensive psychomotor activity, as well as mutism and rigidity. Catatonia is known more as a subtype of schizophrenia, but it is actually more frequently associated with certain forms of depression and mania than with schizophrenia (Fink & Taylor, 2006).

A fifth specifier is used when individuals who experience recurrent depressive episodes show a seasonal pattern, **recurrent major depressive episode with a seasonal pattern**, also commonly known as **seasonal affective disorder**. To meet *DSM-5* criteria for this specifier, the person must have had at least two episodes of depression in the past 2 years occurring at the same time of the year (most commonly fall or winter), and full remission must also have occurred at the same time of the year (most commonly spring). In addition, the person cannot have had other, nonseasonal depressive episodes in the same 2-year period, and most of the person's lifetime depressive episodes must have been of the seasonal variety. Prevalence rates suggest that winter seasonal affective disorder is more common in people living at higher latitudes (northern climates) and in younger people.

It is not at all uncommon for major depression to coexist with dysthymia in some people, a condition given the designation **double depression** (Boland & Keller, 2009; Klein, 2010). People with double depression are moderately depressed on a chronic basis (meeting symptom criteria for dysthymia) but undergo increased problems from time to time, during which they also meet criteria for a major depressive episode. Among clinical samples of people with dysthymia, the experience of double depression appears to be very common, although it may be much less common in people with dysthymic disorder who never seek treatment (Akiskal, 1997). For example, one clinical sample of nearly 100 individuals with early-onset dysthymia (onset before age 21) was followed for 10 years, during which time 84 percent experienced at least one major depressive episode (Klein et al., 2006; see also Keller et al., 1997). Although nearly all individuals with double depression appear to recover from their major depressive episodes (although usually just to their previous level of dysthymia) recurrence is common (Boland & Keller, 2002; Klein, 2008, 2010; Klein et al., 2006). In *DSM-5*, double depression will be classified as a form of persistent depressive disorder along with dysthymia and **chronic major depressive disorder**. The term “persistent” was adopted because it was felt to be less pejorative than the word chronic.

### in review

- What are the major features that differentiate dysthymic disorder and major depressive disorder?
- Distinguish between recurrence and relapse.

- What are three common specifiers of major depressive disorder?
- What is double depression?

## Causal Factors in Unipolar Mood Disorders

In considering the development of unipolar mood disorders, researchers have focused on the possible roles of biological, psychological, and sociocultural factors. Although each set of factors has usually been studied separately, ultimately the goal should be to understand how these different kinds of causal factors are interrelated in order to develop a biopsychosocial model.

### Biological Causal Factors

It has long been known that a variety of diseases and drugs can affect mood, leading sometimes to depression and sometimes to elation or even mania. Indeed, this idea goes back to Hippocrates (c. 400 b.c.), who hypothesized that depression was caused by an excess of “black bile” in the system. As we will discuss, in the past half century investigators attempting to establish a biological basis for unipolar disorders have considered a wide range of factors.

**GENETIC INFLUENCES** *Family studies* have shown that the prevalence of mood disorders is approximately two to three times higher among blood relatives of persons with clinically diagnosed unipolar depression than it is in the population at large (e.g., Levinson, 2006, 2009; Wallace et al., 2002). More importantly, however, *twin studies*, which can provide much more conclusive evidence of genetic influences on a disorder, also suggest a moderate genetic contribution to unipolar depression. Sullivan and colleagues (2000) conducted a quantitative review of numerous twin studies (the total number of twins studied was over 21,000) and found that monozygotic co-twins of a twin with unipolar major depression are about twice as likely to develop major depression as are dizygotic co-twins. Averaging across the results of these studies, this review suggested that about 31 to 42 percent of the variance in liability to major depression is due to genetic influences. The estimate is substantially higher (70 to 80 percent) for more severe, early-onset, or recurrent depressions (see also Levinson, 2009; McGuffin et al., 2007). Notably, however, Sullivan and colleagues' review concluded that even more variance in the liability to most forms of major depression is due to nonshared environmental influences (i.e., experiences that family members do not share) than to genetic factors.

Taken together, the results from family and twin studies make a strong case for a moderate genetic contribution to the causal patterns of unipolar major depression, although not as large a genetic contribution as for bipolar disorder (Farmer et al., 2005; Goodwin & Jamison, 2007). Unfortunately, the evidence for a genetic contribution to milder but chronic forms of unipolar depression such as dysthymia is very slim, probably because

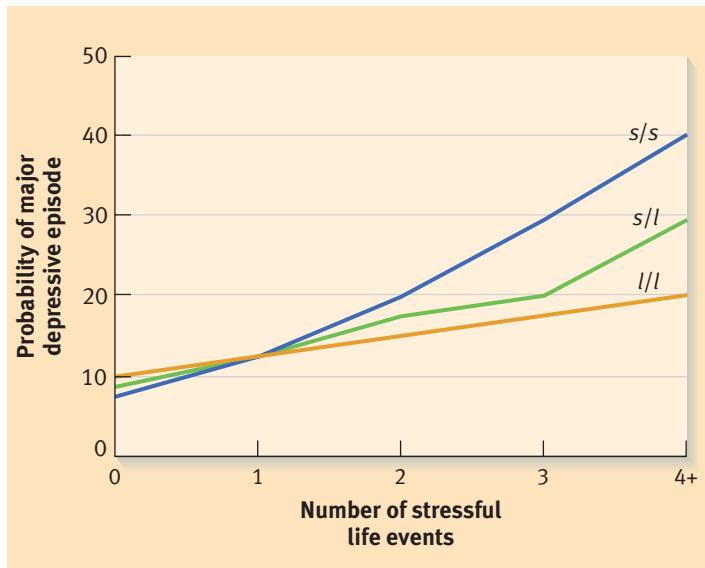

there has been very little research on the topic (Klein, 2008). However, it seems very probable that there is a genetic contribution to dysthymia because of its strong link to elevated levels of the personality trait neuroticism, which is moderately heritable.

Attempts to identify specific genes that may be responsible for these genetic influences have not yet been successful, although there are some promising leads (Levinson, 2006, 2009; Wallace et al., 2002). As discussed in Chapter 3, one very promising candidate for a specific gene that might be implicated is the *serotonin-transporter gene*—a gene involved in the transmission and reuptake of serotonin, one of the key neurotransmitters involved in depression. There are two different kinds of versions or alleles involved—the short allele (*s*) and the long allele (*l*). People either have two short alleles (*ss*), two long alleles (*ll*), or one of each (*sl*). Previous work with animals had suggested that having *ss* alleles might predispose a person to depression relative to a person having *ll* alleles, but human work on this issue provided mixed results. In 2003, Caspi and colleagues published a landmark study in which they tested for the possibility of a *genotype–environment interaction* involving these two alleles of the serotonin-transporter gene. They studied 847 people in New Zealand who had been followed from birth to 26 years of age, at which time the researchers assessed diagnoses of major depressive episodes in the past year and the occurrence of stressful life events in the previous 5 years. Their results were very striking: As illustrated in Figure 7.1, individuals who possessed the genotype with the *ss* alleles were twice

as likely to develop a major depressive episode following four or more stressful life events in the past 5 years as those who possessed the genotype with the *ll* alleles and had experienced four or more stressful events (those with the *sl* alleles were intermediate). Moreover, they found that those who had the *ss* alleles and had experienced severe maltreatment as children were also twice as likely to develop a major depressive episode as those with the *ll* alleles who had had severe maltreatment and also as compared to those with the *ss* alleles who had not been maltreated as children. These findings strongly support a diathesis-stress model; many other (but not all) studies being conducted have found similar results (e.g., Kendler et al., 2005; Uher & McGuffin, 2010). However, in 2009 a quantitative review by Risch and colleagues (2009) challenged these results; this led to a major controversy in the field. Fortunately by 2011 other quantitative reviews had demonstrated that the gene–environment result is robust if the studies use sensitive interview-based measures of life stress (McGuffin, 2010; see also Karg et al., 2011). Such results suggest that the search for candidate genes that are likely to be involved in the etiology of major depression is likely to be much more fruitful if researchers also test for genotype–environment interactions, beyond examining the effects of a genotype itself (see Moffitt et al., 2005).

**NEUROCHEMICAL FACTORS** Ever since the 1960s, the view that depression may arise from disruptions in the delicate balance of neurotransmitter substances that regulate and mediate the activity of the brain’s nerve cells has received a great deal of attention. A large body of evidence suggested that various biological therapies (discussed later in this chapter) that are often used to treat severe mood disorders—such as electroconvulsive therapy and antidepressant medications—affect the concentrations or the activity of neurotransmitters at the synapse. Such early findings encouraged the development of neurochemical theories of the etiology of major depression.

Early attention in the 1960s and 1970s focused primarily on two neurotransmitters of the monoamine class—norepinephrine and serotonin—because researchers observed that antidepressant medications seemed to have the effect of increasing these neurotransmitters’ availability at synaptic junctions (e.g., Thase & Denko, 2008; Thase et al., 2002). This observation led to the once influential *monoamine theory of depression*—that depression was at least sometimes due to an absolute or relative depletion of one or both of these neurotransmitters at important receptor sites in the brain (Schildkraut, 1965). This depletion could come about through impaired synthesis of these neurotransmitters in the presynaptic neuron, through increased degradation of the neurotransmitters once they were released into the synapse, or through altered functioning of postsynaptic receptors (Thase, 2009; Thase et al., 2002). Collectively, these neurotransmitters are now known to be involved in the regulation of behavioral activity, stress, emotional expression, and vegetative functions (involving appetite, sleep, and arousal)—all of which are disturbed in mood

**FIGURE 7.1**

**Number of Stressful Life Events Versus Probability of Major Depressive Episode.** Results demonstrate the association between the number of stressful life events (between ages 21 and 26 years) and probability of a major depressive episode at age 26 as a function of 5-HTT genotype. Life events predicted a diagnosis of major depression among carriers of the *s* allele (*ss* or *sl*), but not among carriers of two *l* alleles (*ll*).

disorders (Garlow & Nemeroff, 2003; Southwick, Vythilingam, Charney, 2005; Thase, 2009).

However, by the 1980s it was clear that no such straightforward mechanisms could possibly be responsible for causing depression (e.g., Krishnan & Nestler, 2010; Thase, 2009). For example, some studies have found exactly the opposite of what is predicted by the monoamine hypothesis—that is, net increases in norepinephrine activity in patients with depression—especially in those with severe or melancholic depression (see Thase & Denko, 2008; Thase et al., 2002). Moreover, only a minority of patients with depression have lowered serotonin activity, and these tend to be patients with high levels of suicidal ideation and behavior. Finally, even though the immediate, short-term effects of antidepressant drugs are to increase the availability of norepinephrine and serotonin, the long-term clinical effects of these drugs do not emerge until 2 to 4 weeks later, when neurotransmitter levels may have normalized.

Other more recent research also suggests that dopamine dysfunction (especially reduced dopaminergic activity) plays a significant role in at least some forms of depression, including depression with atypical features and bipolar depression (e.g., Dunlop & Nemeroff, 2007; Krishnan & Nestler, 2010; Thase, 2009). Because the neurotransmitter dopamine is so prominently involved in the experience of pleasure and reward, such findings are in keeping with the prominence of anhedonia, the inability to experience pleasure, which is such an important symptom of depression.

Unfortunately, the early monoamine theory has not been replaced by a compelling alternative. Altered neurotransmitter activity in several systems is clearly associated with major depression, but research for the past 20 to 25 years has focused on complex interactions of neurotransmitters and how they affect cellular functioning. A number of integrative theories have been proposed that include a role for neurotransmitters, not alone but rather as they interact with other disturbed hormonal and neurophysiological patterns and biological rhythms (e.g., Garlow & Nemeroff, 2003; Thase, 2009). An interesting new focus of some of this research is on understanding how interactions among these different neurobiological systems can promote resilience in the face of major stress (a very common precipitant for depression), which in turn may help explain why only a subset of people experiencing major stressors develop depression (Southwick et al., 2005).

**ABNORMALITIES OF HORMONAL REGULATORY AND IMMUNE SYSTEMS** Research interest has focused on possible hormonal causes or correlates of some forms of mood disorder (Southwick et al., 2005; Thase, 2009; Thase et al., 2002). The majority of attention has been focused on the *hypothalamic-pituitary-adrenal (HPA) axis*, and in particular on the hormone cortisol, which is excreted by the outermost portion of the adrenal glands and is regulated through a complex feedback loop (refer back to Figures 3.5 and 5.1). The human stress response

is associated with elevated activity of the HPA axis, which is partly controlled by norepinephrine and serotonin. The perception of stress or threat can lead to norepinephrine activity in the hypothalamus, causing the release of corticotrophin-releasing hormone (CRH) from the hypothalamus. This in turn triggers release of adrenocorticotropic hormone (ACTH) from the pituitary. The ACTH then typically travels through the blood to the adrenal cortex of the adrenal glands, where cortisol is released. Elevated cortisol activity is highly adaptive in the short term because it promotes survival in response to life-threatening or overwhelming life circumstances. However, sustained elevations are harmful to the organism, including promoting hypertension, heart disease, and obesity (which are all elevated in depression) (Stetler & Miller, 2011; Thase, 2009). Blood plasma levels of cortisol are known to be elevated in some 20 to 40 percent of outpatients with depression and in about 60 to 80 percent of hospitalized patients with severe depression (Thase et al., 2002). Sustained elevations in cortisol—a “hallmark of mammalian stress responses”—can result from increased CRH activation (for example, during sustained stress or threat), increased secretion of ACTH, or the failure of feedback mechanisms.

One line of evidence that implicates the failure of feedback mechanisms in some patients with depression comes from robust findings that in about 45 percent of patients with serious depression, *dexamethasone*, a potent suppressor of plasma cortisol in normal individuals, either fails entirely to suppress cortisol or fails to sustain its suppression (Carroll, 2009; Thase et al., 2002). This means that the HPA axis is not operating properly in these “dexamethasone nonsuppressors.” It was initially thought that dexamethasone nonsuppressor patients constituted a distinct subgroup of people with severe or melancholic depression (e.g., Holsboer, 1992). However, subsequent research has shown that several other groups of psychiatric patients, such as those with panic disorder, also exhibit high rates of nonsuppression. This suggests that nonsuppression may merely be a nonspecific indicator of generalized mental distress.

Research has also revealed that patients having depression with elevated cortisol also tend to show memory impairments and problems with abstract thinking and complex problem solving (Belanoff et al., 2001). Some of these cognitive problems may be related to other findings showing that prolonged elevations in cortisol, such as those seen in moderate to severe depression, result in cell death in the hippocampus—a part of the limbic system heavily involved in memory functioning (e.g., Southwick et al., 2005; Thase, 2009). Other interesting research has shown that stress in infancy and early childhood can promote long-term changes that increase the reactivity of the HPA axis, which may in turn help explain why children reared in environments with early adversity are at higher risk for developing depression later in life when they are exposed to acute stressors (e.g., Southwick et al., 2005).

The other endocrine axis that has relevance to depression is the *hypothalamic-pituitary-thyroid axis* because disturbances to this axis are also linked to mood disorders (Garlow & Nemeroff, 2003; Thase, 2009; Thase et al., 2002). For example, people with low thyroid levels (*hypothyroidism*) often become depressed. In addition, about 20 to 30 percent of patients with depression who have normal thyroid levels nevertheless show dysregulation of this axis. Moreover, preliminary findings suggest that some patients who have not responded to traditional antidepressant treatments may show improvement when administered thyrotropin-releasing hormone, which leads to increased thyroid hormone levels (Garlow & Nemeroff, 2003; Thase, 2009).

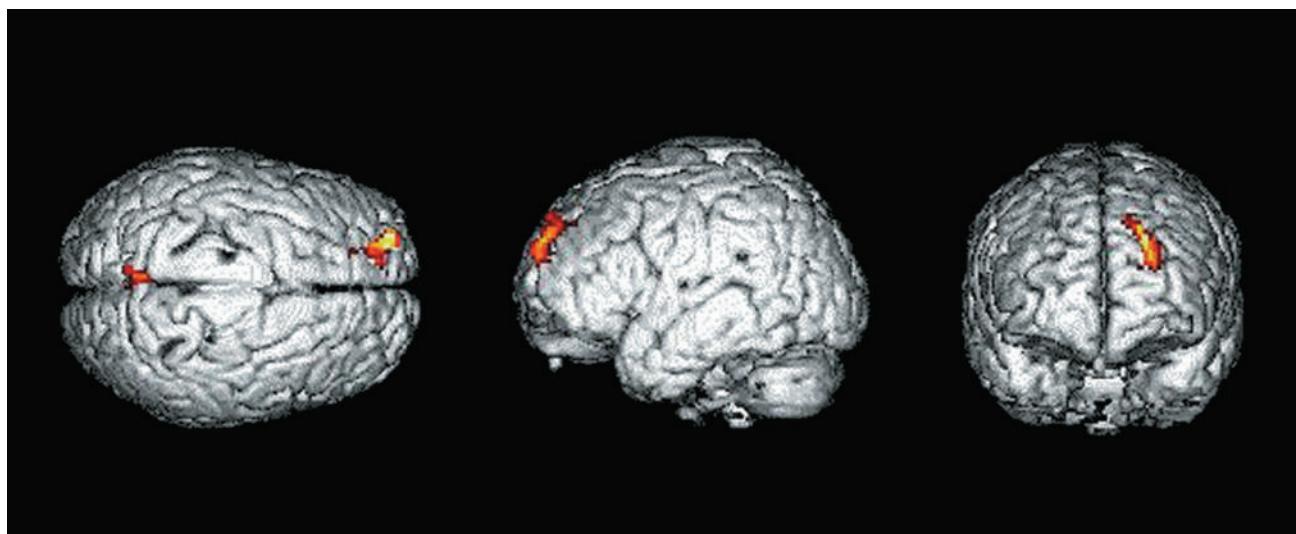

Finally, in recent years many studies have shown that depression is also accompanied by dysregulation of the *immune system*. For example, in a quantitative review Dowlati and colleagues (2010) have shown that depression is associated with activation of the inflammatory response system as evidenced by increased production of proinflammatory cytokines such as interleukin and interferon. Both of these can contribute directly to the development of depressive symptoms.

#### NEUROPHYSIOLOGICAL AND NEUROANATOMICAL INFLUENCES

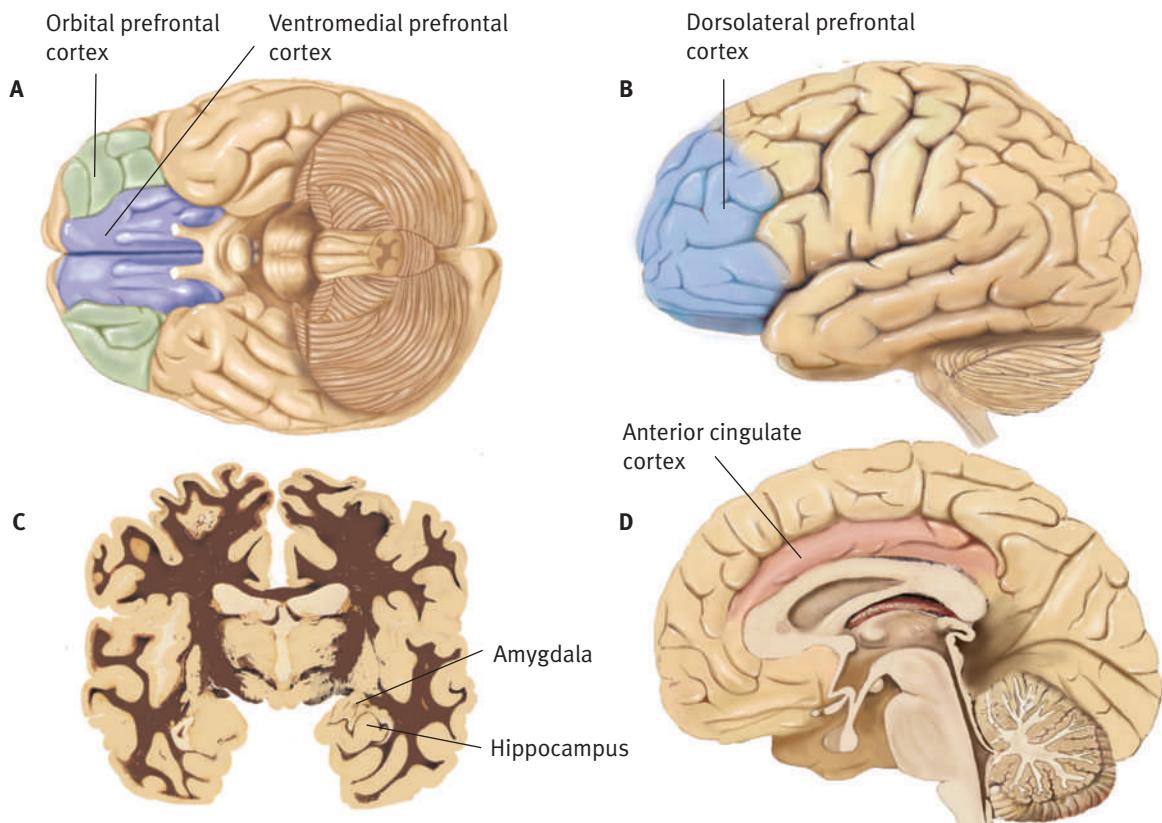

**Exciting neurophysiological research in recent years has followed up on earlier neurological findings that damage (for example, from a stroke) to the left, but not the right, anterior prefrontal cortex often leads to depression (e.g., Davidson et al., 2009; Robinson & Downhill, 1995).** This led to the idea that depression in people without brain damage may nonetheless be linked to lowered levels of brain activity in this same region. A number of studies have supported this idea. When one measures the electroencephalographic (EEG) activity of both cerebral

hemispheres in people who are depressed, one finds an asymmetry or imbalance in the EEG activity of the two sides of the prefrontal regions of the brain. In particular, people with depression show relatively low activity in the left hemisphere in these regions and relatively high activity in the right hemisphere (Davidson et al., 2009; Stewart et al., 2010, 2011). Similar findings have been reported using PET neuroimaging techniques (see Davidson et al., 2009; Phillips et al., 2003). Notably, patients in remission show the same pattern (Henriques & Davidson, 1990; Stewart et al., 2010, 2011), as do children at risk for depression (Bruder et al., 2007). These latter findings hold promise as a way of identifying persons at risk both for an initial episode and for recurrent episodes. Indeed, a recent study found that left frontal asymmetry in never-depressed individuals predicted onset of major and minor depressive episodes over a 3-year period (Nusslock et al., 2011). The relatively lower activity on the left side of the prefrontal cortex in depression is thought to be related to symptoms of reduced positive affect and approach behaviors to rewarding stimuli, and increased right-side activity is thought to underlie increased anxiety symptoms and increased negative affect associated with increased vigilance for threatening information (Pizzagalli et al., 2002).

Abnormalities have also been detected in several other brain areas in patients with depression as illustrated in Figure 7.2 (Davidson et al., 2009; Koolschijn et al., 2009). For example, several regions of the prefrontal cortex, including the *orbital prefrontal cortex*, which is involved in responsiveness to reward (e.g., Haber & Knutson, 2010), show decreased volume in individuals with recurrent depression relative to normal controls (Koolschijn et al., 2009; Phillips et al., 2003). Lower levels of activity in the *dorsolateral prefrontal cortex*, which are associated with decreased

Functional MRI changes (see Chapter 4) in depressed patients in response to affective stimuli from pre- to posttreatment. These red and yellow images illustrate (in three different views) the increase in left prefrontal activation that occurred in a group of depressed patients following treatment compared to their activation pattern during an acute depressive episode. Thus, the red and yellow images depict the increase in cerebral blood in the left prefrontal area in response to affective stimuli from before and after successful antidepressant treatment. The second scan was obtained 8 weeks following the first scan. Patients were treated with an antidepressant medication during those 8 weeks. (This image courtesy of Richard Davidson.)

**FIGURE 7.2**

The key brain regions involved in affect and mood disorders are the (A) orbital prefrontal cortex and ventromedial prefrontal cortex, (B) dorsolateral prefrontal cortex, (C) hippocampus and amygdala, and (D) anterior cingulate cortex.

Source: From R. J. Davidson, Diego Pizzagalli, and Jack Nitschke. (2002). The representation and regulation of emotion in depression. In I. H. Gotlib and C. L. Hammen (Eds.), *Handbook of Depression* (pp. 219–44). New York: Guilford.

cognitive control, have also been observed in individuals with depression compared to controls (Disner et al., 2011; see also Chang et al., 2011), and seem to normalize following treatment with antidepressant medication (Fales et al., 2009). Another area involved is the *hippocampus*, which is critical to learning and memory and regulation of adrenocorticotrophic hormone. As already noted, prolonged depression often leads to decreased hippocampal volume, at least in older people with depression. This could be due to cell atrophy or cell death (e.g., Koolschijn et al., 2009; Sapolsky, 2000). In addition, evidence of decreased hippocampal volume in never-depressed individuals who are at high (versus low) risk for depression suggests that reductions in hippocampal volume may precede the onset of depression (Chen et al., 2010).

A third such area is the *anterior cingulate cortex*, which both shows decreased volume and abnormally low levels of activation in patients with depression (Koolschijn et al., 2009). This area is involved in selective attention, which is important in prioritizing the most important information available, and therefore in self-regulation and adaptability—all important processes that are disrupted in depression.

Finally, the *amygdala*, which is involved in the perception of threat and in directing attention, tends to show increased activation in individuals with depression (and anxiety disorders), which may be related to their biased attention to negative emotional information (Davidson et al., 2009; Disner et al., 2011; Phillips et al., 2003).

**SLEEP AND OTHER BIOLOGICAL RHYTHMS** Although findings of sleep disturbances in patients with depression have existed as long as depression has been studied, only recently have some of these findings been linked to more general disturbances in biological rhythms.

**Sleep** Sleep is characterized by five stages that occur in a relatively invariant sequence throughout the night (Stages 1 to 4 of non-REM sleep and REM sleep make up a sleep cycle). REM sleep (rapid eye movement sleep) is characterized by rapid eye movements and dreaming as well as other bodily changes; the first REM period does not usually begin until near the end of the first sleep cycle, about 75 to 80 minutes into sleep. This normal sleep–wake cycle is thought to be regulated by the *suprachiasmatic nucleus* of the hypothalamus (e.g., Steiger, 2007; Thase, 2009). Patients who are depressed often show one or more of a variety of sleep problems, ranging from early morning awakening, periodic awakening during the night (poor sleep maintenance), and, for some, difficulty falling asleep. Such changes occur in about 80 percent of hospitalized patients with depression and in about 50 percent of outpatients with depression, and are particularly pronounced in patients with melancholic features.

Moreover, research using EEG recordings has found that many patients with depression enter the first period of REM sleep after only 60 minutes or less of sleep (i.e., 15 to 20 minutes sooner than patients who are not depressed do) and also show greater amounts of REM sleep during the early cycles

than are seen in persons without depression. The intensity and frequency of their rapid eye movements are also greater than in patients who are not depressed (Thase et al., 2002). Because this is the period of the night when most deep sleep (Stages 3 and 4) usually occurs, the person with depression also gets a lower-than-normal amount of deep sleep. Both the reduced latency to enter REM sleep and the decreased amount of deep sleep often precede the onset of depression and persist following recovery, which suggests that they may be vulnerability markers for certain forms of major depression (Hasler et al., 2004; Thase et al., 2002).

**Circadian Rhythms** Humans have many circadian (24-hour, or daily) cycles other than sleep, including body temperature, propensity to REM sleep, and secretion of cortisol, thyroid-stimulating hormone, and growth hormone (Thase, 2009; Thase et al., 2002). These circadian rhythms are controlled by two related central “oscillators,” which act as internal biological clocks. Research has found some abnormalities in all of these rhythms in patients with depression, though not all patients show abnormalities in all rhythms (Howland & Thase, 1999; Thase, 2009). Although the exact nature of the dysfunctions is not yet known, some kind of circadian rhythm dysfunction may play a causal role in many of the clinical features of depression. Two current theories are (1) that the size or magnitude of the circadian rhythms is blunted, and (2) that the various circadian rhythms that are normally well synchronized with each other become desynchronized or uncoupled (Howland & Thase, 1999; Thase et al., 2002).

**Sunlight and Seasons** Another, rather different kind of rhythm abnormality or disturbance is seen in people with *seasonal affective disorder*, in which most of those affected seem to be responsive to the total quantity of available light in the environment (Oren & Rosenthal, 1992). A majority (but not all) become depressed in the fall and winter and normalize in the spring and summer (Goodwin & Jamison, 2007; Howland & Thase, 1999). Research in animals has also documented that many seasonal variations in basic functions such as sleep, activity, and appetite are related to the amount of light in a day (which, except near the equator, is much greater in summer than in winter). Patients with depression who fit the seasonal pattern usually show increased appetite and hypersomnia rather than decreased appetite and insomnia (Howland & Thase, 1999). They also have clear disturbances in their circadian cycles, showing weaker 24-hour patterns than are found in individuals who are not depressed (Goodwin & Jamison, 2007; Howland & Thase, 1999). A good deal of research on patients with seasonal affective disorder supports the therapeutic use of controlled exposure to light, even artificial light, which may work by reestablishing normal biological rhythms (Fava & Rosenbaum, 1995; Goodwin & Jamison, 2007). Although anti-depressant medications can also be useful, the use of light therapy is more cost efficient in the long term (Cheung et al., 2012).

People who live in higher latitudes (northern climates for those in the northern hemisphere) are more likely to exhibit seasonal affective disorder, in which depression occurs primarily in the fall and winter months and tends to remit in the spring or summer months.

### BIOLOGICAL EXPLANATIONS FOR SEX DIFFERENCES

Before we leave the topic of possible biological causal factors for depression, we should note that it has been suggested that hormonal factors such as normal fluctuations in ovarian hormones account for sex differences in depression (Deecker et al., 2008). However, studies examining this hypothesis have yielded inconsistent results and overall are not very supportive (Nolen-Hoeksema, 2002; Nolen-Hoeksema & Hilt, 2009). It seems that for the majority of women, hormonal changes occurring at various points (e.g., at the onset of puberty, before menstruation, in the postpartum period, and at menopause) do not play a significant role in causing depression. However, it remains possible that there is a causal association that has not yet been discovered because of real methodological difficulties in conducting conclusive research on this topic (Naninck et al., 2011; Sanborn & Hayward, 2003). Moreover, for a small minority of women who are already at high risk (for example, by being at high genetic risk), hormonal fluctuations may trigger depressive episodes, possibly by causing changes in the normal processes that regulate neurotransmitter systems (Deecker et al., 2008; Naninck et al., 2011). Some studies have suggested that women have a greater genetic vulnerability to depression than men, but many other studies have not supported this idea (e.g., Nolen-Hoeksema, 2002; Nolen-Hoeksema & Hilt, 2009; Wallace et al., 2002).

### Psychological Causal Factors

The evidence for important psychological causal factors in most unipolar mood disorders is at least as strong as the evidence for biological factors. However, it is likely that the effects of at least some psychological factors such as stressful life events are mediated by a cascade of underlying biological changes that they initiate. One way in which stressors may act is through their effects on biochemical and hormonal balances and on biological rhythms (Hammen, 2005; Monroe, 2008).

**STRESSFUL LIFE EVENTS AS CAUSAL FACTORS** Psychological stressors are known to be involved in the onset of a variety of disorders, ranging from some of the anxiety disorders to

schizophrenia, but nowhere has their role been more carefully studied than in the case of unipolar major depression. Many studies have shown that severely stressful life events often serve as precipitating factors for unipolar depression (e.g., Hammen, 2005; Monroe & Harkness, 2005; Monroe et al., 2009). This is especially true for young female adults for whom stressful life events are more likely to show a stronger stress-depression relationship than is the case for men (Harkness et al., 2010).

Most of the episodic stressful life events involved in precipitating depression concern loss of a loved one, serious threats to important close relationships or to one's occupation, or severe economic or serious health problems (Monroe & Hadjiyannakis, 2002; Monroe et al., 2009). For example, separations through death or divorce are strongly associated with depression, although such losses also tend to precede other disorders such as panic disorder and generalized anxiety (Kendler, Hettema et al., 2003; Kessler et al., 1997). Losses that involve an element of humiliation can be especially potent. The stress of being the caregiver to a spouse with a debilitating disease such as Alzheimer's is also known to be associated with the onset of both major depression and generalized anxiety disorder in the caregiver (e.g., Russo et al., 1995).

An important distinction has been made between stressful life events that are independent of the person's behavior and personality (*independent life events*, such as losing a job because one's company is shutting down or having one's house hit by a hurricane) and events that may have been at least partly generated by the depressed person's behavior or personality (*dependent life events*). For example, people with depression sometimes generate stressful life events through their poor interpersonal problem solving (such as being unable to resolve conflicts with a spouse), which is often associated with depression. The poor problem solving in turn leads to higher levels of interpersonal stress, which in turn leads to further symptoms of depression. Another example of a dependent life event is failing to keep up with routine tasks such as paying bills, which may lead to a variety of troubles. Evidence to date suggests that dependent life events play an even stronger role in the onset of major depression than do independent life events (Hammen, 2005; Kendler et al., 1999a).

Research on stress and the onset of depression is complicated by the fact that people with depression have a distinctly negative view of themselves and the world around them (Beck, 1967; Clark, Beck, & Alford, 1999). Thus, their own perceptions of stress may result—at least to some extent—from the cognitive symptoms of their disorder rather than cause their disorder (Dohrenwend, 2006; Monroe, 2008; Monroe & Hadjiyannakis, 2002). That is, their pessimistic outlook may lead them to evaluate events as stressful that an independent evaluator (or a friend who is not depressed) would not. Therefore, researchers have developed more sophisticated interview-based measures of life stress that do not rely on the depressed person's self-report of how stressful

an event is and that take into account the biographical context of a person's life. Trained independent raters evaluate what the impact of a particular event would be expected to be for an average person who has experienced this event in these particular life circumstances; the person's subjective evaluations of stress are not recorded or taken into account in the rating of impact (Monroe, 2008). For example, the stress value of divorce for a woman who has already begun to establish a new relationship would probably not be rated as highly as the divorce of a woman whose husband left her for a younger woman (e.g., Dohrenwend et al., 1995; Monroe & Hadjiyannakis, 2002). There is widespread agreement that conclusions derived from studies using these more sophisticated interview-based techniques are more reliable and valid in predicting depressive episodes (e.g., Monroe, 2008; Monroe & Reid, 2008; Uher & McGuffin, 2010).

Several recent reviews of studies that employed these sophisticated measurements of life stress show that severely stressful episodic life events play a causal role (most often within a month or so after the event) in about 20 to 50 percent of cases (e.g., Hammen, 2005; Kendler, Kessler et al., 2010; Monroe & Harkness, 2005). Moreover, people with depression who have experienced a stressful life event tend to show more severe depressive symptoms than those who have not experienced a stressful life event (Monroe & Hadjiyannakis, 2002). This relationship between severely stressful life events and depression is much stronger in people who are having their first onset than in those undergoing recurrent episodes (e.g., Kendler et al., 2000; Monroe & Harkness, 2005). Indeed, Monroe and Harkness (2005) estimated that about 70 percent of people with a first onset of depression have had a recent major stressful life event, whereas only about 40 percent of people with a recurrent episode have had a recent major life event.

**Mildly Stressful Events and Chronic Stress** Whether mildly stressful events are also associated with the onset of depression is much more controversial, with conflicting findings in the literature. However, studies applying the more sophisticated and complex strategies for assessing life stress have generally not found minor stressful events to be associated with the onset of clinically significant depression (e.g., Dohrenwend et al., 1995; Stueve et al., 1998). An interesting hypothesis has recently been raised that minor events may play more of a role in the onset of recurrent episodes than in the initial episode (Monroe & Harkness, 2005; Monroe et al., 2009). At least one recent study has confirmed this by showing that recurrent episodes are often precipitated by stressful life events of relatively mild impact, which do not tend to be involved in precipitating initial depressive episodes (Stroud et al., 2011).

Although the relationship of chronic stress to the onset of depression has not been as thoroughly studied as has the relationship with episodic life events, a number of good

studies have demonstrated that chronic stress is associated with increased risk for the onset, maintenance, and recurrence of major depression (Hammen, 2005; Monroe et al., 2007). Different studies have used the term *chronic stress* (or *chronic strain* or *difficulties*) in different ways, although it usually refers to one or more forms of stress ongoing for at least several months (e.g., poverty, lasting marital discord, medical problems, having a disabled child). One well-validated chronic stress interview assesses chronic stress in 8 to 10 different domains (e.g., intimate relationships, close friends, family relationships, health of self and family members, etc.; Hammen, 2005).

**Vulnerability and Responses to Stressors** It is important to keep in mind that there are important individual differences in how people respond to the experiences of episodic or chronic life stress. For example, women (and perhaps men) at genetic risk for depression not only experience more stressful life events (Kendler et al., 1999a; Kendler & Karkowski-Shuman, 1997) but also are more sensitive to them (Kendler, Kessler et al., 1995; Kendler, Kessler et al., 2010). In one large study, women at genetic risk were three times more likely than those not at genetic risk to respond to severely stressful life events with depression (a good example of a genotype–environment interaction). Conversely, those at low genetic risk for depression are less vulnerable to the effects of major stressors (e.g., Caspi et al., 2003; Kendler, Kessler et al., 1995, 2010).

In addition to genetic variables, there are a host of other psychological and social variables that may make some people more vulnerable, and other people less vulnerable, to developing depression after experiencing one or more stressful life events (e.g., see Brown & Harris, 1978, for a classic landmark study). In the past 25 years, many researchers have sought to determine which vulnerability and protective factors are most powerful in predicting onset and maintenance of depression.

**DIFFERENT TYPES OF VULNERABILITIES FOR UNIPOLAR DEPRESSION** The range of psychological vulnerabilities that have been studied includes personality traits, negative styles of thinking about the world and one's experiences, early childhood adversity, and lack of social support.

**Personality and Cognitive Diatheses** Researchers have concluded that neuroticism is the primary personality variable that serves as a vulnerability factor for depression (and anxiety disorders as well; for reviews, see Clark, Watson, & Mineka, 1994; Klein et al., 2009; Kotov et al., 2010; see also Lahey, 2009; Zinbarg et al., 2011). Recall that *neuroticism*, or *negative affectivity*, refers to a stable and heritable personality trait that involves a temperamental sensitivity to negative stimuli. Thus, people who have high levels of this trait are prone to experiencing a broad range of negative moods, including not only sadness

but also anxiety, guilt, and hostility. Moreover, several studies have also shown that neuroticism predicts the occurrence of more stressful life events, which (as already discussed) frequently lead to depression (e.g., Kendler, Gardner, & Prescott, 2003; Uliaszek et al., 2012). In addition to serving as a vulnerability factor, neuroticism is associated with a worse prognosis for complete recovery from depression. Finally, some researchers attribute sex differences in depression to sex differences in neuroticism (e.g., Kendler et al., 2002; Sutin et al., 2010).

There is some more limited evidence that high levels of introversion (or low positive affectivity) may also serve as vulnerability factors for depression, either alone or when combined with neuroticism (e.g., Gershuny & Sher, 1998; Watson et al., 2005). Positive affectivity involves a disposition to feel joyful, energetic, bold, proud, enthusiastic, and confident; people low on this disposition tend to feel unenthusiastic, unenergetic, dull, flat, and bored. It is therefore not surprising that this might make them more prone to developing clinical depression, although the evidence for this is very mixed.

The cognitive diatheses that have been studied for depression generally focus on particular negative patterns of thinking that make people who are prone to depression more likely to become depressed when faced with one or more stressful life events. For example, people who attribute negative events to internal, stable, and global causes may be more prone to becoming depressed than are people who attribute the same events to external, unstable, and specific causes (e.g., Abramson et al., 1978; Abramson et al., 1989; Abramson et al., 2002). A pessimistic or depressive attribution for receiving a low grade in an exam might be, “I’m stupid,” whereas a more optimistic attribution for the same event might be, “The teacher deliberately wrote a difficult test to make us all realize we need to study harder.”

If a woman living in poverty is already genetically at risk for depression, the stresses associated with living in poverty may be especially likely to precipitate a major depression in her.

Children who have lost a parent through death or permanent separation may become vulnerable to depression if they receive poor subsequent care from another parent or guardian and if their environment and routine are disrupted.

**Early Adversity as a Diathesis** A range of adversities in the early environment (such as family turmoil, parental psychopathology, physical or sexual abuse, and other forms of intrusive, harsh, and coercive parenting) can create both a short-term and a long-term vulnerability to depression. Such factors operate, at least in part, by increasing an individual's sensitivity to stressful life events in adulthood, with similar findings having been observed in animals (e.g., Gunnar & Quevedo, 2007; Harkness & Lumley, 2008; Slavich et al., 2011). The long-term effects of such early environmental adversities may be mediated by both biological variables (such as alterations in the regulation of the hypothalamic-pituitary stress response system) and psychological variables (such as lower self-esteem, insecure attachment relationships, difficulty relating to peers, and pessimistic attributions; e.g., Goodman & Brand, 2009; Harkness & Lumley, 2008). However, it is also important to realize that certain individuals who have undergone early adversity remain resilient, and if the exposure to early adversity is moderate rather than severe a form of stress inoculation may occur that makes the individual less susceptible to the effects of later stress (e.g., Parker et al., 2004). These stress-inoculation effects seem to be mediated by strengthening socioemotional and neuroendocrine resistance to subsequent stressors.

**Summary** As we have discussed, several different types of biological and psychological diatheses for unipolar depression have been studied, and some of these have been formulated as diathesis-stress theories, as we review in the following sections. Nevertheless it is important to keep in mind that these theories of vulnerability are not mutually exclusive, and some may simply be describing the same diathesis in different terms or at different levels of analysis. For example, there is a moderately strong genetic basis for neuroticism, and neuroticism is strongly correlated with pessimism (Clark, Watson, & Mineka, 1994; Zinbarg et al., 2010; Zinbarg et al., 2013), so these proposed diatheses are clearly somewhat interrelated. Moreover, dysfunctional early parenting, emotional abuse, and parental loss have been strongly implicated in the formation of some of the other cognitive diatheses (Alloy et al., 2004; Bowlby, 1980; Goodman & Brand,

2009). Thus, these two proposed diatheses may simply differ in whether they operate distally (poor early parenting) or proximally (negative thinking patterns) in contributing to vulnerability for depression.

We now turn to five major psychological theories of depression that have received much attention over the years.

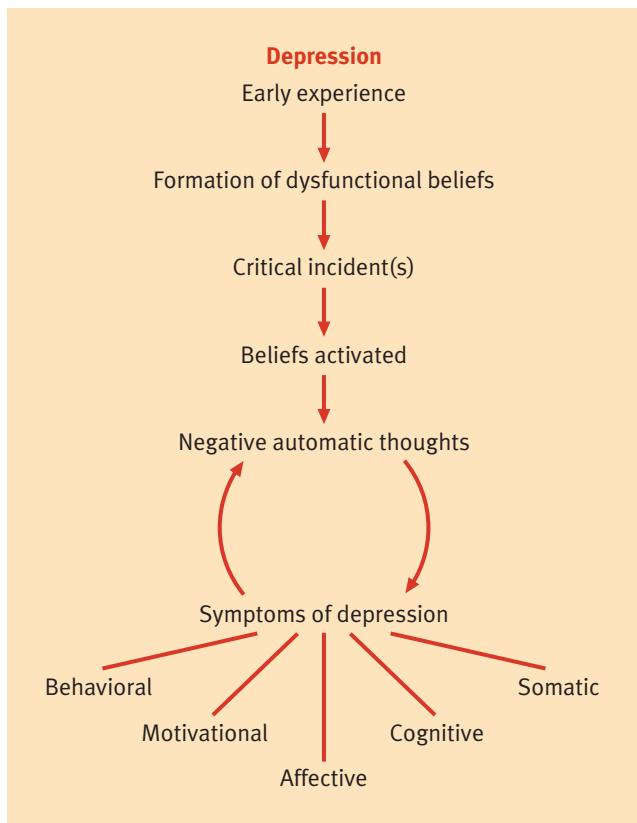

**PSYCHODYNAMIC THEORIES** In his classic paper "Mourning and Melancholia" (1917), Freud noted the important similarity between the symptoms of clinical depression and the symptoms seen in people mourning the loss of a loved one. Freud and a colleague, Karl Abraham (1927), both hypothesized that when a loved one dies the mourner regresses to the oral stage of development (when the infant cannot distinguish self from others) and introjects or incorporates the lost person, feeling all the same feelings toward the self as toward the lost person. These feelings were thought to include anger and hostility because Freud believed that we unconsciously hold negative feelings toward those we love, in part because of their power over us. This is what led to the psychodynamic idea that depression is anger turned inward. Freud hypothesized that depression could also occur in response to imagined or symbolic losses. For example, a student who fails in school or who fails at a romantic relationship may experience this symbolically as a loss of his or her parents' love.

Later psychodynamic theorists proposed a number of variants on Freud and Abraham's early psychodynamic theories (see Levy & Wasserman, 2009, for a brief summary). Perhaps the most important contribution of the psychodynamic approaches to depression has been their noting the importance of loss (both real and symbolic or imagined) to the onset of depression and noting the striking similarities between the symptoms of mourning and the symptoms of depression (Bowlby, 1980). Even theorists who disagree with many of the specific details of these theories recognize that their own theories must account for these basic observations.

**BEHAVIORAL THEORIES** In the 1970s and 1980s, several theorists in the behavioral tradition developed behavioral theories of depression, proposing that people become depressed either when their responses no longer produce positive reinforcement or when their rate of negative experiences increases (such as when experiencing stressful life events; e.g., Ferster, 1974; Lewinsohn, 1974; Lewinsohn & Gotlib, 1995; Lewinsohn et al., 1985). Such theories are consistent with research showing that people with depression do indeed receive fewer positive verbal and social reinforcements from their families and friends than do people who are not depressed and also experience more negative events. Moreover, they have lower activity levels, and their moods seem to vary with both their positive and their negative experiences rates (see Lewinsohn & Gotlib, 1995; Martell, 2009). Nevertheless, although such findings are consistent with behavioral theories, they do not show that depression is *caused* by these factors. Instead, it may be that some of the primary symptoms

of depression, such as pessimism and low levels of energy, cause the person with depression to experience lower rates of reinforcement, which in turn may help maintain the depression. For this and other reasons, behavioral theories of the causes of depression are no longer very influential. However, as discussed later, there is exciting new research demonstrating that a novel form of behavioral treatment inspired by these behavioral theories—behavioral activation treatment—seems to be a very effective way to treat depression (Dimidjian et al., 2011; Martell, 2009).

**BECK'S COGNITIVE THEORY** Since 1967 one of the most influential theories of depression has been that of Aaron Beck (b. 1921), a psychiatrist who became disenchanted with psychodynamic theories of depression early in his career and developed his own cognitive theory of depression (e.g., Beck, 1967; Clark, Beck, & Alford, 1999). Whereas the most prominent symptoms of depression have generally been considered to be the affective or mood symptoms, Beck hypothesized that the cognitive symptoms of depression often precede and cause the affective or mood symptoms rather than vice versa (see Figure 7.3). For example, if

**FIGURE 7.3**

**Beck's Cognitive Model of Depression.** According to Beck's cognitive model of depression, certain kinds of early experiences can lead to the formation of dysfunctional assumptions that leave a person vulnerable to depression later in life if certain critical incidents (stressors) activate those assumptions. Once activated, these dysfunctional assumptions trigger automatic thoughts that in turn produce depressive symptoms, which further fuel the depressive automatic thoughts. (Adapted from Fennell, 1989.)

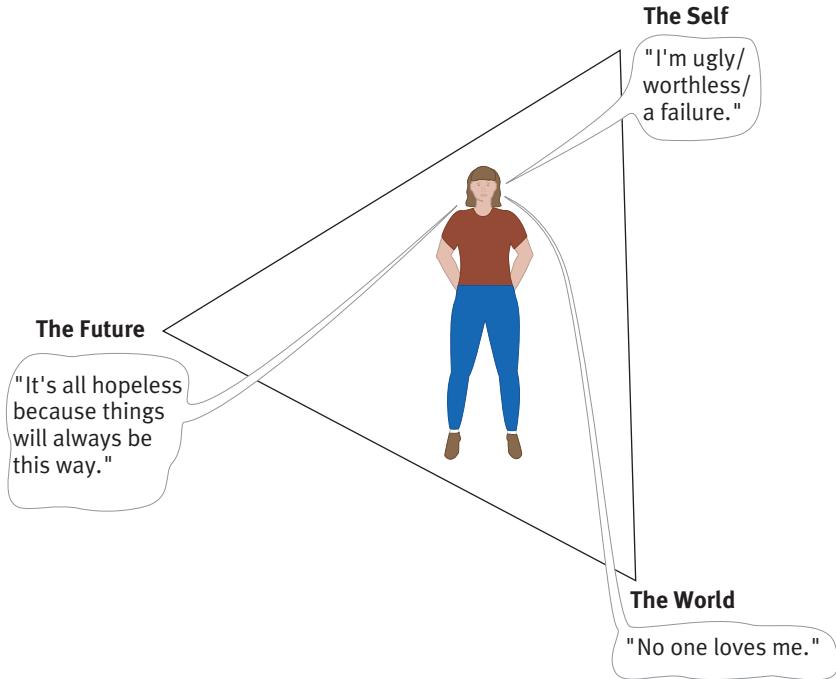

you think that you are a failure or that you are ugly, it would not be surprising for those thoughts to lead to a depressed mood.

Beck's theory, a diathesis-stress theory in which negative cognitions are central, has become somewhat more elaborate over the years while still retaining its primary tenets (e.g., Beck, 1967, 1983; Clark & Beck, 2010). First, there are the underlying dysfunctional beliefs, known as **depressogenic schemas**, which are rigid, extreme, and counterproductive. An example of a dysfunctional belief (that a person is usually not consciously aware of) is, "If everyone doesn't love me, then my life is worthless." According to cognitive theory, such a belief would predispose the person holding it to develop depression if he or she perceived social rejection. Alternatively, a person with the dysfunctional belief, "If I'm not perfectly successful, then I'm a nobody" would be vulnerable to developing negative thoughts and depressed mood if she or he felt like a failure. Note that Beck did not maintain that simply having these **dysfunctional beliefs** is sufficient to make someone depressed; instead, he maintained that these dysfunctional beliefs need to be activated by the occurrence of some form of stress (e.g., perceiving social rejection or feeling like a failure).

These depression-producing beliefs or schemas are thought to develop during childhood and adolescence as a function of negative experiences with parents and significant others, and they are thought to serve as the underlying diathesis, or vulnerability, to developing depression (Beck, 1967; Ingram et al., 2006; Morley & Moran, 2011). Although they may lie dormant for years in the absence of significant stressors, when dysfunctional beliefs are activated by current stressors or depressed mood, they tend to fuel the current thinking pattern, creating a pattern of **negative automatic thoughts**—thoughts that often occur just below the surface of awareness and involve unpleasant, pessimistic predictions. These pessimistic predictions tend to center on the three themes of what Beck calls the **negative cognitive triad**: (1) negative thoughts about the self ("I'm ugly"; "I'm worthless"; "I'm a failure"); (2) negative thoughts about one's experiences and the surrounding world ("No one loves me"; "People treat me badly"); and (3) negative thoughts about one's future ("It's hopeless because things will always be this way"; Clark, Beck, & Alford, 1999; see Figure 7.4 on p. 231).

Beck also postulated that the negative cognitive triad tends to be maintained by a variety of negative cognitive biases or errors (see also Scher et al., 2005). Each of these involves biased processing of negative self-relevant information. Examples include:

- *Dichotomous or all-or-none reasoning*, which involves a tendency to think in extremes. For example, someone might discount a less-than-perfect performance by saying, "If I can't get it 100 percent right, there's no point in doing it at all."
- *Selective abstraction*, which involves a tendency to focus on one negative detail of a situation while ignoring other elements of the situation. Someone might say, "I didn't have a moment of pleasure or fun today" not because this is true but because he or she selectively remembers only the negative things that happened.

**FIGURE 7.4**

**Negative Cognitive Triad.** Beck's cognitive model of depression describes a pattern of negative automatic thoughts. These pessimistic predictions center on three themes: the self, the world, and the future.

- *Arbitrary inference*, which involves jumping to a conclusion based on minimal or no evidence. A depressed person might say, after an initial homework assignment from a cognitive therapist did not work, "This therapy will never work for me." (Examples from Fennell, 1989, p. 193)

It is easy to see how each of these cognitive distortions tends to maintain the negative cognitive triad. That is, if the content of your thoughts regarding your views of your self, your world, and your future is already negative and you tend to minimize the good things that happen to you or draw negative conclusions based on minimal evidence, those negative thoughts are not likely to disappear. In addition, just as the underlying dysfunctional beliefs (such as, "If everybody doesn't love me, then my life is worthless") elicit the negative cognitive triad when activated, so too does the negative thinking produced by the negative triad serve to reinforce those underlying beliefs. Thus each of these components of cognitive theory serves to reinforce the others, as shown in Figure 7.3 on p. 230. Moreover, these negative thoughts can produce some of the other symptoms of depression such as sadness, dejection, and lack of motivation.

#### Evaluating Beck's Theory as a Descriptive Theory

Over the past 35 years, an enormous amount of research has been conducted to test various aspects of Beck's theory. As we will see, it has generated a very effective form of treatment for depression known as cognitive therapy. In addition, it has

been well supported as a descriptive theory that explains many prominent characteristics of depression (e.g., D. A. Clark, Beck, & Alford, 1999; Haaga et al., 1991). Patients with depression of all the subtypes are considerably more negative in their thinking, especially about themselves or issues highly relevant to the self, than are persons who are not depressed and they are also more negative than they usually are when they are not depressed. Moreover, persons with depression do think more negatively about themselves and the world around them, especially their own personal world, than do persons who are not depressed, and are quite negative about the future, especially their own future (the negative cognitive triad). By contrast, people who are not depressed show a tendency to process emotional information in an overly optimistic, self-enhancing manner, which may serve as a protective factor against depression (Mezulis et al., 2004).

Beck's theory originally proposed that stressors are necessary to activate depressogenic schemas or dysfunctional beliefs that lie dormant between episodes, but more recent research has shown that stressors are not necessary to activate the latent depressive schemas between episodes. Indeed, simply inducing a depressed mood (e.g., through listening to sad music or recalling sad memories) in an individual who was previously depressed (that is, at risk) is generally sufficient to activate latent depressogenic schemas (e.g., Ingram et al., 2006; LeMoult et al., 2009; Scher et al., 2005).

In addition to evidence for dysfunctional beliefs and negative automatic thoughts, there is also considerable evidence for certain cognitive biases for negative self-relevant information in depression. For example, people with depression show better or biased recall of negative information and negative autobiographical memories, whereas people who are not depressed tend to show biased recall of positive emotional information and positive autobiographical memories (Gotlib & Joormann, 2010; Hertel & Brozovich, 2010; Mathews & MacLeod, 2005; Mineka et al., 2003). In addition, people with depression are more likely than people who are not depressed to draw negative conclusions that go beyond the information presented in a scenario and to underestimate the positive feedback they have received (D. A. Clark, Beck, & Alford, 1999). It is easy to see how, if one is already depressed, remembering primarily the bad things that have happened is likely to maintain or exacerbate the depression. Teasdale (1988, 1996) aptly called this the "vicious cycle of depression."

#### Evaluating the Causal Aspects of Beck's Theory

Although research supports most of the descriptive aspects of Beck's theory, research directed toward confirming the causal hypotheses of Beck's theory has yielded more mixed results. The causal hypotheses are usually tested with some kind

of prospective study design. People who are not depressed are tested for their cognitive vulnerability (usually, dysfunctional beliefs) at Time 1 and then are followed for 1 or more months or years, after which measurements of life stress are administered. Only some studies have found that dysfunctional beliefs or attitudes at Time 1, in interaction with stressful life events, predict depression at Time 2. However, some of the studies that yielded negative results may have used inadequate study designs. Several more recent studies using more adequate designs have found results quite supportive of the causal aspects of Beck's theory (e.g., Hankin et al., 2004; Lewinsohn et al., 2001). For example, Lewinsohn and colleagues (2001) assessed about 1,500 adolescents for their dysfunctional beliefs or attitudes and then followed them for 1 year, at which point stressful life events during that year were assessed. Results indicated that those who had started with high levels of dysfunctional beliefs and who experienced high stress were more likely to develop major depression than those with low stress or than those with low dysfunctional beliefs and high stress. Another study with a large community sample of 700 women (average age was 41) also found that dysfunctional beliefs at the outset of a 3-year follow-up period predicted new onsets and recurrences of major depressive episodes over the next 3 years (Otto et al., 2007). However, unlike in the Lewinsohn, Joiner, and Rohde (2001) study, there was no evidence in the Otto and colleagues study for a diathesis-stress interaction, and dysfunctional beliefs did not have additional predictive value beyond that afforded by knowing a prior history of the person's depressive episodes. Thus, because of inconsistencies in results across studies, more research is still needed to fully assess the causal aspects of Beck's cognitive theory of depression.

**THE HELPLESSNESS AND HOPELESSNESS THEORIES OF DEPRESSION** Whereas Beck's theory grew out of his clinical observations and research on the pervasive patterns of negative thinking seen in depressed patients, the learned helplessness theory of depression originated out of observations in an animal research laboratory. Martin Seligman (1974, 1975) first proposed that the laboratory phenomenon known as **learned helplessness** might provide a useful animal model of depression. In the late 1960s, Seligman and his colleagues (Maier et al., 1969; Overmier & Seligman, 1967) noted that laboratory dogs who were first exposed to uncontrollable shocks later acted in a passive and helpless manner when they were in a situation where they could control the shocks. In contrast, animals first exposed to equal amounts of controllable shocks had no trouble learning to control the shocks.

Seligman and his colleagues (e.g., Maier et al., 1969; Overmier & Seligman, 1967) developed the learned helplessness hypothesis to explain these effects. It states that when animals or humans find that they have no control over aversive events (such as shock), they may learn that they are helpless, which makes them unmotivated to try to respond

in the future. Instead they exhibit passivity and even depressive symptoms. They are also slow to learn that any response they do make is effective, which may parallel the negative cognitive set in human depression. Seligman's observations that the animals looked depressed captured his attention and ultimately led to his proposing a learned helplessness model of depression (Seligman, 1974, 1975). Subsequent research demonstrated that helpless animals also show other depressive symptoms such as lower levels of aggression, loss of appetite and weight, and changes in monoamine neurotransmitter levels. After demonstrating that learned helplessness also occurs in humans (e.g., Hiroto & Seligman, 1975), he went on to propose that learned helplessness may underlie some types of human depression. That is, people undergoing stressful life events over which they have little or no control may develop a syndrome like the helplessness syndrome seen in animals.

**The Reformulated Helplessness Theory** Some of the research with humans on helplessness soon led to a major reformulation of the helplessness theory, addressing some of the complexities of what humans do when faced with uncontrollable events (Abramson et al., 1978). In particular, Abramson and colleagues proposed that when people (probably unlike animals) are exposed to uncontrollable negative events, they ask themselves why, and the kinds of **attributions** that people make are, in turn, central to whether they become depressed. These investigators proposed three critical dimensions on which attributions are made: (1) internal/external, (2) global/specific, and (3) stable/unstable. They proposed that a depressogenic or pessimistic attribution for a negative event is an internal, stable, and global one. For example, if your boyfriend treats you badly and you conclude that "It's because I'm ugly and boring," you are much more likely to become depressed than if you conclude that "It's because he's in a bad mood today and he is taking it out on me."

Abramson and colleagues (1978) proposed that people who have a relatively stable and consistent **pessimistic attributional style** have a vulnerability or diathesis for depression when faced with uncontrollable negative life events. This kind of cognitive style seems to develop, at least in part, through social learning (Alloy, Abramson, & Smith, 2006). For example, children may learn this cognitive style by observing and modeling inferences made by their parents. Alternatively or additionally, the parents may communicate their own inferences about negative events happening to their children, or engage in generally negative parenting practices such as high levels of negative psychological control (criticism, intrusiveness, and guilt) as well as a lack of warmth and caring.

This *reformulated helplessness theory* led to a great deal of research. Many studies demonstrated that depressed people do indeed have this kind of pessimistic attributional style, but of course this does not mean that pessimistic attributional style

plays a causal role (e.g., Abramson et al., 1995; Buchanan & Seligman, 1995). Using designs similar to those used to test the causal aspects of cognitive theory, many studies have examined the ability of a pessimistic attributional style to predict the onset of depression in interaction with negative life events (Abramson et al., 1989; Alloy et al., 2008). Some results have supported this theory and some have not.

The helplessness theory has been used to explain sex differences in depression. This theory proposes that by virtue of their roles in society, women are more prone to experiencing a sense of lack of control over negative life events. These feelings of helplessness might stem from poverty, discrimination in the workplace leading to unemployment or underemployment, the relative imbalance of power in many heterosexual relationships, high rates of sexual and physical abuse against women (either currently or in childhood), role overload (e.g., being a working wife and mother), and less perceived control over traits that men value when choosing a long-term mate, such as beauty, thinness, and youth (e.g., Heim et al., 2000; Ben Hamida et al., 1998; Nolen-Hoeksema & Hilt, 2009). There is at least some evidence that each of these conditions is associated with higher-than-expected rates of depression, although whether the effects involve a sense of helplessness has not yet been established (Brems, 1995; Nolen-Hoeksema et al., 1999; Whiffen & Clark, 1997). Combining the neuroticism theory with the helplessness theory, it is important to note that there is evidence that people who are high on neuroticism are more sensitive to the effects of adversity relative to those low on neuroticism (a genotype–environment interaction; Kendler et al., 2004; Lahey, 2009). So given that women have higher levels of neuroticism and experience more uncontrollable stress, the increased prevalence of depression in women becomes less surprising.

**The Hopelessness Theory of Depression** A further revision of this theory, known as the *hopelessness theory*, was later presented (Abramson et al., 1989; see Alloy et al., 2008). Abramson and colleagues (1989) propose that having a pessimistic attributional style in conjunction with one or more negative life events was not sufficient to produce depression unless one first experienced a state of hopelessness. A hopelessness expectancy was defined by the perception that one had no control over what was going to happen and by the absolute certainty that an important bad outcome was going to occur or that a highly desired good outcome was not going to occur. They also proposed that the internal/external dimension of attributions was not important to depression. Instead, they propose two other dimensions of pessimistic attributional style as being important components of this cognitive diathesis. Specifically, they propose that depression-prone individuals not only tend to make global and stable attributions for negative events but also tend to make negative inferences about other likely negative consequences of the event (e.g., that this means more bad things will also happen) and negative inferences about the implications of the event for the self-concept (e.g., that one is unworthy or deficient; Abramson et al., 2002).

Research over the past 25 years has been testing this theory. A major longitudinal prospective study of several hundred college students who were hypothesized to be at high risk for unipolar depression (because they had both a pessimistic attributional style and high levels of dysfunctional beliefs) has begun to yield evidence quite supportive of some of the major tenets of the hopelessness theory (e.g., Abramson et al., 2002; Alloy, Abramson, Whitehouse et al., 2006; Alloy et al., 2008). For example, in a 2.5-year follow-up period, students in the high-risk group who had never previously been depressed at the outset of the study were about four times more likely (16.2 percent versus 3.6 percent) to develop a first episode of major depression (or comorbid depression and anxiety) than those in the low-risk group. For those who had already had a previous episode of depression prior to entry into the study, the high-risk group was about three times more likely to experience a recurrent episode of major depression in the 2.5-year follow-up period.

Additional support for the hopelessness theory has been accumulating as well. Several smaller studies with similar designs to the investigation of Alloy, Abramson, and colleagues have shown evidence for the interaction of cognitive vulnerability with life stress in predicting depressive symptoms and onset of diagnosable depression (Hankin et al., 2004), although others have not (see Alloy et al., 2008). Furthermore, research has begun to integrate hopelessness theory with a motivational theory of depression that posits that depression is associated with decreased approach behavior (e.g., Nusslock et al., 2011). Specifically, some researchers have hypothesized that cognitively vulnerable individuals are at risk for decreased approach-related behavior as a result of increased hopelessness under stress, thereby contributing to depression. There is at least initial empirical support for this notion. For example, in one investigation of undergraduate students, cognitive vulnerability interacted with life stress to predict a decrease in goal-directed behavior, which was then associated with higher levels of depressive symptoms (Haefel et al., 2008). Furthermore, this predictive relationship between cognitive vulnerability and stress with goal-directed behavior was mediated by increased feelings of hopelessness. Additional tests of the hopelessness theory and its predictions are needed, but future research on the hopelessness theory is likely to continue to provide important insights into psychosocial causes of depression.

**The Ruminative Response Styles Theory of Depression** Nolen-Hoeksema's ruminative response style cognitive theory of depression (e.g., 1991, 2000, 2012; Nolen-Hoeksema & Hilt, 2009) focuses on different kinds of responses that people have when they experience feelings and symptoms of sadness and distress, and how their differing response styles affect the course of their depressed feelings. Specifically, when some people have such feelings, they tend to focus intently on how they feel and why they feel that way—a process called **rumination**, which involves a pattern of repetitive and relatively

passive mental activity. Other people, by contrast, have a more action-oriented or problem-solving response to such feelings and, for example, distract themselves with another activity or actually try to do something that will solve the problems that are leading to the sadness and distress. Research by Nolen-Hoeksema and colleagues has consistently shown that there are stable individual differences in the tendency to ruminate and that people who ruminate a great deal tend to have more lengthy periods of depressive symptoms. They are also more likely to develop full-blown episodes of major depressive disorder (Nolen-Hoeksema, 2000; Nolen-Hoeksema & Hilt, 2009).

Interestingly, it seems that women are more likely than men to ruminate when they become depressed (Nolen-Hoeksema & Corte, 2004; Nolen-Hoeksema & Aldao, 2011). Moreover, self-focused rumination leads to increased recall of more negative autobiographical memories, thereby feeding a vicious circle of depression (Hertel & Brozovich, 2010; Lyubomirsky et al., 1998; Nolen-Hoeksema et al., 2008). The importance of these sex differences in rumination is underscored when we consider that when gender differences in rumination are statistically controlled, gender differences in depression are no longer significant (Nolen-Hoeksema & Hilt, 2009).

Men, by contrast, are more likely to engage in a distracting activity (or consume alcohol) when they get in a depressed mood, and distraction seems to reduce depression (Nolen-Hoeksema & Corte, 2004; Nolen-Hoeksema, 2012; Nolen-Hoeksema et al., 2008). Distraction might include going to a movie, playing a sport, or avoiding thinking about why they are depressed. The origin of these sex differences in response to depression is unclear, but if further research supports this hypothesis it would certainly suggest that effective prevention efforts might include teaching girls to seek distraction rather than to ruminate as a response to depression.

The ruminative response styles theory of depression has been integrated with the two previously discussed cognitive theories of depression. For example, research reviewed recently by Alloy, Abramson, and colleagues (2008) shows that for people with high levels of dysfunctional attitudes and/or pessimistic attributional styles, their tendencies to ruminate moderated the effects of the negative cognitive styles on increasing vulnerability to depression. Specifically, those who had negative cognitive styles who also tended to ruminate a lot were most likely to develop depressive episodes. The researchers suggest that people with negative cognitive styles have a lot of negative content to their thoughts but that only if they dwell on this and brood about it (high ruminators) are they especially likely to develop clinical depression (see also Robinson & Alloy, 2003).

### Comorbidity of Anxiety and Mood Disorders

The issue of whether depression and anxiety can be differentiated

Women are more likely than men to ruminate when they are depressed. Men, in contrast, tend to engage in distracting activities when they get into a depressed mood.

in a reliable and valid way has received a good deal of attention over the years. Only in the past two decades, however, have researchers begun to make significant advances in understanding the real scope of the problem. The overlap between measures of depression and anxiety occurs at all levels of analysis: patient self-report, clinician ratings, diagnosis, and family and genetic factors (Clark & Watson, 1991; Mineka et al., 1998; Watson, 2005). That is, persons who rate themselves high on symptoms of anxiety also tend to rate themselves high on symptoms of depression, and clinicians rating these same individuals do the same thing. The overlap also occurs at the diagnostic level. One review of the literature estimated that just over half of the patients who receive a diagnosis of a mood disorder also receive a diagnosis of an anxiety disorder at some point in their lives, and vice versa (e.g., Hettema, 2008; Mineka et al., 1998; Watson, 2005).

Finally, there is considerable evidence from genetic and family studies of the close relationship between anxiety and unipolar depressive disorders (Garber & Weersing, 2010; Kendler, 1996; Mineka et al., 1998). Several very large twin studies and an important review have shown that liability for unipolar depression and liability for generalized anxiety disorder come from the same genetic factors, and which disorder develops is a result of what environmental experiences occur (Kendler, 1996; Watson, 2005). The genetic relationships between panic disorder and depression and between the other anxiety disorders and depression are more modest (Kendler, Walters et al., 1995; Mineka et al., 1998). The shared genetically based factor among these disorders seems to be at least in part the personality trait of neuroticism—a major risk factor for all of these disorders (Hettema, 2008; Watson et al., 2006; Zinbarg, Mineka et al., 2013).

At present the dominant theoretical approach to the overlap between depressive and anxiety symptoms is to assume that most of the measures used to assess both sets of symptoms tap

the broad mood and personality dimension of negative affect, which includes affective states such as distress, anger, fear, guilt, and worry (Clark, Watson, & Mineka, 1994; Griffith et al., 2010; Watson et al., 2006). Depressed and anxious individuals cannot be differentiated on the basis of their high level of negative affect. But these researchers have also shown that anxiety and depression can be distinguished from one another on the basis of a second dimension of mood and personality known as positive affect, which includes affective states such as excitement, delight, interest, and pride. Depressed persons tend to be characterized by low levels of positive affect, but anxious individuals usually are not (with the exception of people with social phobia; Watson et al., 2006; Naragon-Gainey et al., 2009). That is, only depressed individuals show the signs of fatigue and lack of energy and enthusiasm characteristic of low positive affect. A number of investigators have also shown that some anxious people (especially panic patients), but not depressed people, tend to be characterized by high levels of yet another mood dimension

known as anxious hyperarousal, symptoms of which include racing heart, trembling, dizziness, and shortness of breath. This tripartite model of anxiety and depression thus explains what features anxiety and depression share (high negative affect) and what features they differ on (low positive affect for depression and anxious hyperarousal for panic; Mineka et al., 1998). Each of the other anxiety disorders has its own separate and relatively unique component as well (Barlow, 2002; Mineka et al., 1998; Prenoveau et al., 2010; Watson, 2005; see also Watson et al., 2007, for another variant on this approach).

Several aspects of the comorbidity between anxiety and mood disorders at the diagnostic level raise interesting questions about what common and what distinct causal factors may exist. For example, there is usually a sequential relationship between the symptoms of anxiety and depression, both within an episode and between episodes. Bowlby (1973, 1980) describes a biphasic response to separation and loss in which agitation and anxiety are followed by despair and depression. And across a lifetime,

## developments in RESEARCH

### Why Do Sex Differences in Unipolar Depression Emerge During Adolescence?

It is interesting to consider why the sex difference in depression starts in adolescence (Essau et al., 2010; Hankin & Abramson, 2001; Hankin et al., 2008), beginning between ages 12 and 13 and reaching its most dramatic peak between ages 14 and 16, although it is actually more tied to pubertal status than to age per se (Becker et al., 2007; Conley & Rudolph, 2009; Sanborn & Hayward, 2003). This is a time of rapid physiological, environmental, and psychological changes known to create turmoil for many adolescents, but why are adolescent females more likely to become depressed? Hankin, Abramson, and colleagues (Hankin & Abramson, 2001; Hankin et al., 2008) have proposed an intriguing cognitive vulnerability-stress model of the development of gender differences during adolescence. Building on ideas from the reformulated helplessness and hopelessness models of depression for adults, they summarize research indicating that children and adolescents, like adults, are prone to experiencing increases in depressive symptoms if they have a pessimistic attributional style and experience stressful life events (e.g., Hankin & Abramson, 2001; Hankin, 2006). Moreover, during early adolescence, gender differences in attributional style, in rumination, and in stressful life events emerge such that girls tend to have a more pessimistic attributional style, to show more rumination, and to experience more negative life events (especially interpersonal events; Rudolph, 2009). Thus one can see how, with all three of these risk factors showing gender differences in adolescence, a synergistic effect might lead to the dramatic rise in depression in adolescent girls. Moreover, Hankin and Abramson (2001; see also Hankin et al., 2008) review evidence that the experience of negative life events

may contribute to greater cognitive vulnerability, which in turn further increases susceptibility to depressive symptoms. Furthermore, depressive symptoms in adolescent girls, as in adults, are likely to result in more dependent life stress being generated, which in turn may exacerbate depression (Liu & Alloy, 2010; Rudolph, 2009). Finally, girls not only experience more negative life events than boys but also encode them in greater detail and show better memory for emotional events (though not for non-emotional events).

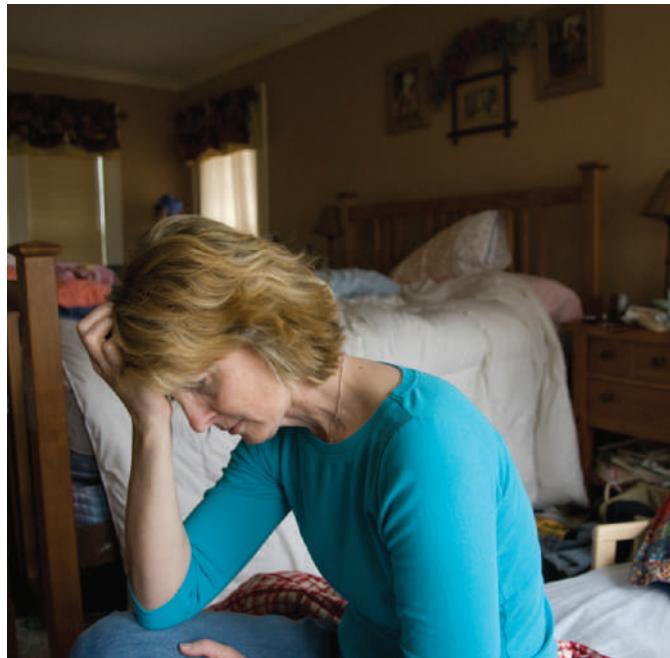

Hankin and Abramson (2001) also emphasized the role of negative cognitions about attractiveness and body image in the emergence of sex differences in depression during adolescence. There is evidence that the development of secondary sexual characteristics is harder psychologically for girls than for boys. Body dissatisfaction goes up for females at this time, and down for males; moreover, body dissatisfaction is more closely related to self-esteem for girls than for boys. Much of girls' dissatisfaction with their bodies comes from their realization of the discrepancy between our society's ideal of a thin, prepubescent body shape for females and the fact that they are gaining fat as they mature sexually. Hankin and Abramson (2001) summarized evidence that girls are more likely than boys to make pessimistic attributions and other negative inferences about negative events that may occur (such as negative remarks) related to the domain of physical attractiveness. Given that physical attractiveness may be more motivationally significant for girls than for boys, it becomes plausible that this may be one important factor that makes depression especially likely in adolescent girls.

individuals are more likely to experience an anxiety disorder first and a depressive disorder later (T. A. Brown et al., 2001; Garber & Weersing, 2010; Merikangas et al., 2003).

**INTERPERSONAL EFFECTS OF MOOD DISORDERS** Although there is no interpersonal theory of depression that is as clearly articulated as the cognitive theories, there has been a considerable amount of research on interpersonal factors in depression. Interpersonal problems and social-skills deficits may well play a causal role in at least some cases of depression. In addition, depression creates many interpersonal difficulties—with strangers and friends as well as with family members (Hammen, 1995, 2005; Joiner & Timmons, 2009; Petit & Joiner, 2006).

#### Lack of Social Support and Social-Skills Deficits

Brown and Harris (1978), in their classic study of community women in a poor area of inner London, reported that women without a close, confiding relationship were more likely than those with at least one close confidant to become depressed if they experienced a severely stressful event. Many more studies have since supported the idea that people who are lonely, socially isolated, or lacking social support are more vulnerable to becoming depressed and that individuals with depression have smaller and less supportive social networks, which tends to precede the onset of depression (e.g., Cacioppo et al., 2006; Gotlib & Hammen, 1992; Ibarra-Rovillard & Kuiper, 2011). In addition, some people with depression have social-skills deficits. For example, they seem to speak more slowly and monotonously and to maintain less eye contact; they are also less skilled than people without depression at solving interpersonal problems (e.g., Ingram et al., 1999; Joiner & Timmons, 2009).

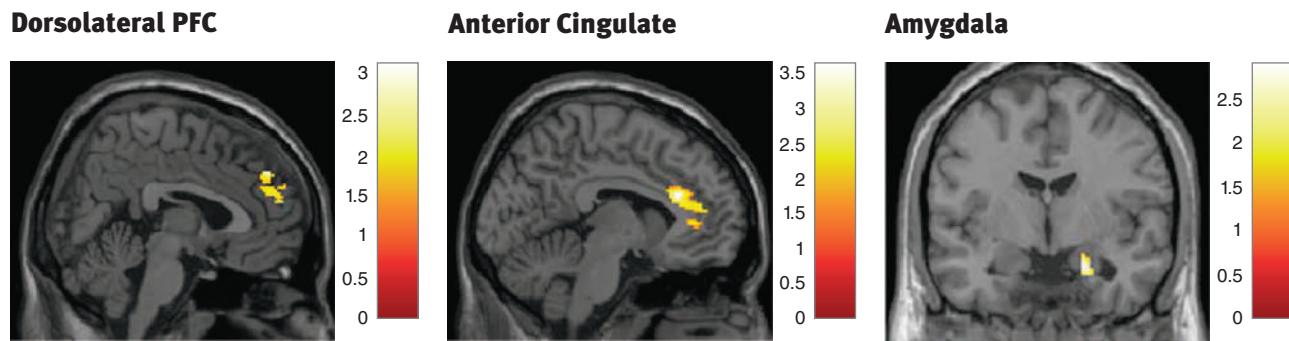

Why are people without social support networks more prone to depression when faced with major stressors?

**The Effects of Depression on Others** Not only do people with depression have interpersonal problems, but, unfortunately, their own behavior also seems to make these problems worse. For example, the behavior of an individual who is depressed often places others in the position of providing sympathy, support, and care. However, positive reinforcement does not necessarily follow. Depressive behavior can, and over time frequently does, elicit negative feelings (sometimes including hostility) and rejection in other people, including strangers, roommates, and spouses (Coyne, 1976; Ingram et al., 1999; Joiner & Timmons, 2009). Although these negative feelings may initially make the person who is not depressed feel guilty, which leads to sympathy and support in the short term, ultimately a downwardly spiraling relationship usually results, making the person with depression feel worse (e.g., Joiner, 2002; Joiner & Metalsky, 1995). Social rejection may be especially likely if the person with depression engages in excessive reassurance seeking (e.g., Joiner & Timmons, 2009; Prinstein et al., 2005).

**Marriage and Family Life** Interpersonal aspects of depression have also been carefully studied in the context of marital and family relationships. A significant proportion of couples experiencing marital distress have at least one partner with clinical depression, and there is a high correlation between marital dissatisfaction and depression for both women and men (e.g., Beach & Jones, 2002; Rehman et al., 2008; Whisman, 2007). In addition, marital distress spells a poor prognosis for a spouse with depression whose symptoms have remitted. That is, a person whose depression clears up is likely to relapse if he or she has an unsatisfying marriage, especially one characterized by high levels of critical and hostile comments from the spouse (Butzlaff & Hooley, 1998; Hooley, 2007).

Why should criticism be linked to relapse? One possibility is that criticism perturbs some of the neural circuitry that underlies depression. Moreover, *even after full recovery*, criticism may still be a powerful trigger for those who are vulnerable to depression. In a novel study, Hooley and colleagues (2009) exposed healthy (never depressed) controls and women with a past history of depression to critical remarks from their own mothers. While they were lying in a brain scanner, each participant heard her own mother making personally relevant critical remarks. Even though all the young women in the recovered-depressed group were completely well and had no symptoms of depression, their brains still responded differently from the healthy controls when challenged by criticism. As you can see in Figure 7.5 on page 237, there are differences in several brain areas that, as you have already learned, have been implicated in depression. When they heard criticism from their mothers, the recovered-depressed participants showed less brain activation in the dorsolateral prefrontal cortex and anterior cingulate cortex than the never-depressed controls did. In contrast, during criticism, brain activity in the amygdala was much higher in the recovered-depressed participants than it was in the controls. What was especially interesting was that all of this occurred

**FIGURE 7.5**

**Brain Activation in Response to Maternal Criticism.** When healthy (never depressed) participants hear criticism from their own mothers they show significantly greater activation in dorsolateral prefrontal cortex and anterior cingulate cortex than do people who have a history of depression but who are currently fully recovered. Amygdala activation during criticism is significantly greater in formerly depressed participants than it is in controls. (Hooley et al., 2009.)

without the recovered-depressed subjects being aware that they were responding differently to the criticisms. Taken together, these findings suggest that criticism might be associated with relapse in depression because it is capable of activating some of the neural circuits that are thought to be involved in the disorder. They also suggest that people who are vulnerable to depression may be especially sensitive to criticism even after they have made a full recovery.

Marital distress and depression may co-occur because the depressed partner's behavior triggers negative affect in the spouse. Individuals with depression may also be so preoccupied with themselves that they are not very sensitive or responsive to the needs of their spouses. A review by Beach and Jones (2002) adapted Hammen's (1991) stress-generation model of depression to help explain the two-way relationship between marital discord and depression (that is, marital distress can lead to depression, and depression can lead to marital distress). As noted earlier, a significant amount of the stress that individuals with depression experience is somehow at least partly generated by their own behaviors, but this stress in turn also serves to exacerbate depressive symptoms. The effects of depression in one family member extend to children of all ages as well. Parental depression puts children at high risk for many problems, but especially for depression (Goodman, 2007; Hammen, 2009; Hammen et al., 2011). Although these effects occur with both fathers and mothers with depression, the effects of maternal depression are somewhat larger (Hammen, 2009). Children of parents with depression who become depressed themselves tend to become depressed earlier and to show a more severe and persistent course than control children who become depressed who do not have a parent with depression (see Hammen, 2009).

Some of these effects probably occur because these children inherit a variety of traits such as temperament (including shyness, behavioral inhibition, and neuroticism), low levels

of positive emotions, and poor ability to regulate emotions that are all known risk factors for depression (e.g., Durbin et al., 2005; see Hammen, 2009, for a review). In addition, many studies have documented the damaging effects of negative interactional patterns between mothers with depression and their children. For example, mothers with depression show more friction and have fewer playful, mutually rewarding interactions with their children (see Goodman & Gotlib, 1999; Murray & Cooper, 1997). They are also less sensitively attuned to their infants and less affirming of their infants' experiences (Goodman & Brand, 2009). Furthermore, their young children are given multiple opportunities for observational learning of negative cognitions, depressive behavior, and depressed affect. Thus, although genetically determined vulnerability is clearly involved, psychosocial influences clearly also play an important role (Hammen, 2009; Natsuaki et al., 2010), and evidence is accumulating that inadequate parenting is what mediates the association between parental depression and their children's depression (Goodman, 2007).

### in review

- Summarize the major biological causal factors for unipolar depression, including genetic, biochemical, neuroendocrinological, and neurophysiological factors.
- What is the role of stressful life events in unipolar depression, and what kinds of diatheses have been proposed to interact with them?
- Describe the following theories of depression: Beck's cognitive theory, the helplessness and hopelessness theories, ruminative response styles theory, and interpersonal theories.

## Bipolar and Related Disorders

As discussed earlier in the chapter, *bipolar disorders* are distinguished from unipolar disorders by the presence of manic or hypomanic episodes, which are nearly always preceded or

- A. For at least 2 years (at least 1 year in children and adolescents) there have been numerous periods with hypomanic symptoms that do not meet criteria for a hypomanic episode and numerous periods with depressive symptoms that do not meet criteria for a major depressive episode.
- B. During the above 2-year period (1 year in children and adolescents), the hypomanic and depressive periods have been present for at least half the time and the individual has not been without the symptoms for more than 2 months at a time.
- C. Criteria for a major depressive, manic, or hypomanic episode have never been met.
- D. The symptoms in Criterion A are not better explained by schizoaffective disorder, schizophrenia, schizophasic disorder, delusional disorder, or other specified or unspecified schizophrenia spectrum and other psychotic disorder.
- E. The symptoms are not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or another medical condition (e.g., hyperthyroidism).
- F. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

followed by periods of depression. A person who experiences a manic episode has a markedly elevated, euphoric, and expansive mood, often interrupted by occasional outbursts of intense irritability or even violence—particularly when others refuse to go along with the manic person's wishes and schemes. These extreme moods must persist for at least a week for this diagnosis to be made. In addition, three or more additional symptoms must occur in the same time period. There must also be significant impairment of occupational and social functioning, and hospitalization is often necessary during manic episodes. Hypomanic episodes can also occur; these involve milder versions of the same symptoms and last at least 4 days. Although the symptoms listed are the same for manic and hypomanic episodes, there is much less impairment in hypomania, and hospitalization is not required.

## Cyclothymic Disorder

It has long been recognized that some people are subject to cyclical mood changes less severe than the mood swings seen in bipolar disorder. Historically these were referred to as *cyclothymic temperament* (or *personality*; Goodwin & Jamison, 2007). If such symptoms persist for at least 2 years, the person may receive a diagnosis of **cyclothymic disorder**. In *DSM-5*, cyclothymia is defined as a less serious version of full-blown bipolar disorder because it lacks certain extreme symptoms and psychotic features such as delusions and the marked impairment caused by full-blown manic or major depressive episodes.

In the depressed phase of cyclothymic disorder, a person's mood is dejected, and he or she experiences a distinct loss of interest or pleasure in customary activities and pastimes. In addition, the person may show other symptoms such as low energy, feelings of inadequacy, social withdrawal, and a pessimistic, brooding attitude. Essentially, the symptoms are similar to those in someone with dysthymia except without the duration criterion.

Symptoms of the hypomanic phase of cyclothymia are essentially the opposite of the symptoms of dysthymia. In this phase of the disorder, the person may become especially creative and productive because of increased physical and mental energy. There may be significant periods between episodes in which the person with cyclothymia functions in a relatively adaptive manner. For a diagnosis of cyclothymia (see *DSM-5* box), there must be at least a 2-year span during which there are numerous periods with hypomanic and depressed symptoms (1 year for adolescents and children), and the symptoms must cause clinically significant distress or impairment in functioning (although not as severe as in bipolar disorder). Individuals with cyclothymia are at greatly increased risk of later developing full-blown bipolar I or II disorder (e.g., Akiskal & Pinto, 2009; Goodman &

Jamison, 2007). For this reason it is often recommended that they receive clinical attention.

The following case illustrates cyclothymia.

→ **A Cyclothymic Car Salesman** A 29-year-old car salesman was referred by his current girlfriend, a psychiatric nurse, who suspected he had a mood disorder even though the patient was reluctant to admit that he might be a "moody" person. According to him, since the age of 14 he has experienced repeated alternating cycles that he terms "good times and bad times." During a "bad" period, usually lasting 4 to 7 days, he sleeps 10 to 14 hours daily [and] lacks energy, confidence, and motivation—"just vegetating," as he puts it. Often he abruptly shifts, characteristically upon waking up in the morning, to a 3- to 4-day stretch of overconfidence, heightened social awareness, promiscuity, and sharpened

thinking—"things would flash in my mind." At such times he indulges in alcohol to enhance the experience, but also to help him sleep. Occasionally the "good" periods last 7 to 10 days but culminate in irritable and hostile outbursts, which often herald the transition back to another period of "bad" days. . . .

In school, A's and B's alternated with C's and D's, with the result that the patient was considered a bright student whose performance was mediocre overall because of "unstable motivation." As a car salesman his performance has also been uneven, with "good days" canceling out the "bad days"; yet even during his "good days" he is sometimes perilously argumentative with customers and loses sales that appeared sure. Although considered a charming man in many social circles, he alienates friends when he is hostile and irritable. . . . (Spitzer et al., 2002, pp. 155–56)

.....

**TABLE 7.2**  
**Distinguishing between Bipolar I and Bipolar II Disorder**

**Bipolar I:**

- The most important aspect of bipolar I disorder is the presence of mania.
- People with bipolar I disorder experience episodes of mania and periods of depression. Even if the periods of depression do not reach the threshold for a major depressive episode, the diagnosis of bipolar I disorder is still given.

**Bipolar II:**

- People with bipolar II disorder experience periods of hypomania but their symptoms are below the threshold for full-blown mania.
- The person diagnosed with bipolar II disorder also experiences periods of depressed mood that meet the criteria for major depression.

## Bipolar Disorders (I and II)

Although recurrent cycles of mania and melancholia were recognized as early as the sixth century, it remained for Kraepelin, in 1899, to introduce the term *manic-depressive insanity* and to clarify the clinical picture. Kraepelin described the disorder as a series of attacks of elation and depression, with periods of relative normality in between. Today we call this illness bipolar disorder, although the term *manic-depressive* illness is still commonly used as well.

**Bipolar I disorder** is distinguished from major depressive disorder by the presence of mania (see Table 7.2 for a summary). A **mixed episode** is characterized by symptoms of both full-blown manic and major depressive episodes for at least 1 week, whether the symptoms are intermixed or alternate rapidly every few days. Such cases were once thought to be relatively rare but have increasingly been recognized as relatively common (e.g., Cassidy et al., 1998; Goodwin & Jamison, 2007). Indeed Goodwin & Jamison's (2007) review of 18 studies reported that an average of 28 percent of bipolar patients at least occasionally experience mixed states. Moreover, many patients in a manic episode have some symptoms of depressed mood, anxiety, guilt, and suicidal thoughts, even if these are not severe enough to qualify as a mixed episode. Recent careful longitudinal follow-up of people presenting with a full-blown mixed episode or even a subthreshold mixed episode has shown that these individuals have a worse long-term outcome than those originally presenting with a depressive or a manic episode (Baldessarini et al., 2010; Dodd et al., 2010).

Watch the Video Ann: Bipolar Disorder on MyPsychLab.

If a person shows only manic symptoms, it is nevertheless assumed that a bipolar disorder exists and that a depressive episode will eventually occur. Although some researchers have noted the probable existence of a unipolar type of manic disorder (i.e., "pure mania" e.g., Kessler et al., 1997; Solomon et al., 2003), critics of this diagnosis argue that such patients usually have bipolar relatives and may well have had mild depressions that went unrecognized (Goodwin & Jamison, 2007; Winokur & Tsuang, 1996).

The following case illustrates both phases of Bipolar I disorder:

→ **Roller Coaster** When Ernest Eaton's desperate wife finally got him to agree to a comprehensive inpatient evaluation, he was 37, unemployed, and had been essentially non-functional for several years. After a week during which he was partying all night and shopping all day, Mrs. Eaton said she would leave him if he did not check into a psychiatric hospital. The admitting psychiatrist found him to be a fast-talking, jovial, seductive man with no evidence of delusions or hallucinations.

Mr. Eaton's troubles began 7 years before when he . . . had a few months of mild, intermittent depressive symptoms, anxiety, fatigue, insomnia, and loss of appetite, [but] within a few months he was back to his usual self. A few years later . . . after removal of [an asymptomatic] mass . . . Mr. Eaton noted dramatic mood changes. Twenty-five days of remarkable energy, hyperactivity, and euphoria were followed by 5 days of depression during which he

slept a lot and felt that he could hardly move. This pattern of alternating periods of elation and depression, apparently with few "normal" days, repeated itself continuously over the following years.

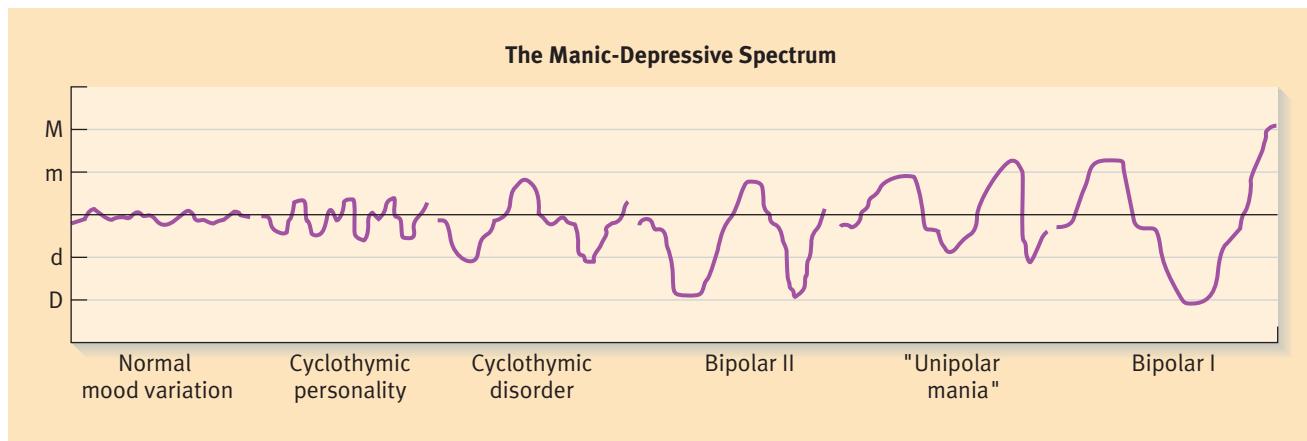

During his energetic periods, Mr. Eaton was optimistic and self-confident but short tempered and easily irritated. His judgment at work was erratic. He spent large sums of money on unnecessary and, for him, uncharacteristic purchases, such as a high-priced stereo system and several Doberman pinschers. He also had several impulsive sexual flings. During his depressed periods, he often stayed in bed all day because of fatigue, lack of motivation, and depressed mood. He felt guilty about the irresponsibilities and excesses of the previous several weeks. He stopped eating, bathing, and shaving. After several days of this withdrawal, Mr. Eaton would rise from bed one morning feeling better and, within 2 days, he would be back at work, often working feverishly, though ineffectively, to catch up on work he had let slide during his depressed periods.

*DSM-5* also identifies a distinct form of bipolar disorder called **bipolar II disorder**, in which the person does not experience full-blown manic (or mixed) episodes but has experienced clear-cut hypomanic episodes as well as major depressive episodes (Akiskal & Benazzi, 2005). Bipolar II disorder is equally or somewhat more common than bipolar I disorder, and, when combined, estimates are that about 2 to 3 percent of the

U.S. population will suffer from one or the other disorder (e.g., Kessler et al., 2007; Kupfer, 2005). Bipolar II disorder evolves into bipolar I disorder in only about 5 to 15 percent of cases, suggesting that they are distinct forms of the disorder (Coryell et al., 1995; Goodwin & Jamison, 2007). Recently, a subthreshold form of bipolar II disorder has also been recognized as careful study has revealed that as many as 40 percent of individuals diagnosed with unipolar MDD have a similar number of hypomanic symptoms, although not with a sufficient number or duration to qualify for a full-blown hypomanic episode (Zimmerman et al., 2009). Along with related findings, such results are leading researchers and clinicians to recognize that unipolar MDD is a far more heterogeneous category than previously recognized.

Bipolar disorder occurs equally in males and females (although depressive episodes are more common in women than men) and usually starts in adolescence and young adulthood, with an average age of onset of 18 to 22 years (Goodwin & Jamison, 2007; Merikangas et al., 2007). Bipolar II disorder has an average age of onset approximately 5 years later than bipolar I disorder (Baldessarini et al., 2010). Both bipolar I and II are typically recurrent disorders, with people experiencing single episodes extremely rarely (Kessler et al., 2007). In about two-thirds of cases, the manic episodes either immediately precede or immediately follow a depressive episode; in other cases, the manic and depressive episodes are separated by intervals of relatively normal functioning. Figure 7.6 illustrates the different patterns of manic, hypomanic, and depressive symptoms and episodes that can be seen in bipolar-spectrum disorders.

**FIGURE 7.6**

**The Manic-Depressive Spectrum.** There is a spectrum of bipolarity in moods. All of us have our ups and downs, which are indicated here as normal mood variation. People with a cyclothymic personality have more marked and regular mood swings, and people with cyclothymic disorder go through periods when they meet the criteria for dysthymia (except for the 2-year duration) and other periods when they meet the criteria for hypomania. People with bipolar II disorder have periods of major depression and periods of hypomania. Unipolar mania is an extremely rare condition. Finally, people with bipolar I disorder have periods of major depression and periods of mania. (Adapted from Goodwin & Jamison, 2009.)

Most patients with bipolar disorder experience periods of remission during which they are relatively symptom-free, although this may occur on only about 50 percent of days (Kupka et al., 2007). Moreover, as many as 20 to 30 percent continue to experience significant impairment (occupational and/or interpersonal) and mood lability most of the time, and as many as 60 percent have chronic occupational or interpersonal problems between episodes. As with unipolar major depression, the recurrences can be seasonal in nature, in which case **bipolar disorder with a seasonal pattern** is diagnosed.

**FEATURES OF BIPOLAR DISORDER** The duration of manic and hypomanic episodes tends to be shorter than the duration of depressive episodes, with typically about three times as many days spent depressed as manic or hypomanic (Goodwin & Jamison, 2007). There has been controversy over whether the symptoms of the depressive episodes of bipolar disorder are clinically distinguishable from those seen in unipolar major depressive episodes (Cuellar et al., 2005; Perris, 1992). Although there is a high degree of overlap in symptoms, there are some significant differences. The most widely replicated differences are that, relative to people with a unipolar depressive episode, people with a bipolar depressive episode tend, on average, to show more mood lability, more psychotic features, more psychomotor retardation, and more substance abuse (Goodwin & Jamison, 2007). By contrast, individuals with unipolar depression, on average, show more anxiety, agitation, insomnia, physical complaints, and weight loss (see also Johnson et al., 2009). In spite of the high degree of similarity in symptoms, research clearly indicates that major depressive episodes in people with bipolar disorder are, on average, more severe than those seen in unipolar disorder, and, not surprisingly, they also cause more role impairment (Kessler et al., 2007).  [Watch the Video Feliziano: Living with Bipolar Disorder on MyPsychLab.](#)

A person who is depressed cannot be diagnosed with bipolar I disorder unless he or she has exhibited at least one manic or mixed episode in the past. Many people with bipolar disorder whose initial episode or episodes are depressive (about 50 percent) are misdiagnosed at first and possibly throughout their lives (for instance, if no manic episodes are observed or reported, or if they die before a manic episode is experienced). Averaging across many studies, one important review estimates that somewhere between 10 and 50 percent of people who have an initial major depressive episode will later have a manic or hypomanic episode and will be diagnosed at that time as having bipolar I or II disorder (Goodwin & Jamison, 2007). Moreover, the younger the person is at the time of the first diagnosis, and the greater the number of recurrent episodes, the more likely he or she is to be diagnosed with bipolar I or II disorder. One study shows that people presenting initially with a major depressive disorder who have a history of creative achievements, professional instability, multiple marriages, and flamboyant behavior may be especially likely to be diagnosed later with bipolar II disorder (Akiskal, 2005).

Misdiagnoses are unfortunate because there are somewhat different treatments of choice for unipolar and bipolar depression. Moreover, there is evidence that some antidepressant drugs used to treat what is thought to be unipolar depression may actually precipitate manic episodes in patients who actually have as-yet-undetected bipolar disorder, thus worsening the course of the illness (Ghaemi et al., 2003; Whybrow, 1997).

On average, people with bipolar disorder suffer from more episodes during their lifetimes than do persons with unipolar disorder (although these episodes tend to be somewhat shorter, averaging 3 to 4 months; Angst & Sellaro, 2000; Solomon et al., 2010). As many as 5 to 10 percent of persons with bipolar disorder experience at least four episodes (either manic or depressive) every year, a pattern known as **rapid cycling**. In fact, those who go through periods of rapid cycling usually experience many more than four episodes a year. Our case example of Ernest Eaton ("Roller Coaster") was diagnosed with bipolar I disorder with rapid cycling. People who develop rapid cycling are slightly more likely to be women, to have a history of more episodes (especially more manic or hypomanic episodes), to have an earlier average age of onset, and to make more suicide attempts (Coryell et al., 2003; Kupka et al., 2005; Nierenberg et al., 2010). Rapid cycling is sometimes precipitated by taking certain kinds of antidepressants (Goodman & Jamison, 2007; Kilzieh & Akiskal, 1999). Fortunately, for about 50 percent of cases, rapid cycling is a temporary phenomenon and gradually disappears within about 2 years (Coryell et al., 1995; Coryell et al., 2003).

Overall, the probabilities of "full recovery" from bipolar disorder are discouraging even with the widespread use of mood-stabilizing medications such as lithium, with one review estimating that patients with bipolar disorder spend about 20 percent of their

Many highly creative people are believed to have had bipolar disorder, going through periods of intense creative productivity during manic phases, and often going through unproductive periods when clinically depressed. One such individual was the British novelist Virginia Woolf (1882–1941). Woolf committed suicide by drowning herself.

lives in episodes (Angst & Sellaro, 2000). One 20-year prospective study in which over 200 patients were followed for an average of 17 years found that 24 percent had relapsed within 6 months of recovery; 77 percent had had at least one new episode within 4 years of recovery; and 82 percent had relapsed within 7 years (Coryell et al., 1995). Another prospective study of 146 bipolar patients found that they experienced some symptoms (mostly sub-syndromal) on an average of 47 percent of the weeks during the 13-year follow-up period. During the follow-up period, depressive symptoms were three times more common than manic or hypomanic symptoms (Judd et al., 2002; see also Judd, Schettler et al., 2003). The long-term course of bipolar disorder is even more severe for patients who have comorbid substance-abuse or dependence disorders (which is even more common than with unipolar disorders; e.g., Levin & Hennessey, 2004; Swann, 2010).

#### in review

- Describe the symptoms and clinical features of cyclothymia and bipolar disorder.
- Describe the typical course of bipolar I and bipolar II disorders.

## Causal Factors in Bipolar Disorders

As for unipolar disorders, a host of causal factors for bipolar disorder have been posited over the past century. However, biological causal factors are clearly dominant, and the role of psychological causal factors has received significantly less attention. The majority of research has focused on bipolar I disorder, which is what we focus on here.

### Biological Causal Factors

A number of biological factors are thought to play a causal role in the onset of bipolar disorder. These factors include genetic, neurochemical, hormonal, neurophysiological, neuroanatomical, and biological rhythm influences.

**GENETIC INFLUENCES** There is a greater genetic contribution to bipolar I disorder than to unipolar disorder. A summary of studies using refined diagnostic procedures suggests that about 8 to 10 percent of the first-degree relatives of a person with bipolar I illness can be expected to have bipolar disorder, relative to 1 percent in the general population (Katz & McGuffin, 1993; Plomin et al., 2008; Willcutt & McQueen, 2010). The first-degree relatives of a person with bipolar disorder are also at elevated risk for unipolar major depression (especially atypical depression), although the reverse is not true (Akiskal & Benazzi, 2005; Goodwin & Jamison, 2007).

Although family studies cannot by themselves establish a genetic basis for the disorder, results from twin studies dating back to the 1950s also point to a genetic basis because the concordance rates for these disorders are much higher for identical than for fraternal twins. For example, one review found that the average concordance rate was about 60 percent for monozygotic twins

and about 12 percent for dizygotic twins (Kelsoe, 1997). The best study to date (McGuffin et al., 2003) found that 67 percent of monozygotic twins with bipolar disorder had a co-twin who shared the diagnosis of bipolar or unipolar disorder (60 percent of these concordant co-twins had bipolar disorder, and 40 percent had unipolar disorder). The concordance rate in dizygotic twins was 19 percent. This and other studies suggest that genes account for about 80 to 90 percent of the variance in the liability to develop bipolar I disorder (Goodwin & Jamison, 2007; McGuffin et al., 2003). This is higher than heritability estimates for unipolar disorder or any of the other major adult psychiatric disorders, including schizophrenia (Torrey et al., 1994). Moreover, genetic influences are even stronger in early- as opposed to late-onset bipolar disorder (Goodwin & Jamison, 2007).

The finding of elevated rates of both bipolar and unipolar forms of the disorder in the relatives of people with bipolar disorder may be explained in several ways. One possibility is that bipolar disorder may be a more severe form of the same underlying disorder as unipolar disorder. If this were the case, then the increased rate of unipolar disorder in relatives of patients with bipolar disorder would occur because bipolar is the more severe disorder—and not all relatives have as severe a form of the disorder as the identified patient (Goodwin & Jamison, 2007; Plomin et al., 2008). At least one strong study, however, found no support for this hypothesis (McGuffin et al., 2003). Instead, the results suggest that about 70 percent of the genetic liability for mania is distinct from the genetic liability for depression. In other words, these results suggest that people with bipolar disorder are genetically susceptible to both depression and to mania, and that these susceptibilities are largely independent. These very important findings need to be replicated before strong conclusions can be made.

Efforts to locate the chromosomal site(s) of the implicated gene or genes in this genetic transmission of bipolar disorder suggest that it is polygenic (Willcutt & McQueen, 2010). Although a great deal of research has been directed at identifying candidate genes through linkage analysis and association studies, no consistent support yet exists for any specific mode of genetic transmission of bipolar disorder, according to several comprehensive reviews (Potash & DePaulo, 2000; Tsuang et al., 2004).

**NEUROCHEMICAL FACTORS** The early monoamine hypothesis for unipolar disorder was extended to bipolar disorder, the hypothesis being that if depression is caused by deficiencies of norepinephrine or serotonin, then perhaps mania is caused by excesses of these neurotransmitters. There is good evidence for increased norepinephrine activity during manic episodes and less consistent evidence for lowered norepinephrine activity during depressive episodes (Goodwin & Jamison, 2007; Manji & Lenox, 2000). However, serotonin activity appears to be low in both depressive and manic phases.

As noted earlier, norepinephrine, serotonin, and dopamine are all involved in regulating our mood states (Howland & Thase, 1999; Southwick et al., 2005). Evidence for the role of

dopamine stems in part from research showing that increased dopaminergic activity in several brain areas may be related to manic symptoms of hyperactivity, grandiosity, and euphoria (Cousins et al., 2009; Goodwin & Jamison, 2007). High doses of drugs such as cocaine and amphetamines, which are known to stimulate dopamine, also produce manic-like behavior (Cousins et al., 2009). Drugs like lithium reduce dopaminergic activity and are antimanic. In depression there appear to be decreases in both norepinephrine and dopamine functioning (Goodwin & Jamison, 2007; Manji & Lenox, 2000). Thus disturbances in the balance of these neurotransmitters seem to be one of the keys to understanding this debilitating illness.

### **ABNORMALITIES OF HORMONAL REGULATORY SYSTEMS**

Some neurohormonal research on bipolar disorder has focused on the HPA axis. Cortisol levels are elevated in bipolar depression (as they are in unipolar depression), but they are usually not elevated during manic episodes (Goodwin & Jamison, 2007). Similarly, bipolar depressed patients show evidence of abnormalities on the dexamethasone suppression test (DST) described earlier at about the same rate as do unipolar depressed patients, and these abnormalities persist even when the patients have been fully remitted and asymptomatic for at least 4 weeks (e.g., Langan & McDonald, 2009; Watson, Gallagher et al., 2004). During a manic episode, however, their rate of DST abnormalities has generally (but not always) been found to be much lower (Goodwin & Jamison, 2007; Manji & Lenox, 2000, although see Langan & McDonald, 2009). Research has also focused on abnormalities of the hypothalamic-pituitary-thyroid axis because abnormalities of thyroid function are frequently accompanied by changes in mood. Many bipolar patients have subtle but significant abnormalities in the functioning of this axis, and administration of thyroid hormone often makes antidepressant drugs work better (Altshuler et al., 2001; Goodwin & Jamison, 2007). However, thyroid hormone can also precipitate manic episodes in patients with bipolar disorder (Goodwin & Jamison, 2007).

### **NEUROPHYSIOLOGIC AND NEUROANATOMIC INFLUENCES**

With positron emission tomography (PET) scans, it is possible to visualize variations in brain glucose metabolic rates in depressed and manic states, although there is far less evidence regarding manic states because of the great difficulties studying patients who are actively manic. Several summaries of the evidence from studies using PET and other neuroimaging techniques show that, whereas blood flow to the left prefrontal cortex is reduced during depression, during mania it is increased in certain other parts of the prefrontal cortex (Goodwin & Jamison, 2007; see also Bermpohl et al., 2010). Thus there are shifting patterns of brain activity during mania and during depressed and normal moods.

Other neurophysiological findings from patients with bipolar disorder have shown both similarities to and differences

from patients with unipolar disorder and normal controls. For example, several recent reviews suggest that there are deficits in activity in the prefrontal cortex in bipolar disorder. These seem related to neuropsychological deficits that people with bipolar disorder show in problem solving, planning, working memory, shifting of attention, and sustained attention on cognitive tasks (e.g., Chen et al., 2011; Haldane & Frangou, 2004; Malhi, Ivanovski, et al., 2004). This is similar to what is seen in unipolar depression, as are deficits in the anterior cingulate cortex (Langan & McDonald, 2009). However, structural imaging studies suggest that certain subcortical structures, including the basal ganglia and amygdala, are enlarged in bipolar disorder but reduced in size in unipolar depression. The decreases in hippocampal volume that are often observed in unipolar depression are generally not found in bipolar depression (Konarski et al., 2008). Some studies using fMRI also find increased activation in bipolar patients in subcortical brain regions involved in emotional processing, such as the thalamus and amygdala, relative to unipolar patients and normals (Chen et al., 2011; Malhi, Lagopoulos et al., 2004; Nusslock et al., 2012). Overall, it is hard to draw firm conclusions in this area yet because there are so many inconsistencies in results across studies. However, there is initial meta-analytic support for dysregulation in frontal-limbic activation in individuals with bipolar disorder compared to controls (Chen et al., 2011). Hopefully more definitive findings will follow when much-needed technological innovations unfold (Goodwin & Jamison, 2007).

### **SLEEP AND OTHER BIOLOGICAL RHYTHMS**

There is considerable evidence regarding disturbances in biological rhythms such as circadian rhythms in bipolar disorder, even after symptoms have mostly remitted (e.g., Goodwin & Jamison, 2007; Harvey, 2008; Jones et al., 2005; Murray & Harvey, 2010). During manic episodes, patients with bipolar disorder tend to sleep very little (seemingly by choice, not because of insomnia), and this is the most common symptom to occur prior to the onset of a manic episode. During depressive episodes, they tend toward hypersomnia (too much sleep). Even between episodes people with bipolar disorder show substantial sleep difficulties, including high rates of insomnia (e.g., Harvey, 2008; Harvey et al., 2005; Millar et al., 2004). Bipolar disorder also sometimes shows a seasonal pattern in the same way unipolar disorder does, suggesting disturbances of seasonal biological rhythms, although these may be the result of circadian abnormalities in which the onset of the sleep-wake cycle is set ahead of the onset of other circadian rhythms. Given the cyclic nature of bipolar disorder itself, this focus on disturbances in biological rhythms holds promise for future integrative theories of the biological underpinnings of bipolar disorder. This is particularly true because patients with bipolar disorder seem especially sensitive to, and easily disturbed by, any changes in their daily cycles that require a resetting of their biological clocks (Goodwin & Jamison, 2007; Jones et al., 2005; Murray & Harvey, 2010).

## Psychological Causal Factors

Although biological factors play a prominent role in the onset of bipolar disorder, psychosocial factors have also been found to be involved in the etiology of the disorder. In particular, stressful life events, poor social support, and certain personality traits and cognitive styles have been identified as important psychological causal factors.

**STRESSFUL LIFE EVENTS** Stressful life events appear to be as important in precipitating bipolar depressive episodes as they are in triggering unipolar depressive episodes. There is also some evidence that stressful life events are sometimes involved in precipitating manic episodes as well (Goodwin & Jamison, 2007). The stressful life events are thought to influence the timing of an episode, perhaps by activating the underlying vulnerability. One study also found that patients who experienced severe negative events took an average of three times longer to recover from manic, depressive, or mixed episodes than those without a severe negative event (395 versus 112 days; Johnson & Miller, 1997). Even minor negative events were found to increase time to recovery.

It has long been argued that as the illness unfolds, the manic and depressive episodes become more autonomous and do not usually seem to be precipitated by stressful events (e.g., Bender & Alloy, 2011; Post, 1992). Some of these conclusions may be premature, however, given that most studies addressing this issue have relied on patients' memories of events before episodes, which may be unreliable (Johnson & Roberts, 1995). In several good prospective studies using more sophisticated stress measurement techniques, Ellicott and colleagues (1990; see also Hammen, 1995) did not find that stress played a less important role in precipitating episodes for people who had had more episodes (see also Alloy et al., 2010; Bender & Alloy, 2011; Hlastala et al., 2000).

How might stressful life events operate to increase the chance of relapse? One hypothesized mechanism is through the destabilizing effects that stressful life events may have on critical biological rhythms. Although evidence in support of this idea is still preliminary, it appears to be a promising hypothesis, especially for manic episodes (e.g., Bender & Alloy, 2011; Malkoff-Schwartz et al., 1998; see Grandin et al., 2006, for a review).

## OTHER PSYCHOLOGICAL FACTORS IN BIPOLAR DISORDER

Other social environmental variables may also affect the course of bipolar disorder. For example, one study found that people with bipolar disorder who reported low social support showed more depressive recurrences over a 1-year follow-up, independent of the effects of stressful life events, which also predicted more recurrences (Cohen et al., 2004; see also Alloy et al., 2010). There is also some evidence that personality and cognitive variables may interact with stressful life events in determining the likelihood of relapse. For example, the personality variable neuroticism has been associated with symptoms of depression

and mania (e.g., Quilty et al., 2009), and two studies have found that neuroticism predicts increases in depressive symptoms in people with bipolar disorder just as it does in unipolar disorder. Moreover, personality variables and cognitive styles that are related to goal-striving, drive, and incentive motivation have been associated with bipolar disorder (e.g., Alloy et al., 2009). For example, two personality variables associated with high levels of achievement striving and increased sensitivity to rewards in the environment predicted increases in manic symptoms—especially during periods of active goal striving or goal attainment (such as studying for an important exam and then doing very well in it; Lozano & Johnson, 2001; Meyer et al., 2001; see also Alloy et al., 2010). Another study found that students with a pessimistic attributional style who also had negative life events showed an increase in depressive symptoms whether they had bipolar or unipolar disorder. Interestingly, however, the bipolar students who had a pessimistic attributional style and experienced negative life events also showed increases in manic symptoms at other points in time (Alloy et al., 2010; Reilly-Harrington et al., 1999).

### in review

- Summarize the major biological causal factors for bipolar disorder, including genetic, biochemical, and other biological factors.
- What role do psychological factors, including stressful life events, seem to play in bipolar disorder?

## Sociocultural Factors Affecting Unipolar and Bipolar Disorders

Research on the association of sociocultural factors with both unipolar and bipolar mood disorders is discussed together because much of the research conducted in this area has not made clear-cut diagnostic distinctions between the two types of disorders. Although the prevalence of mood disorders seems to vary considerably among different societies, it has been difficult to provide conclusive evidence for this because of various methodological problems, including widely differing diagnostic practices in different cultures, and because the symptoms of depression appear to vary considerably across cultures (Chentsova-Dutton & Tsai, 2009; Kaelber et al., 1995; Kleinman, 2004).

### Cross-Cultural Differences in Depressive Symptoms

Depression occurs in all cultures that have been studied. However, the form that it takes differs widely, as does its prevalence (e.g., Chentsova-Dutton & Tsai, 2009; Marsella, 1980). For example, in some non-Western cultures such as China and Japan where rates of depression are relatively low, many of the psychological symptoms of depression are often not present. Instead people tend to exhibit so-called somatic and vegetative manifestations such as sleep disturbance, loss of appetite,

In some cultures the concept of depression as we know it simply does not exist. For example, Australian aborigines who are "depressed" show none of the guilt and self-abnegation commonly seen in more developed countries. They also do not show suicidal tendencies but instead are more likely to vent their hostilities onto others rather than onto themselves.

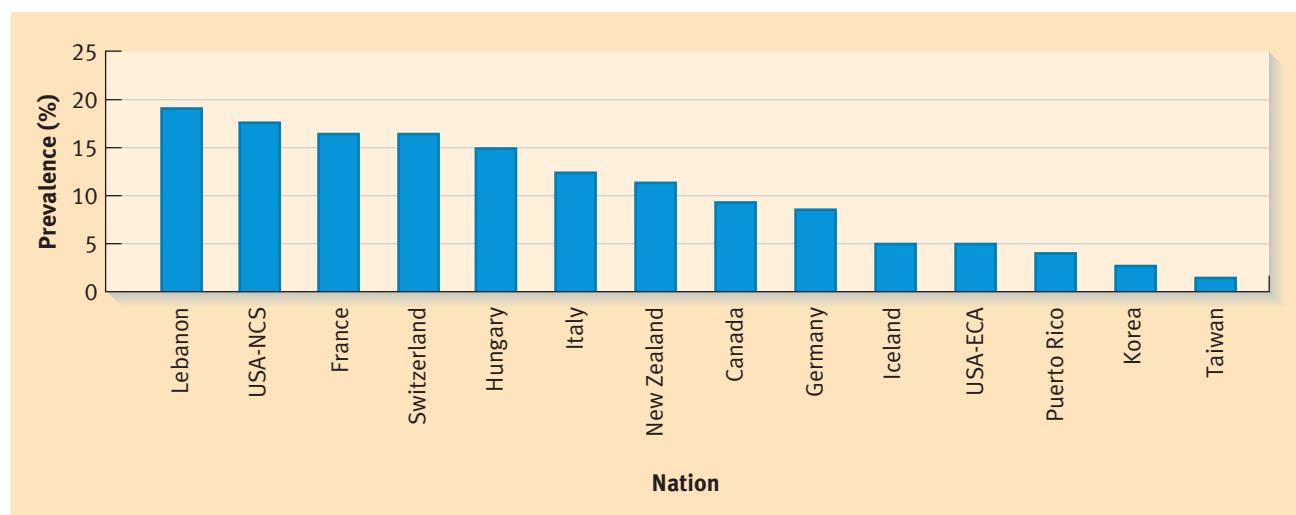

weight loss, and loss of sexual interest (Kleinman, 2004; Ryder et al., 2008; Tsai & Chentsova-Dutton, 2002). The psychological components of depression that often seem to be missing (from a Western standpoint) are the feelings of guilt, suicidal ideation, worthlessness, and self-recrimination, which are so commonly seen in the "developed" countries (Kidson & Jones, 1968; Tsai & Chentsova-Dutton, 2002). Even when these "psychological" symptoms are present, in many cases the affected individuals may think that physical symptoms have more legitimacy and that it is more appropriate to reveal and discuss physical rather than psychological symptoms (Chentsova-Dutton & Tsai, 2009).

Several possible reasons for these symptom differences stem from Asian beliefs in the unity of the mind and body, a lack of expressiveness about emotions more generally, and the stigma attached to mental illness in these cultures

(e.g., Chentsova-Dutton & Tsai, 2009). Another reason why guilt and negative thoughts about the self may be common in Western but not in Asian cultures is that Western cultures view the individual as independent and autonomous, so when failures occur, internal attributions are made. By contrast, in many Asian cultures individuals are viewed as inherently interdependent with others. Nevertheless, as countries like China have incorporated some Western values over the course of becoming increasingly industrialized and urbanized, rates of depression have risen a good deal relative to several decades ago (e.g., Dennis, 2004; Hong et al., 2010; Zhou et al., 2000). Indeed, one study of adolescents from Hong Kong and the United States found levels of depressive symptoms and hopelessness to be higher in the adolescents from Hong Kong (Stewart, Kennard et al., 2004).

### Cross-Cultural Differences in Prevalence

There is some similarity in the lifetime prevalence rates for bipolar spectrum disorders across many different countries ranging from India and Japan to the United States, Lebanon, and New Zealand (0.1 to 4.4 percent; Merikangas et al., 2011). Furthermore, there is remarkable similarity in the patterns of comorbidity across countries, with anxiety disorders being the most common conditions that are comorbid with bipolar disorder as shown in Figure 7.7 (Merikangas et al., 2011). Prevalence rates for depression (whether expressed primarily through somatic or psychological symptoms) vary a great deal across countries, as revealed by many epidemiological studies. For example, in Taiwan the lifetime prevalence has been estimated at 1.5 percent, whereas in the United States and Lebanon it has been estimated at 17 to 19 percent (Tsai & Chentsova-Dutton, 2002). Recurrent suicide

attempts are also higher in Western cultures than in Eastern cultures (Chentsova-Dutton & Tsai, 2009). The reasons for such wide variation are undoubtedly very complex, and much work remains to be done before we fully understand them. The ideas that are being explored include different levels of important psychosocial risk variables in different cultures and different levels of stress. For example, there appear to be cross-cultural differences in hypothesized risk variables such as pessimistic attributional style, although how these differences might translate into different rates of depression is unclear because we do not yet know whether the same risk variables are operative in different cultures. However, research is beginning to explore whether psychosocial risk factors for mood disorders operate across cultures, and there is some initial evidence that factors like rumination, hopelessness, and pessimistic attributional style (Abela et al., 2011) are associated with risk for depression in other countries, such as China (Hong et al., 2010).

## Demographic Differences in the United States

In our own society, the role of sociocultural factors in mood disorders is also evident. The three large epidemiological studies conducted in the United States since the early 1980s did not find any large racial or ethnic differences. However, the most recent National Comorbidity Survey-Replication (Kessler, Chiu et al., 2005) found that the prevalence rates among African Americans were slightly lower than among European white Americans and Hispanics, which were comparable. Consistent with this result, the National Survey of American Life found that the lifetime prevalence of major depression was higher in European white Americans than in African Americans (Williams et al., 2007). However, 12-month prevalence estimates were similar across these two groups, and there was evidence that African Americans might exhibit a more chronic course of depression than European white Americans. Furthermore, Native Americans, by contrast, have significantly elevated rates compared to white Americans (e.g., Hasin et al., 2005). There are no significant differences among such groups for bipolar disorder.

Other epidemiological research indicates that rates of unipolar depression are inversely related to socioeconomic status; that is, higher rates occur in lower socioeconomic groups (e.g., Kessler, Chiu et al., 2005; Monroe et al., 2009). This may well be because low SES leads to adversity and life stress (Dohrenwend, 2000; Monroe & Hadjiyannakis, 2002). However, in spite of earlier indications that rates of bipolar disorder are *elevated* among those in higher socioeconomic groups, current evidence from carefully controlled studies has not found bipolar disorder to be related to socioeconomic class (Goodwin & Jamison, 2007).

Another group that has elevated rates of mood disorders consists of individuals who have high levels of accomplishments in the arts (see Figure 7.8). Indeed, a good deal of evidence has shown that both unipolar and bipolar disorder, but especially bipolar disorder, occur with alarming frequency in

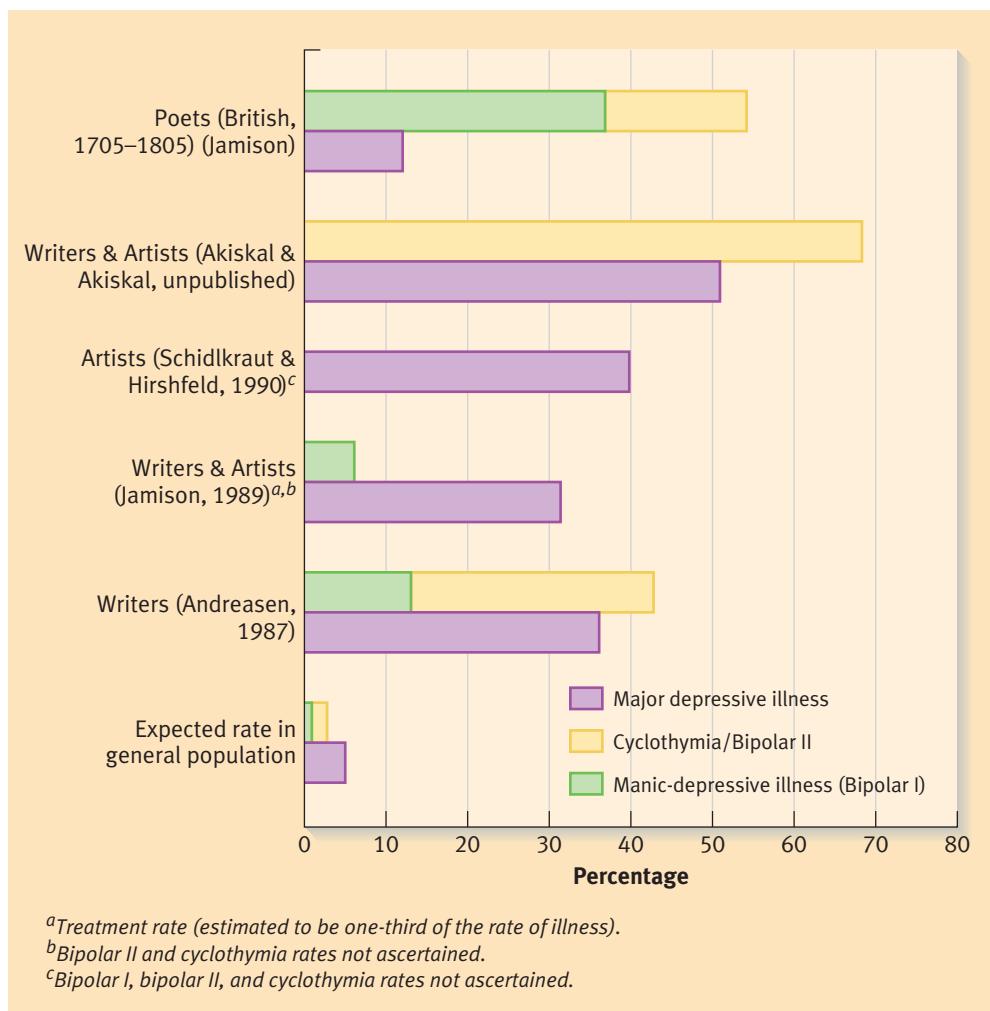

poets, writers, composers, and artists (Jamison, 1993; Murray & Johnson, 2010). Jamison has also documented for a number of such famous creative individuals how their periods of productivity covary with the manic, or hypomanic, and depressive phases of their illnesses. One possible hypothesis to explain this relationship is that mania or hypomania actually facilitates the creative process, and/or that the intense negative emotional experiences of depression provide material for creative activity. A study of the eminent nineteenth-century American poet Emily Dickinson provides support for the latter part of this hypothesis—that is, evidence supports the idea that Dickinson's painful experiences with panic disorder and depression provided ideas for her especially high-quality work during those times. However, a detailed analysis of her hypomanic periods suggests that her hypomanic symptoms increased her motivation and output but not her creativity *per se* (Ramey & Weisberg, 2004).

## in review

- What kinds of cross-cultural differences are there in depressive symptoms, and what kinds of cross-cultural factors influence the prevalence of unipolar depression?
- What are some of the basic demographic differences in the United States influencing rates of unipolar and bipolar disorders?

## Treatments and Outcomes

Many patients who suffer from mood disorders (especially unipolar disorders) never seek treatment. Even without formal treatment, the great majority of individuals with mania and depression will recover (often only temporarily) within less than a year. However, given the enormous amount of personal suffering and lost productivity that these individuals endure, and given the wide variety of treatments that are available today, more and more people who experience these disorders are seeking treatment. There was a rapid increase in the treatment of depression from 1987 to 1997, and there has been a more modest increase since 1998 (Marcus & Olfson, 2010). Interestingly, between 1998 and 2007, there was a decline in the reported use of psychotherapy, although the use of antidepressant medication remained relatively stable. These changes are happening in an era in which there is greatly increased public awareness of the availability of effective treatments and during a time in which significantly less stigma is associated with experiencing a mood disorder. Nevertheless, results from the National Comorbidity Survey-Replication showed that only about 40 percent of people with mood disorders receive minimally adequate treatment, with the other 60 percent receiving no treatment or inadequate care (Wang, Lane et al., 2005). Fortunately, the probability of receiving treatment is somewhat higher for people with severe unipolar depression and with bipolar disorder than for those with less severe depression (Kessler et al., 2007).

## Pharmacotherapy

Antidepressant, mood-stabilizing, and antipsychotic drugs are all used in the treatment of unipolar and bipolar disorders (see Chapter 16 for further information about these medications). The first category of antidepressant medications was developed in the 1950s; these medications are known as **monoamine oxidase inhibitors (MAOIs)** because they inhibit the action of monoamine oxidase—the enzyme responsible for the breakdown of norepinephrine and serotonin once released. The MAOIs can be as effective in treating depression as other categories of medications discussed next, but they can have potentially dangerous, even sometimes fatal, side effects if certain foods rich in the amino acid tyramine (e.g., red wine, beer, aged cheese, salami) are consumed. Thus they are not used very often today unless other classes of medication have failed. Depression with atypical features is the one subtype of depression that seems to respond preferentially to the MAOIs.

For most moderately to seriously depressed patients, including those with dysthymia (Klein, 2008; Kocsis et al., 1997), the drug treatment of choice since the early 1960s until about 1990 was one of the standard antidepressants (called **tricyclic**

**antidepressants** because of their chemical structure) such as imipramine. These are known to increase neurotransmission of the monoamines (primarily norepinephrine and to a lesser extent serotonin; Hollon, Thase, & Markowitz, 2002; Thase & Denko, 2008). The efficacy of the tricyclics in significantly reducing depressive symptoms has been demonstrated in hundreds of studies where the response of depressed patients given these drugs has been compared with the response of patients given a placebo. However, only about 50 percent show what is considered clinically significant improvement, and many of these patients still have significant residual depressive symptoms. Fortunately, about 50 percent of those who do not respond to an initial trial of medication will show a clinically significant response when switched to a different antidepressant or to a combination of medications (Hollon, et al., 2002).

Unfortunately, the tricyclics have unpleasant side effects for some people (dry mouth, constipation, sexual dysfunction, and weight gain may occur), and many patients do not continue long enough with the drug for it to have its antidepressant effects even though side effects frequently do diminish to some degree with time. In addition, because these drugs are highly toxic when

taken in large doses, there is some risk in prescribing them for suicidal patients, who might use them for an overdose.

Primarily because of the side effects and toxicity of tricyclics, physicians have increasingly chosen to prescribe one of the antidepressants from the **selective serotonin reuptake inhibitor (SSRI)** category (Olfson & Marcus, 2009). These SSRI medications are generally no more effective than the tricyclics; indeed some findings suggest that the tricyclics are more effective than SSRIs for severe depression. However, the SSRIs tend to have many fewer side effects and are better tolerated by patients, as well as being less toxic in large doses. The primary negative side effects of the SSRIs are problems with orgasm and lowered interest in sexual activity, although insomnia, increased physical agitation, and gastrointestinal distress also occur in some patients (Thase, 2008).

SSRIs are used not only to treat significant depression but also to treat people with mild depressive symptoms (Gitlin, 2002). Many mental health professionals believe that prescriptions for SSRIs are being written for these milder cases at an excessive rate. Prescribing drugs to essentially healthy people merely because the drugs make them feel more energetic, outgoing, and productive raises many ethical questions. Furthermore, it is even more troubling that some recent quantitative research suggests that antidepressant medication is superior to placebo only for patients with very severe depressive symptoms, with negligible treatment effects observed for those with less severe symptoms (Fournier et al., 2010).

In the past decade, several new atypical antidepressants (neither tricyclics nor SSRIs) have also become increasingly popular, and each has its own advantages (Marcus & Olfson, 2010). For example, bupropion (Wellbutrin) does not have as many side effects (especially sexual side effects) as the SSRIs and, because of its activating effects, is particularly good for depressions with significant weight gain, loss of energy, and oversleeping. In addition, venlafaxine (Effexor) seems superior to the SSRIs in the treatment of severe or chronic depression, although the profile of side effects is similar to that for the SSRIs. Several other atypical antidepressants have also been shown to be effective (see Chapter 16).

### THE COURSE OF TREATMENT WITH ANTIDEPRESSANT DRUGS

Antidepressant drugs usually require at least 3 to 5 weeks to take effect. Generally, if there are no signs of improvement after about 6 weeks, physicians should try a new medication because about 50 percent of those who do not respond to the first drug prescribed do respond to a second one. Also, discontinuing the drugs when symptoms have remitted may result in relapse. Recall that the natural course of an untreated depressive episode is typically 6 to 9 months. Thus, when depressed patients take drugs for 3 to 4 months and then stop because they are feeling better, they are likely to relapse because the underlying depressive episode is actually still present, and only its symptomatic expression has been suppressed (Gitlin, 2002; Hollon et al., 2002; Hollon et al., 2006). Because depression is often a

recurrent disorder, physicians have increasingly recommended that patients continue for very long periods of time on the drugs (ideally at the same dose) in order to prevent recurrence (Nutt, 2010). Thus, these medications can often be effective in prevention, as well as treatment, for patients subject to recurrent episodes (Gitlin, 2009; Hollon et al., 2006; Thase & Denko, 2008). Nevertheless, one study found that 25 percent of patients continuing to receive medication during the maintenance phase of treatment showed recurrence of major depression even while on the drugs (e.g., Solomon et al., 2005). Other studies have indicated that patients showing even a few residual symptoms are most likely to relapse, indicating the importance of trying to treat the patient to full remission of symptoms (e.g., Keller, 2004; Thase & Denko, 2008).

### LITHIUM AND OTHER MOOD-STABILIZING DRUGS

Lithium therapy has now become widely used as a mood stabilizer in the treatment of both depressive and manic episodes of bipolar disorder. The term *mood stabilizer* is often used to describe lithium and related drugs because they have both antimanic and antidepressant effects—that is, they exert mood-stabilizing effects in either direction. **Lithium** has been more widely studied as a treatment of manic episodes than of depressive episodes, and estimates are that about three-quarters of manic patients show at least partial improvement. In the treatment of bipolar depression, lithium may be no more effective than traditional antidepressants (study results are inconsistent), but about three-quarters show at least partial improvement (Keck & McElroy, 2007). However, treatment with antidepressants is associated with significant risk of precipitating manic episodes or rapid cycling, although the risk of this happening is reduced if the person also takes lithium (e.g., Keck & McElroy, 2007; Thase & Denko, 2008).

Lithium is also often effective in preventing cycling between manic and depressive episodes (although not necessarily for patients with rapid cycling), and bipolar patients are frequently maintained on lithium therapy over long time periods, even when not manic or depressed, simply to prevent new episodes. Although early studies indicated that lithium was quite effective in preventing repeated bipolar attacks, more recently several large studies have found that only slightly more than one-third of patients maintained on lithium remained free of an episode over a 5-year follow-up period. Nevertheless, maintenance on lithium does clearly lead to having fewer episodes than are experienced by patients who discontinue their medication. In a quantitative study of patients discontinuing medication, the risk of having a new episode was 28 times higher per month when not on medication than when on medication (Keck & McElroy, 2007).

Lithium therapy can have some unpleasant side effects such as lethargy, cognitive slowing, weight gain, decreased motor coordination, and gastrointestinal difficulties. Long-term use of lithium is occasionally associated with kidney malfunction and sometimes permanent kidney damage, although end stage renal

disease seems to be a very rare consequence of long-term lithium treatment (Goodwin & Jamison, 2007; Tredget et al., 2010). Not surprisingly, these side effects, combined with the fact that many bipolar patients seem to miss the highs and the abundance of energy associated with their hypomanic and manic episodes, sometimes create problems with compliance in taking the drug.

In the past several decades, evidence has emerged for the usefulness of another category of drugs known as the *anticonvulsants* (such as carbamazepine, divalproex, and valproate) in the treatment of bipolar disorder (Keck & McElroy, 2007). These drugs are often effective in patients who do not respond well to lithium or who develop unacceptable side effects from it (Thase & Denko, 2008), and they may also be given in combination with lithium (Post et al., 2010). However, a number of studies have indicated that risk for attempted and completed suicide was nearly two to three times higher for patients on anticonvulsant medications than for those on lithium (Goodwin et al., 2003; Thase & Denko, 2008), suggesting one major advantage of giving lithium to patients who can tolerate its side effects. Both bipolar and unipolar patients who show signs of psychosis (hallucinations and delusions) may also receive treatments with *antipsychotic medications* (see Chapters 13 and 16) in conjunction with their antidepressant or mood-stabilizing drugs (Gitlin, 2009; Keck & McElroy, 2002; Rothschild et al., 2004).

### Alternative Biological Treatments

In addition to the use of pharmacotherapy, there are several other biologically oriented approaches to the treatment of mood disorders. These approaches have been the subject of empirical study in recent years, and they appear to be promising treatment options.

**ELECTROCONVULSIVE THERAPY** Because antidepressants often take 3 to 4 weeks to produce significant improvement, **electroconvulsive therapy (ECT)** is often used with severely depressed patients (especially among the elderly) who may present an immediate and serious suicidal risk, including those with psychotic or melancholic features (Gitlin, 2009; Goodwin & Jamison, 2007). It is also used in patients who cannot take antidepressant medications or who are otherwise resistant to medications (e.g., Heijnen et al., 2010; Mathew et al., 2005). When selection criteria for this form of treatment are carefully observed, a complete remission of symptoms occurs for many patients after about 6 to 12 treatments (with treatments administered about every other day). This means that a majority of severely depressed patients can be vastly better in 2 to 4 weeks (Gitlin, 2009; Mathew et al., 2005). The treatments, which induce seizures, are delivered under general anesthesia and with muscle relaxants. The most common immediate side effect is confusion, although there is some evidence for lasting adverse effects on cognition, such as amnesia and slowed response time (Sackeim et al., 2007). Maintenance dosages of an antidepressant and a mood-stabilizing drug such as lithium are then ordinarily used to maintain the treatment gains achieved until the depression has run its course

(Mathew et al., 2005; Sackeim et al., 2009). ECT is also very useful in the treatment of manic episodes; reviews of the evidence suggest that it is associated with remission or marked improvement in 80 percent of manic patients (Gitlin, 1996; Goodwin & Jamison, 2007). Maintenance on mood-stabilizing drugs following ECT is usually required to prevent relapse.

**TRANSCRANIAL MAGNETIC STIMULATION (TMS)** Although transcranial magnetic stimulation has been available as an alternative biological treatment for some time now, only in the past decade has it begun to receive significant attention. TMS is a noninvasive technique allowing focal stimulation of the brain in patients who are awake. Brief but intense pulsating magnetic fields that induce electrical activity in certain parts of the cortex are delivered (Goodwin & Jamison, 2007; Janicak et al., 2005). The procedure is painless, and thousands of stimulations are delivered in each treatment session. Treatment usually occurs 5 days a week for 2 to 6 weeks. Although not all studies have found TMS to be effective in treating depression (see Couturier, 2005, for one review), many studies have shown it to be quite effective—indeed in some studies quite comparable to unilateral ECT and antidepressant medications (George & Post, 2011; Janicak et al., 2005; Schulze-Rauschenbach et al., 2005). In particular, research suggests that TMS is a promising approach for the treatment of unipolar depression in patients who are moderately resistant to other treatments (George & Post, 2011). Moreover, TMS has advantages over ECT in that cognitive performance and memory are not affected adversely and sometimes even improve, as opposed to ECT, where memory-recall deficits are common (Schulze-Rauschenbach et al., 2005).

**DEEP BRAIN STIMULATION** In recent years, deep brain stimulation has been explored as a treatment approach for individuals with refractory depression who have not responded to other treatment approaches, such as medication, psychotherapy, and ECT. Deep brain stimulation involves implanting an electrode in the brain and then stimulating that area with electric current (Mayberg et al., 2005). Although more research on deep brain stimulation is needed, initial results suggest that it may have potential for treatment of unrelenting depression (see Chapter 16 for more details).

**BRIGHT LIGHT THERAPY** In the past decade an alternative nonpharmacological biological method has received increasing attention—*bright light therapy* (see Pail et al., 2011, for a review). This was originally used in the treatment of seasonal affective disorder, but it has now been shown to be effective in nonseasonal depressions as well (see Golden et al., 2005, for a quantitative review; see also Lieverse et al., 2011).

### Psychotherapy

There are several forms of specialized psychotherapy, developed since the 1970s, that have proved effective in the treatment of unipolar depression, and the magnitude of improvement of the

best of these is approximately equivalent to that observed with medications. Considerable evidence also suggests that these same specialized forms of psychotherapy for depression, alone or in combination with drugs, significantly decrease the likelihood of relapse within a 2-year follow-up period (Hollon et al., 2005; Hollon & Dimidjian, 2009). Other specialized treatments have been developed to address the problems of people (and their families) with bipolar disorder.

**COGNITIVE-BEHAVIORAL THERAPY** One of the two best-known psychotherapies for unipolar depression with documented effectiveness is **cognitive-behavioral therapy (CBT)** (also known as **cognitive therapy**), originally developed by Beck and colleagues (Beck et al., 1979; Clark, Beck, & Alford, 1999). It is a relatively brief form of treatment (usually 10 to 20 sessions) that focuses on here-and-now problems rather than on the more remote causal issues that psychodynamic psychotherapy often addresses. For example, cognitive therapy consists of highly structured, systematic attempts to teach people with unipolar depression to evaluate systematically their dysfunctional beliefs and negative automatic thoughts. They are also taught to identify and correct their biases or distortions in information processing and to uncover and challenge their underlying depressogenic assumptions and beliefs. Cognitive therapy relies heavily on an empirical approach in that patients are taught to treat their beliefs as hypotheses that can be tested through the use of behavioral experiments.

One example of challenging a negative automatic thought through a behavioral experiment can be seen in the following interchange between a cognitive therapist and a depressed patient.

### → Therapy Session: "My Husband Doesn't Love Me Anymore"

PATIENT: My husband doesn't love me any more.

THERAPIST: That must be a very distressing thought. What makes you think that he doesn't love you?

PATIENT: Well, when he comes home in the evening, he never wants to talk to me. He just wants to sit and watch TV. Then he goes straight off to bed.

THERAPIST: OK. Now, is there any evidence, anything he does, that goes against the idea that he doesn't love you?

PATIENT: I can't think of any. Well, no, wait a minute. Actually it was my birthday a couple of weeks ago, and he gave me a watch which is really lovely. I'd seen them advertised and mentioned I liked it, and he took notice and went and got me one.

THERAPIST: Right. Now how does that fit with the idea that he doesn't love you?

PATIENT: Well, I suppose it doesn't really, does it? But then why is he like that in the evening?

THERAPIST: I suppose him not loving you any more is one possible reason. Are there any other possible reasons?

PATIENT: Well, he has been working very hard lately. I mean, he's late home most nights, and he had to go in to the office at the weekend. So I suppose it could be that.

THERAPIST: It could, couldn't it? How could you find out if that's it?

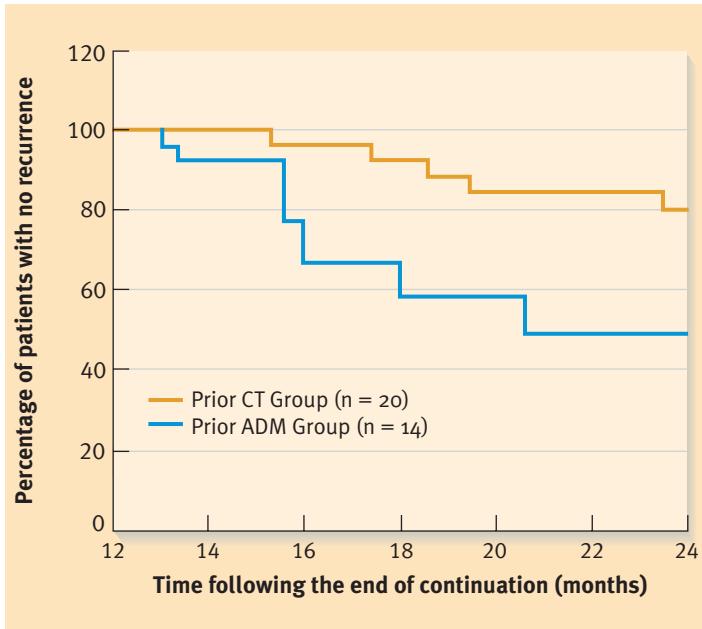

PATIENT: Well, I could say I've noticed how tired he looks and ask him how he's feeling and how the work's going. I haven't done that. I've just been getting annoyed because he doesn't pay any attention to me.

THERAPIST: That sounds like an excellent idea. How would you like to make that a homework task for this week? (From Fennell, M. J. V. (1989). Depression. In K. Hawton, P. M. Salkovskis, J. Kirk, & D. M. Clark (Eds.), *Cognitive behaviour therapy for psychiatric problems: A practical guide*. Oxford University Press.)

.....

The usefulness of cognitive therapy has been amply documented in dozens of studies, including several studies on unipolar depressed inpatients and on patients diagnosed with depression with melancholic features (Craighead et al., 2007; Hollon, Haman, & Brown, 2002; Hollon et al., 2006). When compared with pharmacotherapy, it is at least as effective when delivered by well-trained cognitive therapists. It also seems to have a special advantage in preventing relapse, similar to that obtained by staying on medication (Hollon & Ponniah, 2010; Hollon, 2011). Moreover, evidence is beginning to accumulate that it can prevent recurrence several years following the episode when the treatment occurred (Craighead et al., 2007; Hollon & Dimidjian, 2009). Perhaps not surprisingly, some recent interesting brain-imaging studies have shown that the biological changes in certain brain areas that occur following effective treatment with cognitive therapy versus medications are somewhat different, suggesting that the mechanisms through which they work are also different (e.g., Clark & Beck, 2010; Hollon & Dimidjian, 2009). One possibility is that medications may target the limbic system whereas cognitive therapy may have greater effects on cortical functions.

Whether cognitive therapy is as effective as medication in the treatment of *severe* unipolar depression has been the more controversial question. However, recent evidence suggests that CBT and medications are equally effective in the treatment of severe depression (DeRubeis et al., 1999; Hollon et al., 2006). For example, one important two-site study of moderate to severe depression found that 58 percent responded to either cognitive therapy or medication (DeRubeis et al., 2005). However, by the end of the 2-year follow-up, when all cognitive therapy and medications had been discontinued for 1 year, only 25 percent of patients treated with cognitive therapy had had a relapse versus 50 percent in the medication group (a highly significant difference; Hollon et al., 2005; Hollon & Dimidjian, 2009). This is illustrated in Figure 7.9 on page 251.

**FIGURE 7.9**

Survival curve illustrating how many months following the end of treatment it took patients from the two groups before they had another episode of depression (recurrence). One group had previously received cognitive therapy (CT) and the other group had received antidepressant medication (ADM).

Source: From Hollon, et al. (2005, April). Prevention of relapse following cognitive therapy vs. medications in moderate to severe depression. *Arch. Gen. Psychiat.*, 62(4), 417–26. © 2005 American Medical Association. Reprinted with permission.

Another variant on cognitive therapy, called *mindfulness-based cognitive therapy*, has been developed in recent years to be used with people with highly recurrent depression (e.g., Segal, Williams, & Teasdale, 2002, 2012; Teasdale, 2004). The logic of this treatment is based on findings that people with recurrent depression are likely to have negative thinking patterns activated when they are simply in a depressed mood. Perhaps rather than trying to alter the content of their negative thinking as in traditional cognitive therapy, it might be more useful to change the way in which these people relate to their thoughts, feelings, and bodily sensations. This group treatment involves training in mindfulness meditation techniques aimed at developing patients' awareness of their unwanted thoughts, feelings, and sensations so that they no longer automatically try to avoid them but rather learn to accept them for what they are—simply thoughts occurring in the moment rather than a reflection of reality. A recent meta-analysis of findings from six randomized controlled trials of individuals in remission from depression suggests that mindfulness-based cognitive therapy is an effective treatment for reducing risk of relapse in those with a history of three or more prior depressive episodes who have been treated with antidepressant medication (Piet & Hougaard, 2011; Williams & Kuyken, 2012).

Although the vast majority of research on CBT has focused on unipolar depression, recently there have been indications that

a modified form of CBT may be quite useful, in combination with medication, in the treatment of bipolar disorder as well (Lam et al., 2003, 2005; Miklowitz, 2009). There is also preliminary evidence that mindfulness-based cognitive therapy may be useful in treating bipolar patients between episodes (Williams et al., 2008).

**BEHAVIORAL ACTIVATION TREATMENT** A relatively new and promising treatment for unipolar depression is called **behavioral activation treatment**. This treatment approach focuses intensively on getting patients to become more active and engaged with their environment and with their interpersonal relationships. These techniques include scheduling daily activities and rating pleasure and mastery while engaging in them, exploring alternative behaviors to reach goals, and role-playing to address specific deficits. Traditional cognitive therapy attends to these same issues but to a lesser extent. Behavioral activation treatment, by contrast, does not focus on implementing cognitive changes directly but rather on changing behavior. The goals are to increase levels of positive reinforcement and to reduce avoidance and withdrawal (Dimidjian et al., 2011). Early results were very promising, suggesting it may be as effective as more traditional cognitive therapies (Jacobson et al., 2001), and there is now meta-analytic support for this notion (Mazzucchelli et al., 2009). Indeed, one study found that moderately to severely depressed patients who received behavioral activation treatment did as well as those on medication and even slightly better than those who received cognitive therapy (Dimidjian et al., 2006). However, the slight superiority of behavioral activation treatment relative to cognitive therapy was not maintained, with some results indicating a trend for cognitive therapy to be slightly superior at follow-up (Dobson et al., 2008). Because it is easier to train therapists to administer behavioral activation treatment than cognitive therapy, it seems likely that there will be increased attention paid to this relatively new treatment in the coming years.

**INTERPERSONAL THERAPY** The **interpersonal therapy (IPT)** approach has not yet been subjected to as extensive an evaluation as cognitive-behavioral therapy, nor is it as widely available. However, the studies that have been completed strongly support its effectiveness for treating unipolar depression (see Cuijpers et al., 2011, for a quantitative review; see also Hollon & Ponniah, 2010). Indeed, interpersonal therapy seems to be about as effective as medications or cognitive-behavioral treatment (Hollon et al., 2002; Weissman & Markowitz, 2002). This IPT approach focuses on current relationship issues, trying to help the person understand and change maladaptive interaction patterns (Bleiberg & Markowitz, 2008). Interpersonal therapy can also be useful in long-term follow-up for individuals with severe recurrent unipolar depression (Frank et al., 1990; Weissman & Markowitz,

2002). Patients who received continued treatment with IPT once a month or who received continued medication were much less likely to have a recurrence than those maintained on a placebo over a 3-year follow-up period (although those maintained on medication were even less likely to relapse than those treated with monthly IPT). Furthermore, there is meta-analytic support for the notion that a combined maintenance treatment of IPT and medication is associated with lower recurrence rates than maintenance medication treatment alone (Cuijpers et al., 2011).

In addition, IPT has been adapted for treatment of bipolar disorder by adding a focus on stabilizing daily social rhythms that, if they become destabilized, may play a role in precipitating bipolar episodes. In this new treatment, called *interpersonal and social rhythm therapy*, patients are taught to recognize the effect of interpersonal events on their social and circadian rhythms and to regularize these rhythms. As an adjunct to medication, this treatment seems promising (Miklowitz & Craighead, 2007; Miklowitz, 2009b).

**FAMILY AND MARITAL THERAPY** In any treatment program, it is important to deal with unusual stressors in a patient's life because an unfavorable life situation may lead to a recurrence of the depression and may necessitate longer treatment. This point has been well established in studies indicating that relapse in unipolar and bipolar disorders, as in schizophrenia, is correlated with certain negative aspects of family life (Hooley, 2007; Hooley & Hiller, 2001). Behavior by a spouse that can be interpreted by a former patient as criticism seems especially likely to produce depression relapse. For example, for bipolar disorder, some types of family interventions directed at reducing the level of expressed emotion or hostility, and at increasing the information available to the family about how to cope with the disorder, have been found to be very useful in preventing relapse in these situations (e.g., Miklowitz, 2009; Miklowitz & Craighead, 2007). For married people who have unipolar depression and marital discord, marital therapy (focusing on the marital discord rather than on the depressed spouse alone) is as effective as cognitive therapy in reducing unipolar depression in the depressed spouse. Marital therapy has the further advantage of producing greater increases in marital satisfaction than cognitive therapy (Beach & Jones, 2002).

**CONCLUSIONS** Even without formal therapy, the great majority of patients with mania and depression recover from a given episode in less than a year. With the modern methods of treatment discussed here, the general outlook for a given episode if treatment is obtained has become increasingly favorable for many, but by no means all, diagnosed individuals. However, at least half never receive even minimally adequate treatment. Although relapses and recurrences often occur, these can now often be prevented or at least reduced in frequency by maintenance therapy—through continuation of medication and follow-up therapy sessions at regular intervals.

At the same time, the mortality rate for individuals with depression is significantly higher than that for the general population, partly because of the higher incidence of suicide but also because there is an excess of deaths due to natural causes (see Coryell & Winokur, 1992; Goodwin & Jamison, 2007), including coronary heart disease (e.g., Glassman, 2005; Whang et al., 2009; see Chapter 5). Patients with mania also have a high risk of death from accidents (often with alcohol as a contributing factor), neglect of proper health precautions, or physical exhaustion (Goodwin & Jamison, 2007). Thus, the need for still-more-effective treatment methods, both immediate and long term, clearly remains. Also, a great need remains to study the factors that put people at risk for depressive disorders and to apply relevant findings to early intervention and prevention.

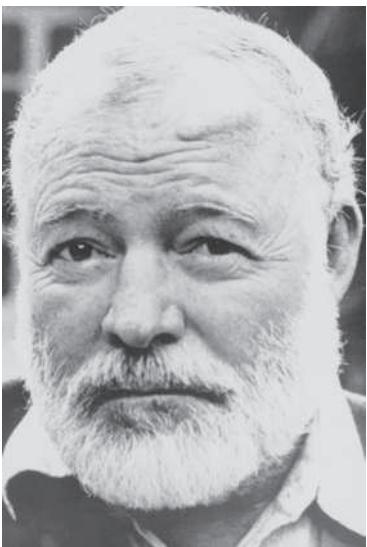

### in review

- Evaluate the effectiveness of antidepressant medications, mood-stabilizing drugs such as lithium, and electroconvulsive therapy in the treatment of unipolar and bipolar disorders.
- Describe the three major forms of psychotherapy that have been shown to be effective for treating depression.

## Suicide: The Clinical Picture and the Causal Pattern

The risk of **suicide**—taking one's own life—is a significant factor in all types of depression. Although people also commit suicide for reasons other than depression, estimates are that about 50 to 90 percent of those who complete the act do so during a depressive episode or while in the recovery phase (Holma et al., 2010; van Praag, 2005). Paradoxically, the act often occurs at a point when the person appears to be emerging from the deepest phase of the depressive episode. The risk of suicide is about 1 percent during the year in which a depressive episode occurs, but the lifetime risk for someone who has recurrent depressive episodes is about 15 percent (D. C. Clark, 1995; Stolberg et al., 2002). Moreover, even when suicide is not associated with depression, it is still generally associated with some other mental disorder; estimates are that approximately 90 percent of people who either attempted or successfully committed suicide had some psychiatric disorder at the time, although only about half of those had been diagnosed prior to the suicide (Goodwin & Jamison, 2007; Kessler, Berglund, Borges et al., 2005; Nock et al., 2010). Moreover, individuals with two or more mental disorders are at even greater risk than those with only one (Nock et al., 2008, 2010).

Suicide now ranks among the 10 leading causes of death in most Western countries (Kessler et al., 2005). In the United States, it is the 10th leading cause of death, with current estimates of about 35,000 suicides each year (Kochanek et al., 2011). Moreover, most experts agree that the number of actual suicides is at least several times higher than the number officially reported

Ernest Hemingway (left) committed suicide on July 2, 1961. Thirty-five years later to the day, his granddaughter Margaux (right) took her own life as well. The Hemingway family has endured five suicides over four generations—Ernest's father Clarence, Ernest and his siblings Ursula and Leicester, and granddaughter Margaux.

because many self-inflicted deaths are attributed in official records to other, more “respectable” causes (e.g., O’Donnell & Farmer, 1995; M. M. Silverman, 1997). In addition to completed suicides, estimates are that approximately half a million people attempt suicide each year and that nearly 3 percent of Americans have made a suicide attempt at some time in their lives (Goodwin & Jamison, 2007). Approximately 9 percent have experienced suicidal ideation or thoughts (Nock et al., 2008).

Statistics, however accurate, cannot begin to convey the tragedy of suicide in human terms. Most people who commit suicide are ambivalent about taking their own lives and make this irreversible choice when they are alone and in a state of severe psychological distress and anguish, unable to see their problems objectively or to evaluate alternative courses of action. Thus one tragedy is that many do not really want to die. A second tragic concern arises from the long-lasting distress among those left behind. Studies of survivors show that the loss of a loved one through suicide “is one of the greatest burdens individuals and families may endure” (Dunne, 1992, p. 222).

In the discussion that follows, we will focus on various aspects of the incidence and clinical picture of suicide, on factors that appear to be of causal significance, on degrees of intent and ways of communicating it, and on issues of treatment and prevention. Who commits suicide? What are the motives for taking one’s own life? What general sociocultural variables appear to be relevant to an understanding of suicide? These are the questions we will consider next.

### Who Attempts and Who Commits Suicide?

Until recently, *suicide attempts* were most common in people between 25 and 44 years old (Stolberg et al., 2002), but it is now people between 18 and 24 years old who have the highest rates

(Kessler, Berglund, Borges et al., 2005). In the United States, women are about three times as likely to *attempt* suicide as men (Goodwin & Jamison, 2007; Holma et al., 2010). Rates of suicide attempts are also about three or four times higher in people who are separated or divorced than in those with any other marital status. Most attempts occur in the context of interpersonal discord or other severe life stress. The story is different, however, for *completed suicides*, which are far less frequent than suicide attempts. In the United States, recent reports indicate that suicide was the seventh leading cause of death for men (accounting for 2.3 percent of total deaths), whereas it was the 15th leading cause of death for women (accounting for 0.6 percent of total deaths; Kochanek et al., 2011). The only exception to these patterns of gender differences seems to be in people who have bipolar disorder, among whom as many, or even more, women as men actually complete suicide (Goodwin & Jamison, 2007; Tondo et al., 2003). The highest rate of completed suicides is in the elderly (aged 65 and over). Although these rates had been coming down since 1930, especially for elderly men (Stolberg et al., 2002), the 1980s and 1990s saw a trend back upward. Among elderly victims, a high proportion are divorced or widowed or suffer from a chronic physical illness that can lead to increased risk for suicide, very often because the person is depressed (Conwell, Duberstein, & Caine, 2002). However, full-blown mental disorders are relatively rare in those elderly persons who commit suicide compared to their prevalence among people in younger age groups who commit suicide (Harwood et al., 2006). For women, the method most commonly used is drug ingestion; men tend to use methods more likely to be lethal, particularly gunshot, which may be a good part of the reason why completed suicides are higher among men.

Besides the elderly, those with mood disorders, and separated or divorced people, there are a number of other high-risk groups among adults. For example, people with fairly severe and recurrent mood disorders have the highest risk of suicide (about a 15 percent lifetime risk). Those with less severe forms of mood disorders show only a somewhat elevated risk (Goodwin & Jamison, 2007). Some researchers have estimated that people with schizophrenia have about a 10 to 13 percent risk, and those hospitalized for alcohol dependence have about a 3 to 4 percent risk, relative to the average risk of 1.4 percent in the general population (e.g., Haas, 1997; Joiner et al., 2005; Stolberg et al., 2002). Rates of attempted and completed suicides are also elevated in individuals with borderline personality disorder and antisocial personality disorder (see Chapter 10). Furthermore, a history of conduct disorder has been found to be a strong predictor of suicide attempts as well (Borges et al., 2010). In addition, risk for different suicidal behaviors may differ as a function of psychopathology. For example, in the National Comorbidity Survey-Replication, major depression was found to be the strongest risk factor for suicidal ideation

but not for suicide plans or attempts among individuals with ideation (Nock, Hwang et al., 2010). In contrast, anxiety, impulse-control, and substance use disorders were the strongest predictors of suicide plans and attempts. Finally, people living alone or with low levels of perceived social support and people from socially disorganized areas are also at heightened risk (e.g., Holma et al., 2010). Certain highly creative or successful scientists, health professionals (e.g., physicians and psychologists), business people, composers, writers, and artists are also at higher-than-average risk (Jamison, 1999). Recently in the United States suicide rates have been tragically high among people in the military after they have returned from combat in Iraq or Afghanistan; PTSD has often been implicated as playing a role.

### Suicide in Children

A very disturbing trend is that rates of completed suicide among children, while still very low, have been increasing (Stolberg et al., 2002; van Orden et al., 2008). Suicide in children under age 10 is extremely rare. In children between ages 10 to 14 suicide is also rare in absolute terms (accounting for approximately 5 percent of deaths) but is nevertheless the fourth leading cause of death in the United States for this age group (Kochanek et al., 2011). Further, the trend is by no means limited to those from deprived or troubled backgrounds. Children are at increased risk for suicide if they have lost a parent or have been abused (Jamison, 1999). Several forms of psychopathology—depression, antisocial behavior, and high impulsivity—are also known to be risk factors for suicide in children.

### Suicide in Adolescents and Young Adults

For people between the ages of 15 and 24, the rate of successful suicides essentially tripled between the mid-1950s and the mid-1980s. Suicide now ranks as the third most common cause of death in the United States for 15- to 19-year-olds (after accidents and homicide), accounting for approximately 11 percent of total deaths (Kochanek et al., 2011). The increases in suicide rates for adolescents are not unique to this country but, rather, have been observed in most of the many countries studied (Jamison, 1999).

As for suicide attempts, one large survey of 15,000 high school students across 32 states has estimated the rates of self-reported suicide attempts within a 12-month period to be an alarming 8.5 percent, with about twice that many reporting that they have at least seriously considered it (Spirito & Esposito-Smythers, 2006). In recent years, these have been the highest rates of suicide attempts at any point in the human life span. Most of these attempts have very low lethality and do not require medical attention, but they do need to be taken seriously. Indeed, prior suicide attempts have occurred in about 25 to 33 percent of completed suicides. Suicide rates in college students are also high, and it is the second leading cause of death

in this group. One large survey found that about 10 percent of college students had seriously contemplated suicide in the past year and that most of these attempters had had some sort of plan (Jamison, 1999).

**KNOWN RISK FACTORS FOR ADOLESCENT SUICIDE** Studies have found that mood disorders, conduct disorder, and substance abuse (especially alcohol) are relatively more common in both completers and nonfatal attempters. Among those with two or more of these disorders, risk for completion increases. Unfortunately, recent evidence suggests that treatment of adolescent mood disorders with antidepressant medication also seems to produce a very slightly increased risk for suicidal ideation (or thoughts) and behavior in children and adolescents, and so now pharmaceutical companies must put warnings to this effect on these medications (e.g., Whittington et al., 2005).

Why has there been such a surge in suicide attempts and completed suicides in adolescence? One obvious reason is that this is a period during which depression, anxiety, alcohol and drug use, and conduct disorder problems also show increasing prevalence, and these are all factors associated with increased risk for suicide (e.g., Evans, Hawton, & Rodham, 2004). Increased availability of firearms has also probably played a role as well. Exposure to suicides (especially those of celebrities) through the media, where they are often portrayed in dramatic terms, has probably also contributed to these aggregate increases in adolescent suicide, perhaps because adolescents are highly susceptible to suggestion and imitative behavior (Hawton & Williams, 2002; Jamison, 1999). One review estimated that between 1 and 13 percent of adolescent suicides occur as a result of contagion factors (Velting & Gould, 1997). Finally, the fact that the media rarely discuss the mental disorders suffered by the suicide victims may further increase the likelihood of imitation.

Many college students also seem very vulnerable to the development of suicidal ideation and plans. The combined stressors of academic demands, social interaction problems, and career choices—perhaps interacting with challenges to their basic values—evidently make it impossible for some students to continue making the adjustments their life situations demand. For an overview of warning signs for student suicide, see “The World Around Us” box on p. 255.

### Other Psychosocial Factors Associated with Suicide

The most frequently discussed personality traits associated with suicide are impulsivity (especially a lack of premeditation), aggression, pessimism, and negative affectivity, which all seem to increase the risk for suicide (Hawton, 2005; Quendino et al., 2004; Yen et al., 2009). Though the specific factors that lead a person to suicide may take many forms,

## Warning Signs for Student Suicide

A marked change in a student's mood and behavior may be a significant warning of possible suicide. Characteristically, the student becomes depressed and withdrawn, undergoes a marked decline in self-esteem, and shows deterioration in personal hygiene. He or she may also show uncharacteristically impulsive or reckless behavior, including self-mutilating behavior. The student may also write about death or suicide. These signs are accompanied by a profound loss of interest in studies. Often he or she stops attending classes and stays at home most of the day. The student's distress is usually communicated to at least one other person, often in the form of a veiled suicide warning.

When college students attempt suicide, one of the first explanations to occur to those around them is that they may have been doing poorly in school. As a group, however, they are superior students, and although they tend to expect a great deal of themselves in terms of academic achievement, their grades and academic competition are not regarded as significant precipitating stressors. Also, although many lose interest in their studies

before becoming suicidal and thus receive worse grades, this loss of interest appears to be associated with depression and withdrawal caused by other problems. Moreover, in that minority of cases where academic failure does appear to trigger suicidal behavior, the underlying cause of the behavior seems to be loss of self-esteem and failure to live up to parental expectations rather than academic failure itself.

For most suicidal students, both male and female, the major precipitating stressor appears to be either the failure to establish, or the loss of, a close interpersonal relationship. Often the breakup of a romance is the key precipitating factor. It has also been noted that significantly more suicide attempts and suicides are made by students from families that have experienced separation, divorce, or the death of a parent.

Although most colleges and universities have mental health facilities to assist distressed students, few suicidal students seek professional help. Thus it is of vital importance for those around a suicidal student to notice any warning signs and try to obtain assistance.

suicide is often associated with negative events such as severe financial reversals, imprisonment, and interpersonal crises of various sorts. For example, rates of suicide rose sharply (i.e., quadrupled) in the United States, Great Britain, and Hong Kong from 2008 to 2010 after the economic crisis took hold in 2007. Some believe the common denominator may be that these events lead either to the loss of a sense of meaning in life or to hopelessness about the future, both of which can produce a mental state that looks to suicide as a possible way out. However, hopelessness about the future may be a better long-term predictor of suicide (say, 1 or 2 years later) than it is for the short term (for instance, weeks or months later; Coryell & Young, 2005; Goodwin & Jamison, 2007). There is also initial evidence that people who have a strong implicit association between the self and death or suicide are at elevated risk of future suicide attempts, even over and above the effects of other known risk factors (Nock et al., 2010). Other symptoms that seem to predict suicide more reliably in the short term in patients with major depression include severe anxiety, panic attacks, severe anhedonia (inability to experience pleasure), global insomnia, delusions, and alcohol abuse (Busch et al., 2003; Goodwin & Jamison, 2007). Indeed, in one study of 76 people who had committed suicide while being hospitalized, the hospital records revealed that 79 percent of these people had been severely anxious and agitated in the week prior to committing suicide (Busch et al., 2003).

Shneidman, a leading suicidologist for over 35 years, has written extensively about the "suicidal mind." For example, he wrote,

*In almost every case suicide is caused by . . . psychological pain, or "psychache." . . . Suicidal death, in other words, is an escape from pain. . . . Pain is nature's great signal. Pain warns us; pain both mobilizes us and saps our strength; pain, by its very nature, makes us want to stop it or escape from it. . . . Psychache is the hurt, anguish, or ache that takes hold in the mind . . . the pain of excessively felt shame, guilt, fear, anxiety, loneliness, angst, and dread of growing old or of dying badly. . . . [I]ts introspective reality is undeniable. Suicide happens when the psychache is deemed unbearable and death is actively sought to stop the unceasing flow of painful consciousness.*  
(Shneidman, 1997, pp. 23, 24, 29)

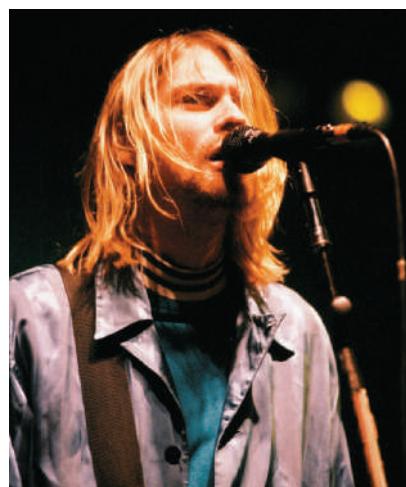

But what psychological factors lead one to this state? Research indicates that suicide is the end product of a long sequence of events that begins in childhood. People who become suicidal often come from backgrounds in which there was some combination of a good deal of family psychopathology, child maltreatment, and family instability (e.g., Borges et al., 2010; Molnar et al., 2001). These early experiences are in turn associated with the child (and later the adult) having low self-esteem, hopelessness, and poor problem-solving skills. Such experiences may affect the person's cognitive functioning in a very negative

way, and these cognitive deficits may in turn mediate the link with suicidal behavior (e.g., Yang & Clum, 1996).

## Biological Causal Factors

There is strong evidence that suicide sometimes runs in families and that genetic factors may play a role in the risk for suicide (Goodwin & Jamison, 2007). For example, averaging across 22 studies, the concordance rate for suicide in identical twins is about three times higher than that in fraternal twins (Baldessarini & Hennen, 2004). Moreover, this genetic vulnerability seems to be at least partly independent of the genetic vulnerability for major depression (e.g., Brezo et al., 2010).

There is also increasing evidence that this genetic vulnerability may be linked to the neurochemical correlates of suicide that have now been found in numerous studies. Specifically, suicide victims often have alterations in serotonin functioning, with reduced serotonergic activity being associated with increased suicide risk—especially for violent suicide. Such studies have been conducted not only in postmortem studies of suicide victims but also in people who have made suicide attempts and survived. This association appears to be independent of psychiatric diagnosis, including suicide victims with depression, schizophrenia, and personality disorders. People hospitalized for a suicide attempt who have low serotonin levels are also 10 times more likely to kill themselves in the next year than are those without low serotonin levels. Several studies have tried to document an association between suicide and the short allele serotonin-transporter gene (which controls the uptake of serotonin from the synapse), previously discussed as being implicated in the vulnerability to depression. Although

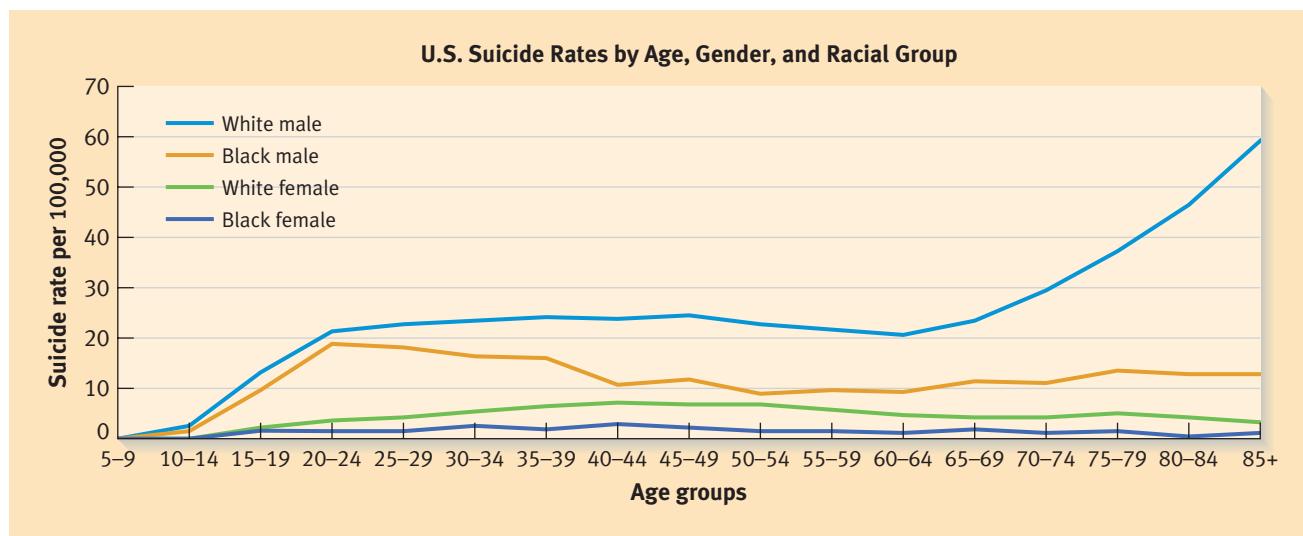

Kurt Cobain, lead vocalist of the rock band Nirvana, died from a self-inflicted gunshot wound on April 8, 1994. He left behind his wife, Courtney Love, and their daughter, Frances, to deal with the emotional burden of his suicide. Forty to sixty percent of those who successfully commit suicide are depressed.

not all studies have found positive results, a quantitative review of these studies did find that people with one or two copies of the short allele are at heightened risk for suicide following stressful life events (Lin & Tsai, 2004). There is also growing support for associations between additional serotonergic gene variants and suicide attempts (Brezo et al., 2010).

## Sociocultural Factors

Substantial differences in suicide rates occur among different ethnic or racial groups in the United States. For example, whites have significantly higher rates of suicide than African Americans, except among young males, where rates are similar between white and African American men (see Figure 7.10). Only young Native American men show a suicide rate similar to that of white males.

**FIGURE 7.10**

**U.S. Suicide Rates by Age, Gender, and Racial Group** Suicide rates are higher in males than in females and higher in whites than in African Americans.

Source: National Institute of Mental Health, October 20, 2002. Data: Centers for Disease Control and Prevention, National Center for Health Statistics.

Suicide rates also appear to vary considerably from one society to another. The United States has a rate of approximately 11 per 100,000. Countries with low rates (less than 9 per 100,000) include Greece, Italy, Spain, and the United Kingdom (Maris et al., 2000). In contrast, Hungary, with an annual incidence of more than 40 per 100,000, has the world's highest rate (almost four times that of the United States). Other Western countries with high suicide rates—20 per 100,000 or higher—are Switzerland, Finland, Austria, Sweden, Denmark, and Germany. Rates in Japan and China are also high; indeed, in China the estimated suicide rate is three times the global average (Hesketh et al., 2002). Moreover, almost 30 percent of suicides worldwide are estimated to occur in China and India (WHO, 2009). Some have estimated the global mortality from suicide at 16 to 18 per 100,000 (Mathers et al., 2006; WHO, 2009). These estimates should, however, be considered in light of the fact that there are wide differences across countries in the criteria used for determining whether a death was due to suicide, and such differences may well contribute to the apparent differences in suicide rates.

Religious taboos concerning suicide and the attitudes of a society toward death are also apparently important determinants of suicide rates. Both Catholicism and Islam strongly condemn suicide, and suicide rates in Catholic and Islamic countries are correspondingly low. In fact, most societies have developed strong sanctions against suicide, and many still regard it as a crime as well as a sin.

Japan is one of the few societies in which suicide has been socially approved under certain circumstances—such as conditions that bring disgrace to an individual or group. During World War II, many Japanese villagers and Japanese military personnel were reported to have committed mass suicide when faced with defeat and imminent capture by Allied forces. There were also reports of group suicide by Japanese military personnel under threat of defeat. In the case of the kamikaze, approximately 1,000 young Japanese pilots deliberately crashed their explosives-laden planes into American warships during the war's final stages as a way of demonstrating complete personal commitment to the national purpose. Comparable acts of self-destruction occur today in the Middle East, where Muslim extremists and terrorists all too often commit suicide in order to ensure that a bomb explodes in a designated target area. In the case of the Al Qaeda attacks on September 11, 2001, terrorists took over commercial jets and then flew them into the World Trade Center and the Pentagon, killing themselves and over 3,000 innocent people. A few years later in Iraq, after the fall of Saddam Hussein, suicide bombers formed a major part of the insurgency in Iraq against U.S. and other foreign soldiers, as well as against members of Iraq's newly formed government forces.

There are also interesting cross-cultural gender differences in whether men or women are more likely to attempt and complete suicide. Although women are more likely to attempt and men to complete suicide in the United States, in India, Poland, and Finland men are more likely than women to engage in nonfatal

suicide attempts. In China, India, and Papua New Guinea, women are more likely to complete suicide than men (Canetto, 1997; Jamison, 1999).

In a pioneering study of sociocultural factors in suicide, the French sociologist Emile Durkheim (1897/1951) attempted to relate differences in suicide rates to differences in group cohesiveness. Analyzing records of suicides in different countries and during different historical periods, Durkheim concluded that the greatest deterrent to committing suicide in times of personal stress is a sense of involvement and identity with other people. More contemporary studies tend to confirm this idea, showing, for example, that being married and having children tends to protect one from suicide (Maris, 1997; Stolberg et al., 2002).

Durkheim's views also seem relevant to understanding the higher incidence of suicide among individuals subjected to conditions of uncertainty and social disorganization in the absence of strong group ties. For example, there is a well-known association between unemployment and suicide (especially for men), which may well be related to the effects that unemployment has on mental health (Gunnell, 2005; Jamison, 1999). Similarly, suicide rates have been found to be higher among groups subject to severe social pressures. For example, in 1932, at the height of the Great Depression in the United States, the suicide rate increased from less than 10 to 17.4 per 100,000.

### in review

- Which groups of people are most likely to attempt suicide, and which groups are most likely to complete suicide? What are some of the major precipitants of suicide?
- Summarize the psychological, biological, and sociocultural causal factors associated with suicide.

## Suicidal Ambivalence

Ambivalence often accompanies thoughts of suicide. Some people (most often women) do not really wish to die but instead want to communicate a dramatic message to others concerning their distress. Their suicide attempts tend to involve nonlethal methods such as minimal drug ingestion or minor wrist cutting. They usually arrange matters so that intervention by others is almost inevitable. In stark contrast, a small minority of suicidal people are seemingly intent on dying. They give little or no warning of their intent, and they generally rely on the more violent and certain means of suicide such as shooting themselves or jumping from high places. A third subset of people are ambivalent about dying and tend to leave the question of death to fate. A person in this group may entertain and tend to use methods that are often dangerous but moderately slow acting, such as drug ingestion. The feeling during such attempts can be summed up as, "If I die, the conflict is settled, but if I am rescued that is what was meant to be."

After an unsuccessful attempt, a marked reduction in emotional turmoil usually occurs, especially if the attempt was

expected to be lethal, such as jumping in front of a moving train. This reduction in turmoil is usually not stable, however, and subsequent suicidal behavior may follow (e.g., Holma et al., 2010). In the year after a suicide attempt, repetition of the behavior occurs in 15 to 25 percent (Zahl & Hawton, 2004b) of cases, and there is an increased risk that the second or third attempt will be fatal, especially if the first attempt was a serious one. Long-term follow-ups of those who have made a suicide attempt show that about 7 to 10 percent will eventually die by suicide, a risk about five times greater than the average risk of 1.4 percent (Stolberg et al., 2002). Of people who do kill themselves, about 20 to 40 percent have a history of one or more previous attempts; however, more than half of those who commit suicide have no previous attempts (Stolberg et al., 2002; Zahl & Hawton, 2004b).

### Communication of Suicidal Intent

Research has clearly disproved the tragic belief that those who threaten to take their lives seldom do so. One review of many studies conducted around the world that involved interviewing friends and relatives of people who had committed suicide revealed that more than 40 percent had communicated their suicidal intent in very clear and specific terms and that another 30 percent had talked about death or dying in the months preceding their suicide. These communications were usually made to several people and occurred a few weeks or months before the suicide (D. C. Clark, 1995). Nevertheless, most of those interviewed said the suicide came as a surprise. It is also interesting that most of these communications of intent were to friends and family members and not to mental health professionals. Indeed, nearly 50 percent of people who die by suicide have never seen a mental health professional in their lifetime, and only about 20 percent are under the care of one at the time of their death (Goodwin & Jamison, 2007).

On the other hand, if a clinician knows that someone has been suicidal (for example, he or she is being hospitalized for a suicide attempt), he or she should also not take the patient's denial of suicidal intent as necessarily being valid. One fascinating study of clinical correlates of inpatients who had committed suicide revealed some sobering statistics: Among patients who were being hospitalized for having had either suicidal ideation or intent, nearly 80 percent denied suicidal ideation the last time they spoke with a clinician before actually committing suicide; moreover, over 50 percent of those who committed suicide did so while on a 15-minute suicide watch or under 1-on-1 observation (Busch et al., 2003).

### Suicide Notes

Several investigators have analyzed suicide notes in an effort to understand the motives and feelings of people who take their own lives. Several large studies of completed suicides found that only about 15 to 25 percent left notes, usually addressed

to relatives or friends (Jamison, 1999; Maris, 1997). The notes, typically coherent and legible, either had been mailed or were found on the person's body or near the suicide scene. Some notes included statements of love and concern, which may have been motivated by the desire to be remembered positively and to reassure the survivor of the worth of the relationship. Occasionally, though, notes contained very hostile content, such as, "I used to love you but I die hating you and my brother too" (Jamison, 1999, p. 78).

Although one might think that such notes would express deep and tragic emotions, this is typically not the case. Many notes are often quite short and straightforward: "I am tired of living" or "I could not bear it any longer" or "No one is to blame for this. It's just that I could never be reconciled with life itself. God have mercy on my soul" (Jamison, 1999, pp. 77–78).

### Suicide Prevention and Intervention

Preventing suicide is extremely difficult. Most people who are depressed and contemplating suicide do not realize that their thinking is restricted and irrational and that they are in need of assistance. Rather than seeking psychological help, they are more likely to visit a doctor's office with multiple vague complaints of physical symptoms that the doctor often does not detect as symptoms of depression or alcoholism. Others are brought to the attention of mental health personnel by family members or friends who are concerned because the person appears depressed or has made suicide threats. The vast majority, however, do not receive the help they desperately need. This is unfortunate because if a person's cry for help can be heard in time it is often possible to intervene successfully.

Currently, there are three main thrusts of preventive efforts: treatment of the person's current mental disorder(s) as noted above, crisis intervention, and working with high-risk groups.

### Treatment of Mental Disorders

One way to help prevent suicide might be through treating the underlying mental disorder(s) the potentially suicidal person has. In the case of depression, such treatment is often in the form of antidepressant medications or lithium. Lithium seems to be an especially powerful anti-suicide agent over the long term (although not in the acute situation; Goodwin & Jamison, 2007). Benzodiazepines can also be useful in treating the severe anxiety and panic that so often precede suicide attempts. Although there is not a great deal of work using cognitive-behavioral treatments for suicide, one important study examined adults who had already made at least one attempt and gave them 10 sessions of cognitive therapy focused on suicide prevention. This treatment was quite beneficial in reducing further attempts (Brown, 2005). In the 18 months subsequent to receiving treatment, patients in the cognitive-therapy group were 50 percent less likely to reattempt suicide than patients in the usual care

group, and their depressive and hopelessness symptoms were also lower than those of the usual care group. Subsequent research suggests that cognitive-behavioral therapy for suicide prevention is also feasible for use with adolescents who have attempted suicide (Stanley et al., 2009).

### Crisis Intervention

The primary objective of crisis intervention is to help a person cope with an immediate life crisis. If a serious suicide attempt has been made, the first step involves emergency medical treatment, followed by referral to inpatient or outpatient mental health facilities in order to reduce the risk for future attempts (e.g., Stolberg et al., 2002).

When people contemplating suicide are willing to discuss their problems with someone at a suicide prevention center, it is often possible to avert an actual suicide attempt. Here the primary objective is to help these people regain their ability to cope with their immediate problems as quickly as possible. Emphasis is usually placed on (1) maintaining supportive and often highly directive contact with the person over a short period of time—usually one to six contacts; (2) helping the person to realize that acute distress is impairing his or her ability to assess the situation accurately and to see that there are better ways of dealing with the problem; and (3) helping the person to see that the present distress and emotional turmoil will not be endless.

Since the 1960s, the availability of competent assistance at times of suicidal crisis has been expanded through the establishment of *suicide hotlines* for suicide prevention centers. There are now more than several thousand such hotlines in the United States, but questions have been raised about the quality of care offered by the majority of them (e.g., Seeley, 1997). These

centers are geared primarily toward crisis intervention, usually via the 24-hour-a-day availability of telephone contact. Suicide hotlines are usually staffed primarily by nonprofessionals who are supervised by psychologists and psychiatrists. The worker attempts to establish the seriousness of the caller's intent and simultaneously tries to show empathy and to convince the person not to attempt suicide. Efforts are also made to mobilize support from family or friends. Unfortunately, good information on the assessment of the effects of these hotlines and suicide prevention centers has not revealed much impact on suicide rates.

### Focus on High-Risk Groups and Other Measures

Many investigators have emphasized the need for broad-based prevention programs aimed at alleviating the life problems of people who are in groups at high risk for suicide (Maris et al., 2000). Few such programs have actually been initiated, but one approach has been to involve older men—a high-risk group—in social and interpersonal activities that help others. Playing such roles may lessen these men's sense of isolation and meaninglessness, which often stems from forced retirement, financial problems, the deaths of loved ones, impaired physical health, and feeling unwanted. Other programs have been targeted at young adolescents who are at higher risk because of previous suicidal ideation and behavior or mood or substance-use disorders (Zahl & Hawton, 2004a).

#### in review

- What is meant by suicidal ambivalence, and how might it be related to communication of suicidal intent?
- What are the goals of suicide intervention programs, and how successful do they seem to be?

## UNRESOLVED issues

### Is There a Right to Die?

Most of us respect the preservation of human life as a worthwhile value. Thus, in our society, suicide is generally considered not only tragic but also "wrong." Efforts to prevent suicide, however, involve ethical problems. If people wish to take their own lives, what obligation—or right—do others have to interfere? Not all societies have taken the position that others should interfere when someone wishes to commit suicide. For example, the classical Greeks believed in dignity in death, and people who were extremely ill could get permission from the state to commit suicide. Officials of the state gave out hemlock (a poison) to those who received such permission (Humphry & Wickett, 1986). Today, in certain Western European countries such as the Netherlands and Belgium the law allows terminally ill people to be given access to drugs that

they can use to commit suicide (Bosshard et al., 2008; Maris et al., 2000). In 1994 the state of Oregon passed the Oregon Death with Dignity Act (ODDA) allowing physician-assisted suicide for terminally ill patients who request a prescription for lethal medications that they will ingest to end their own lives (e.g., Purvis, 2012; Sears & Stanton, 2001). As of 2007 an estimated 341 people had taken their lives under the ODDA.

Passage of the ODDA was (and is) highly controversial in the United States and was challenged several times by U.S. Attorney General John Ashcroft in federal courts. So far the law remains in effect even after being reviewed by the Supreme Court, where it was upheld in January 2006. Furthermore, in 2008 Washington became the second state to pass a death with

dignity act, and in Montana a court ruling made it legal as well. Nevertheless, there is still very heated debate all over the country about the right of people who are terminally ill or who suffer chronic and debilitating pain to shorten their agony. One group, the Hemlock Society, supports the rights of terminally ill people to get help in ending their own lives when they wish; the society also provides support groups for people making this decision.

Several other groups press related issues at a legislative level. One physician in Michigan, Dr. Jack Kevorkian (1928–2011), helped over 130 gravely ill people commit suicide and, in so doing, tried to get Michigan to pass laws permitting such acts. For years the state tried to block Kevorkian from assisting in any further suicides, and at several points he was even imprisoned, and his medical license revoked, because he refused to obey injunctions not to assist with any more suicides. In 1998 Kevorkian invited further attention—and prosecution—when he released a videotape to the CBS program *60 Minutes*, and millions watched him assisting in a suicide. He was later charged, and convicted in April 1999, of second-degree murder and was released and paroled for good behavior in 2007 after serving 8 years of a 10- to 25-year term in prison. In spite of Kevorkian's failure to prompt the passage of laws supporting assisted suicide for such gravely ill individuals (indeed, Michigan passed a law prohibiting assisted suicide!), substantial numbers of people, including many physicians and dying patients, have come to sympathize with this position (Curlin et al., 2008; Purvis, 2012; Wilson, Chochinov et al., 2007; see also Szasz's 1999 book *Fatal Freedom: The Ethics and Politics of Suicide*).

Arguments against this position have included fears that the right to suicide might be abused. For example, people who are terminally ill and severely incapacitated might feel pressured to end their own lives rather than burden their families with their care or with the cost of their care in a medical facility or hospice. However, in places where assisted suicide is legal, such as the Netherlands and Oregon, this has not happened. Indeed, physicians in Oregon seem to have become more aware of and sensitive to the needs of terminally ill patients in terms of recommending hospice care and learning more about prescribing the high doses of pain medication needed to relieve suffering (Ganzini et al., 2001). Consistent with this, most patients in Oregon say they are motivated by a loss of autonomy and dignity rather than a need for help with pain control (Prokopenko & Lehmann, 2012).

But what about the rights of suicidal people who are not terminally ill and who have dependent children, parents, a spouse, or other loved ones who will be adversely affected, perhaps permanently (Lukas & Seiden, 1990; Maris et al., 2000), by their death? Here a person's "right to suicide" is not immediately obvious, and physicians are very unlikely to provide assistance in such cases (Rurup et al., 2005). The right to suicide is even less clear when we consider that, through intervention, many suicidal people regain their perspective and see alternative ways of dealing with their distress.

Rather than focusing on suicide "prevention," some have suggested suicide "intervention" both as a more appropriate term and as descriptive of a more ethically defensible professional approach to suicidal behavior. According to this perspective, suicide intervention embodies a more neutral moral stance than suicide prevention—it means interceding without the implication of preventing the act—and, in certain circumstances, such as when people are terminally ill, it may even encompass the possibility of facilitating the suicidal person's objective (e.g., M. M. Silverman, 1997).

The dilemma about the prevention concept becomes even more intense when prevention requires that a person be hospitalized involuntarily, when personal items (such as belts and sharp objects) are taken away, and when calming medication is more or less forcibly administered. Sometimes considerable restriction is needed to calm the individual. Not uncommonly, particularly in these litigious times, the responsible clinician feels trapped between threats of legal action on both sides of the issue. Moreover, preventive efforts may be fruitless; truly determined persons may find a way to commit suicide even on a "suicide watch." Indeed, about 5 percent of all completed suicides are committed by psychiatric patients while they are hospitalized in inpatient psychiatric units that are supposed to help prevent suicide (Stolberg et al., 2002).

Thus the vexing ethical problems of whether and to what extent one should intervene in cases of threatened suicide have now been complicated by no-less-vexing legal problems. As in other areas of professional practice, clinical judgment is no longer the only consideration in intervention decisions. This is a societal problem, and the solutions—if any—will have to be societal ones.

## summary

### 7.1 What are mood disorders?

- Mood disorders are those in which extreme variations in mood—either low or high—are the predominant feature. Although some variations in mood are normal, for some people the extremity of moods in either direction becomes seriously maladaptive, even to the extent of suicide.

### 7.2 What symptoms are characteristic of depressive disorders?

- Most people with mood disorders have some form of depressive disorder—dysthymia or major depression. Such individuals experience a range of affective, cognitive, motivational, and biological symptoms including persistent sadness, negative thoughts about the self and the future, lack of energy or initiative, too much or too little sleep, and gaining or losing weight.

### 7.3 What are the causal factors in unipolar mood disorders?

- Among biological causal factors for depressive disorder, there is evidence of a moderate genetic contribution to the vulnerability for major depression and probably dysthymia as well. Moreover, major depressions are clearly associated with multiple interacting disturbances in neurochemical, neuroendocrine, and neurophysiological systems. Disruptions in circadian and seasonal rhythms are also prominent features of depression.
- Among psychosocial theories of the causes of depressive disorder are Beck's cognitive theory and the reformulated helplessness and hopelessness theories, which are formulated as diathesis-stress models, and a tendency to ruminate about one's mood or problems exacerbates their effects. The diathesis is cognitive in nature (e.g., dysfunctional beliefs and pessimistic attributional style, respectively), and stressful life events are often important in determining when those diatheses actually lead to depression.
- Personality variables such as neuroticism may also serve as diatheses for depression.
- Psychodynamic and interpersonal theories of unipolar depression emphasize the importance of early experiences (especially early losses and the quality of the parent-child relationship) as setting up a predisposition for depression.

### 7.4 What are bipolar disorders?

- In the bipolar disorders (cyclothymia and bipolar I and II disorders), the person experiences episodes of both depression and hypomania or mania. During manic or hypomanic episodes, the symptoms are essentially the opposite of those experienced during a depressive episode.

### 7.5 What are the causal factors in bipolar disorder?

- Biological causal factors probably play an even more prominent role for bipolar disorders than for unipolar disorders. The genetic contribution to bipolar disorder is among the strongest of such contributions to the major psychiatric disorders. Neurochemical imbalances, abnormalities of the hypothalamic-pituitary-adrenal axis, and disturbances in biological rhythms all play important roles in bipolar disorders.
- Stressful life events may be involved in precipitating manic or depressive episodes, but it is unlikely that they cause the disorder.

### 7.6 What are the treatments and outcomes for mood disorders?

- Biologically based treatments such as medications or electroconvulsive therapy are often used in the treatment of the more severe major disorders. Increasingly, however, specific psychosocial treatments such as cognitive therapy, behavioral activation treatment, and interpersonal therapy are also being used to good effect in many cases of these more severe disorders as well as in the milder forms of mood disorder. Considerable evidence suggests that recurrent depression is best treated by specialized forms of psychotherapy or by maintenance on medications for prolonged periods.

### 7.7 What is the clinical picture and the causal pattern of suicide?

- Suicide is a constant danger with depressive syndromes of any type or severity. Accordingly, an assessment of suicide risk is essential in the proper management of depressive disorders.

### 7.8 What role does ambivalence play in thoughts of suicide?

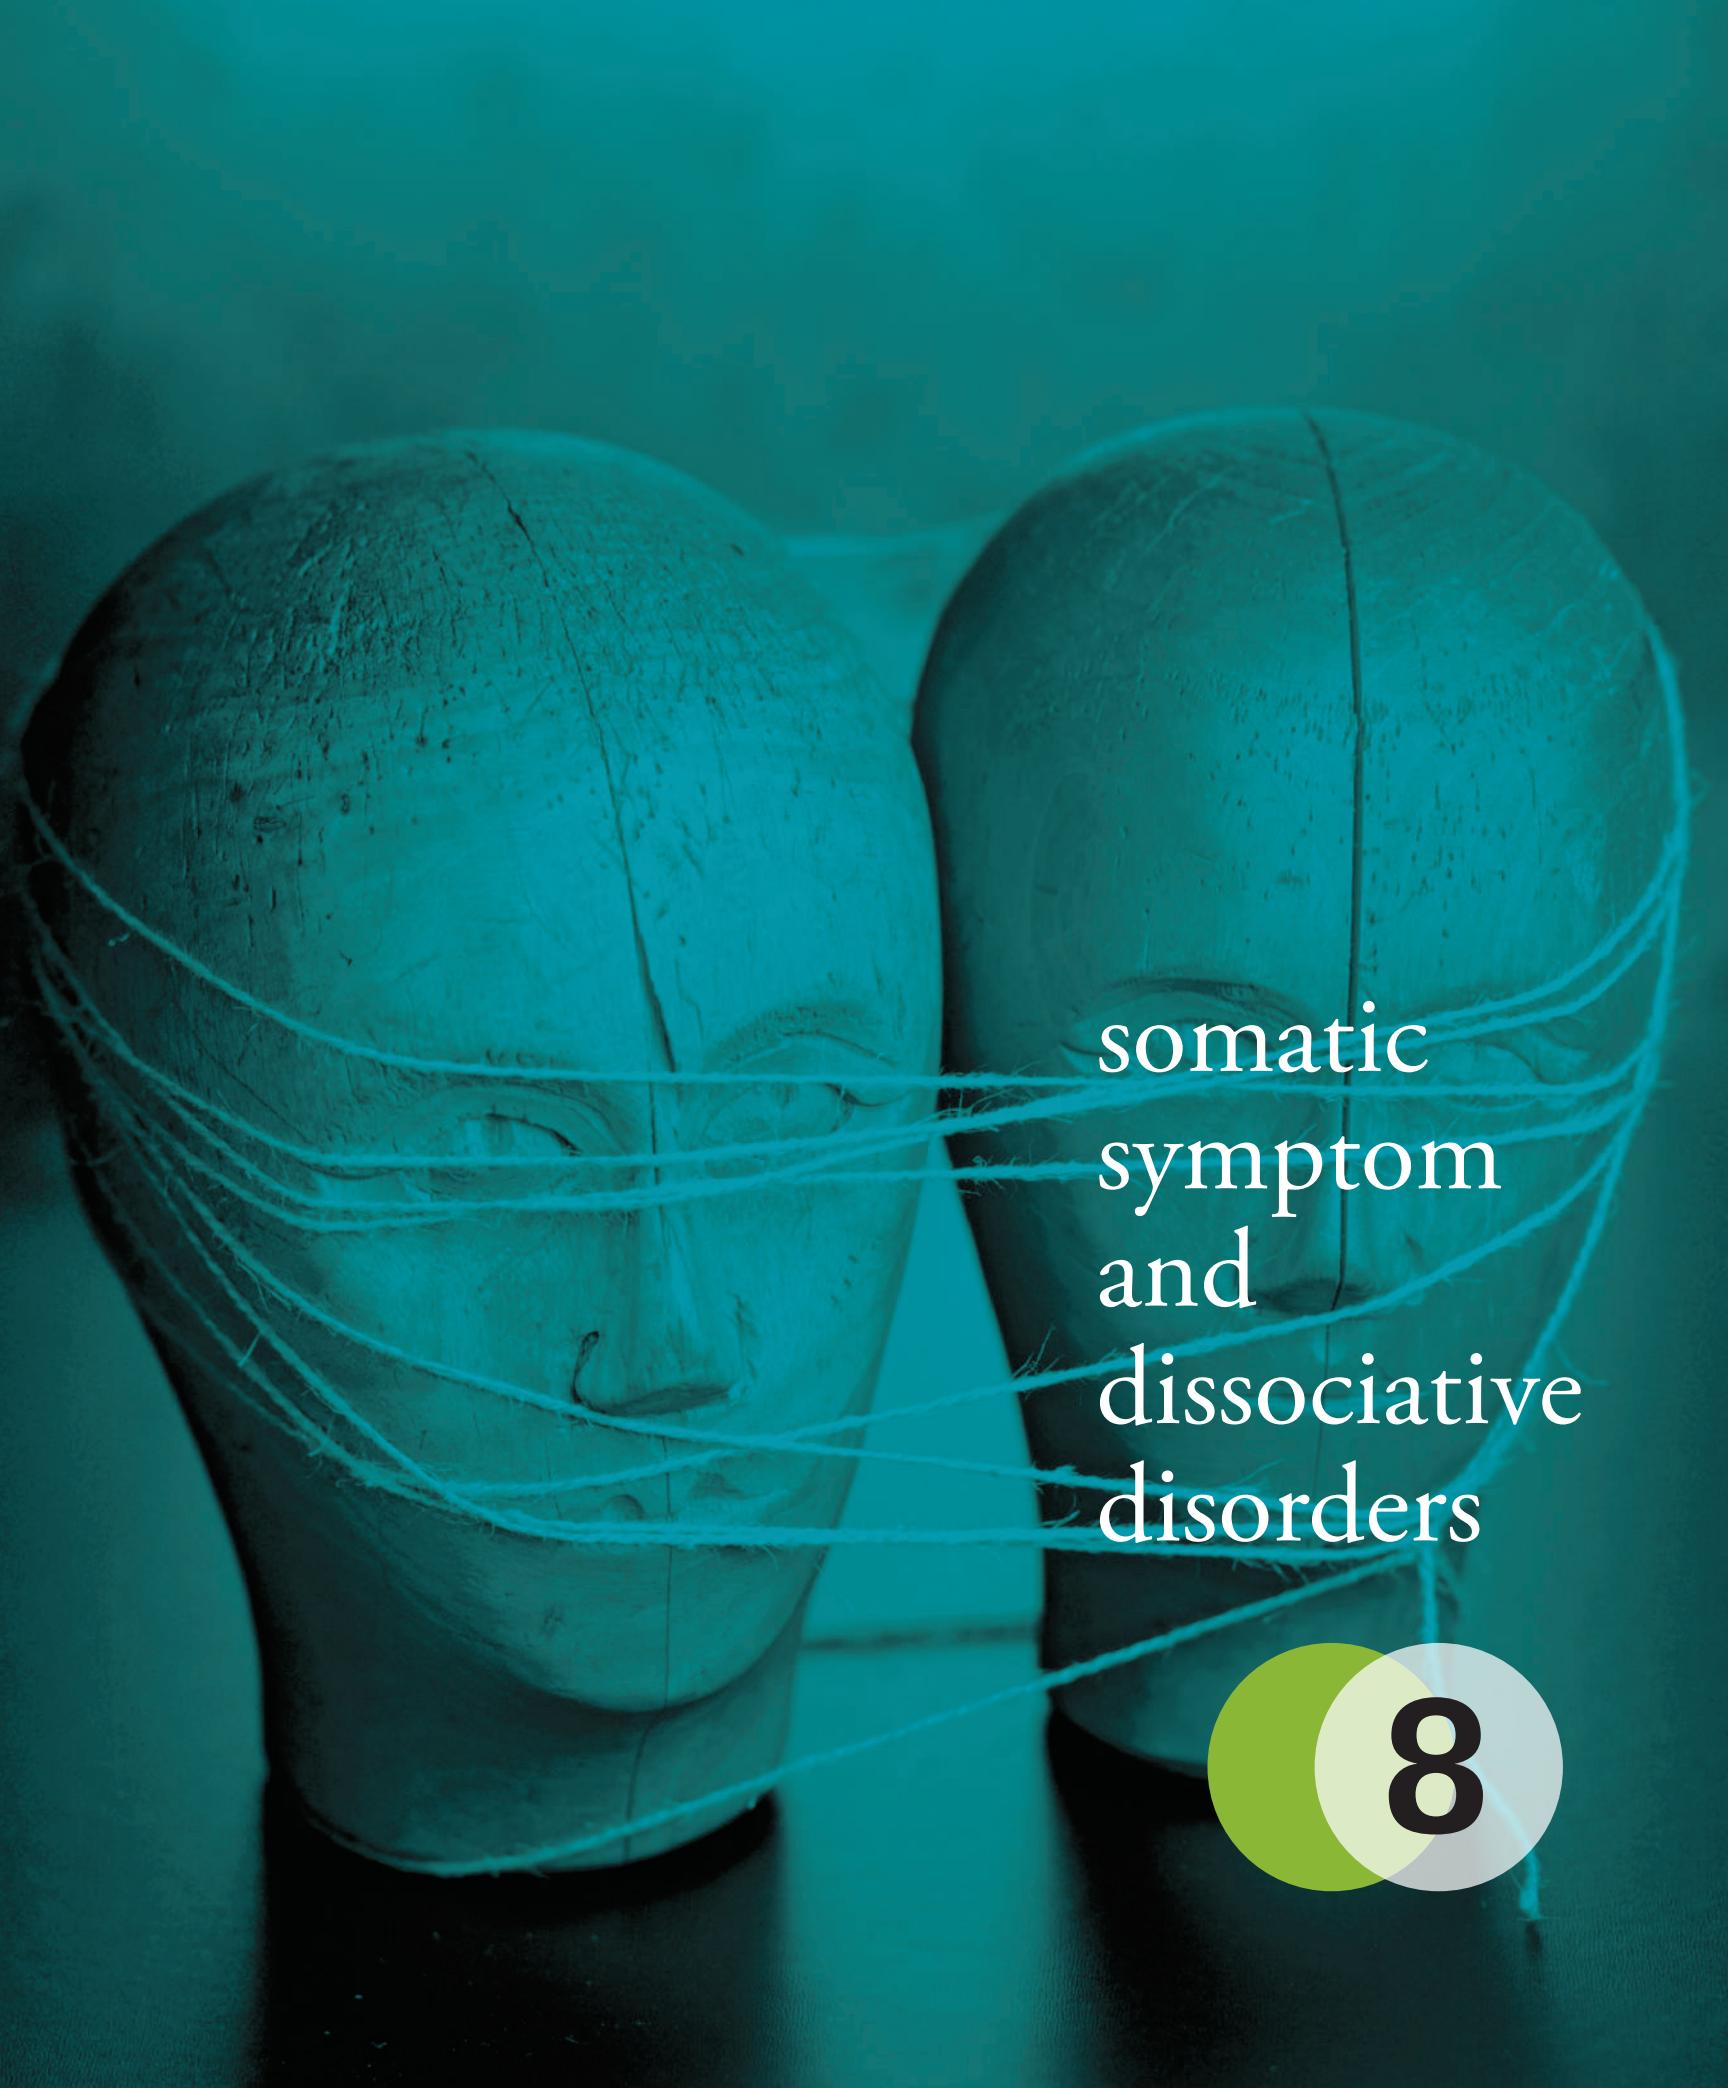

- A small minority of suicides appear unavoidable—chiefly those where the person really wants to die and uses a highly lethal method. However, a substantial amount of suicidal behavior is performed as a means of indirect interpersonal communication.
- Somewhere between these extremes is a large group of people who are ambivalent about killing themselves and who initiate dangerous actions that they may or may not carry to completion, depending on momentary events and impulses.

### 7.9 How can suicide be prevented?

- Suicide prevention (or intervention) programs generally consist of crisis intervention in the form of suicide hotlines. Although these programs undoubtedly avert fatal suicide attempts in some cases, the long-term efficacy of treatment aimed at preventing suicide in those at high risk is much less clear at the present time.

### 8.1

What are somatic symptom disorders?

### 8.2

What is illness anxiety disorder?

### 8.3

What is conversion disorder (functional neurological symptom disorder)?

### 8.4

What is the difference between a factitious disorder and malingering?

### 8.5

What are the primary features of dissociative disorders?

### 8.6

What is depersonalization/derealization disorder?

### 8.7

What is dissociative amnesia?

### 8.8

What is dissociative identity disorder?

Have you ever had the experience, particularly during a time of serious stress, when you felt like you were walking around in a daze or like you just weren't all there? Or have you known people who constantly complained about being sure they had a serious illness even though medical tests failed to show anything wrong? Both of these are examples of mild dissociative and somatic symptoms experienced at least occasionally by many people. However, when these symptoms become frequent and severe and lead to significant distress or impairment, a somatic symptom or dissociative disorder may be diagnosed. *Somatic symptom disorders* (formerly known as **somatoform disorders**) and *dissociative disorders* appear to involve more complex and puzzling patterns of symptoms than those we have so far encountered. As a result, they confront the field of psychopathology with some of its most fascinating and difficult challenges. Unfortunately, however, we do not know much about them—in part because many of them are quite rare and difficult to study.

As we have seen (Chapter 6), both somatic symptom and dissociative disorders were once included with the various anxiety disorders (and neurotic depression) under the general rubric *neuroses*,

where anxiety was thought to be the underlying cause of all neuroses whether or not the anxiety was experienced overtly. But in 1980, when *DSM-III* abandoned attempts to link disorders together on the basis of hypothesized underlying causes (as with neurosis) and instead focused on grouping disorders together on the basis of overt symptomatology, the anxiety, mood, somatic symptom, and dissociative disorders each became separate categories.

## Somatic Symptom and Related Disorders

The **somatic symptom disorders** lie at the interface between abnormal psychology and medicine. They are a group of conditions that involve physical symptoms combined with abnormal thoughts, feelings, and behaviors in response to those symptoms (APA, 2013). **Soma** means “body,” and somatic symptom disorders involve patterns in which individuals complain of bodily symptoms that suggest the presence of medical problems but where there is no obvious medical explanation that can satisfactorily explain the symptoms such as paralysis or pain. Despite a wide range of clinical manifestations, in each case the person is preoccupied with some aspect of her or his health to the extent that she or he shows significant impairments in functioning.

In *DSM-IV* a great deal of emphasis was placed on the idea that the symptoms were medically unexplained. In other words, although the patient's complaints suggested the presence of a medical condition no physical pathology could be found to account for them (Allen & Woolfolk, 2012; Witthöft & Hiller, 2010). In *DSM-5* this idea is less prominent, because it is recognized that medicine is fallible and that a medical explanation for symptoms cannot always be provided. Nonetheless, medically unexplained symptoms are still a key part of some disorders (such as conversion disorder) that we will describe later.

Equally key to these disorders is the fact that the affected patients have no control over their symptoms. They are also not intentionally faking symptoms or attempting to deceive others. For the most part, they genuinely believe something is terribly wrong with them. Not surprisingly, these patients are frequent visitors to their primary-care physicians.

Sometimes, of course, people do deliberately and consciously feign disability or illness. Also placed in the somatic symptoms and related disorders category in *DSM-5* is *factitious disorder*. In **factitious disorder** the person intentionally produces psychological or physical symptoms (or both). Although this may strike you as strange, the person's goal is to obtain and maintain the benefits that playing the “sick role” (even to the extent of undergoing repeated hospitalizations) may provide, including the attention and concern of family and medical personnel. However, there are no tangible external rewards. In this way factitious disorder differs from *malingering*. In **malingering** the person is intentionally producing or grossly exaggerating physical symptoms and is motivated by external incentives such

as avoiding work or military service or evading criminal prosecution (APA, 2013; Maldonado & Spiegel, 2001).

In our discussion, we will focus on four disorders in the somatic symptom and related disorders category. These are (1) somatic symptom disorder; (2) illness anxiety disorder; (3) conversion disorder; and (4) factitious disorder.

## Somatic Symptom Disorders

This new diagnosis includes several disorders that were previously considered to be separate diagnoses in *DSM-IV*. The old disorders of (1) hypochondriasis, (2) somatization disorder, and (3) pain disorder have all now disappeared from *DSM-5*. Most of the people who would in the past have been diagnosed with any one of these disorders will now be diagnosed with a somatic symptom disorder. In each case, individuals must be experiencing chronic somatic symptoms that are distressing to them and they must also be experiencing dysfunctional thoughts, feelings, and/or behaviors. In the past, the diagnosis required evidence that the symptoms were medically unexplained. However, as we noted earlier, this is no longer required for the diagnosis (in part because it is very difficult to prove something is medically unexplainable). Instead the focus in *DSM-5* is on there being at least one of the following three features: (1) disproportionate and persistent thoughts about the seriousness of one's symptoms; (2) persistently high level of anxiety about health or symptoms; and/or (3) excessive time and energy devoted to these symptoms or health concerns (Allen & Woolfolk, 2013). Symptoms have to have persisted for at least six months.

Patients with somatic symptom disorder are usually seen in medical clinics. They are more likely to be female, nonwhite, and less educated than are people with symptoms that have an obvious medical basis. Patients with somatic symptom disorder frequently engage in illness behavior that is dysfunctional, such as seeking additional medical procedures or diagnostic tests when the physician fails to find anything physically wrong with them. Whereas most of us are relieved when tests do not reveal

any problems, people with somatic symptom disorder are likely to think something was missed and therefore seek help from another physician, leading to needlessly high medical bills due to unnecessary tests, hospitalizations, and even surgeries. High levels of functional impairment are common, as is comorbid psychopathology—especially depression and anxiety.

Research suggests that people with somatic symptom disorders tend to have a cognitive style that leads them to be hypersensitive to their bodily sensations. They also experience these sensations as intense, disturbing, and highly aversive. Another characteristic of such patients is that they tend to think catastrophically about their symptoms, often overestimating the medical severity of their condition.

In the following sections, we will be discussing hypochondriasis, pain disorder, and somatization disorder. It's important to note that in *DSM-5*, these disorders were technically dropped and are now part of the somatic symptom disorders. However, the history of and the research on these disorders is still important to understand.

## Hypochondriasis

Approximately 75 percent of people previously diagnosed with hypochondriasis will be diagnosed with somatic symptom disorder in *DSM-5* (APA, 2013). In **hypochondriasis** the person is preoccupied either with fears of contracting a serious disease or with the idea that of having that disease even though they do not. These very distressing preoccupations are thought to all be based on a misinterpretation of one or more bodily signs or symptoms (e.g., being convinced that a slight cough is a sign of lung cancer). Of course the decision that a complaint is hypochondriacal and is based on a misinterpretation of bodily signs or symptoms can only be made after a thorough medical evaluation has failed to find a medical condition that could account for the signs or symptoms. Another typical feature of hypochondriasis

### criteria for Somatic Symptom Disorder

- A. One or more somatic symptoms that are distressing or result in significant disruption of daily life.
- B. Excessive thoughts, feelings, or behaviors related to the somatic symptoms or associated health concerns as manifested by at least one of the following:
  - 1. Disproportionate and persistent thoughts about the seriousness of one's symptoms.
  - 2. Persistently high level of anxiety about health or symptoms.
  - 3. Excessive time and energy devoted to these symptoms or health concerns.
- C. Although any one somatic symptom may not be continuously present, the state of being symptomatic is persistent (typically more than 6 months).

DSM-5

Source: Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, (Copyright 2013). American Psychiatric Association.

is that the person cannot be reassured by the results of a medical evaluation. In other words, the fear or idea of having a disease persists despite lack of medical evidence. Indeed, these individuals are sometimes disappointed when no physical problem is found. The condition has to persist for at least 6 months for the diagnosis to be made so as to not diagnose relatively transient health concerns.

Not surprisingly, people with hypochondriasis usually first see a medical doctor for their physical complaints. Because they are never reassured for long and are inclined to suspect that their doctor has missed something, they sometimes shop for additional doctors, hoping one might discover what their problem really is. Because they repeatedly seek medical advice (e.g., Bleichhardt & Hiller, 2006; Fink et al., 2004), it is hardly surprising that their annual medical costs are much higher than average (e.g., Fink et al., 2010; Hiller et al., 2004). People with hypochondriasis are generally resistant to the idea that their problem is a psychological one that might be best treated by a psychologist or psychiatrist.

Prior to *DSM-5*, hypochondriasis was one of the two most commonly seen somatic symptom disorders with a prevalence in general medical practices of 2 to 7 percent (APA, 2000). Hypochondriasis occurs about equally often in men and women and can start at almost any age, although early adulthood is the most common age of onset. Hypochondriasis is regarded as a persistent disorder if left untreated, although its severity can fluctuate over time. Individuals with hypochondriasis often also suffer from mood disorders, panic disorder, or other types of somatic symptom disorders (Creed & Barsky, 2004). This is one reason why hypochondriasis is now not differentiated from other somatic symptom disorders in *DSM-5*.

**MAJOR CHARACTERISTICS** Individuals with hypochondriasis tend to be highly preoccupied with bodily functions (e.g., heart beats or bowel movements), or with minor physical abnormalities (e.g., a small sore or an occasional cough), or with vague and ambiguous physical sensations (such as a “tired heart” or “aching veins”). They attribute these symptoms to a particular disease and often have intrusive thoughts about it. The diagnoses they make for themselves include cancer, exotic infections, AIDS, and numerous other diseases.

 Watch the Video Henry: Hypochondriasis on

**MyPsychLab**

Although people with hypochondriasis are usually in good physical condition, they are sincere in their conviction that the symptoms they detect represent real illness. In other words, they are not *malingering*—consciously faking symptoms to achieve a specific goal such as winning a personal injury lawsuit. Not surprisingly, given their tendency to doubt the soundness of their doctors’ conclusions (i.e., that they have no medical problem) and recommendations, the relationships they have with their doctors are often marked by conflict and hostility.

The following case captures the typical clinical picture in hypochondriasis. It also demonstrates that a high level of medical sophistication does not necessarily protect someone from developing this or a related disorder.

 **An “Abdominal Mass”** This 38-year-old physician/radiologist initiated his first psychiatric consultation after his 9-year-old son accidentally discovered his father palpating (examining by touch) his own abdomen and said, “What do you think it is this time, Dad?” The radiologist describes the incident and his accompanying anger and shame with tears in his eyes. He also describes his recent return from a 10-day stay at a famous out-of-state medical diagnostic center to which he had been referred by an exasperated gastroenterologist colleague who had reportedly “reached the end of the line” with his radiologist patient. The extensive physical and laboratory examinations performed at the center had revealed no significant physical disease, a conclusion the patient reports with resentment and disappointment rather than relief.

The patient’s history reveals a long-standing pattern of overconcern about personal health matters, beginning at age 13 and exacerbated by his medical school experience. Until fairly recently, however, he had maintained reasonable control over these concerns, in part because he was embarrassed to reveal them to other physicians. He is conscientious and successful in his profession and active in community life. His wife, like his son, has become increasingly impatient with his morbid preoccupation about life-threatening but undetectable diseases.

In describing his current symptoms, the patient refers to his becoming increasingly aware, over the past several months, of various sounds and sensations emanating from his abdomen and of his sometimes being able to feel a “firm mass” in its left lower quadrant. His tentative diagnosis is carcinoma (cancer) of the colon. He tests his stool for blood weekly and palpates his abdomen for 15 to 20 minutes every 2 to 3 days. He has performed several X-ray studies of himself in secrecy after hours at his office.

**CAUSAL FACTORS** Our knowledge of causal factors involved in somatic symptom disorders, including hypochondriasis, is quite minimal. This is especially true when compared to knowledge about the mood and anxiety disorders discussed in the preceding chapters. Currently, cognitive-behavioral views of hypochondriasis are perhaps most widely accepted. These have as a central tenet that it is a disorder of cognition and perception. Misinterpretations of bodily sensations are currently a defining feature of the syndrome, but in the cognitive-behavioral view these misinterpretations also play a causal role. It is believed that

Individuals with hypochondriasis are preoccupied with unrealistic fears of disease. They are convinced that they have symptoms of physical illness, but their complaints typically do not conform to any coherent symptom pattern, and they usually have trouble giving a precise description of their symptoms.

an individual's past experiences with illnesses (in both him- or herself and others, and as observed in the mass media) lead to the development of a set of dysfunctional assumptions about symptoms and diseases that may predispose a person to developing hypochondriasis (Marcus et al., 2007; Salkovskis & Warwick, 2001). These dysfunctional assumptions might include notions such as, "Bodily changes are usually a sign of serious disease, because every symptom has to have an identifiable physical cause" or "If you don't go to the doctor as soon as you notice anything unusual, then it will be too late" (Salkovskis & Bass, 1997, p. 318; see also Marcus et al., 2007).

Because of these dysfunctional assumptions, individuals with hypochondriasis seem to focus excessive attention on symptoms, with experimental studies showing that these individuals do in fact have an attentional bias for illness-related information (Owens et al., 2004; see also Jasper & Witthöft, 2011). Although their physical sensations probably do not differ from those in normal controls (Marcus et al., 2007),

they perceive their symptoms as more dangerous than they really are and judge a particular disease to be more likely or dangerous than it really is. Once they have misinterpreted a symptom, they tend to look for confirming evidence and to discount evidence that they are in good health; in fact, they seem to believe that being healthy means being completely symptom-free (Rief et al., 1998a). They also perceive their probability of being able to cope with the illness as extremely low (Salkovskis & Bass, 1997) and see themselves as weak and unable to tolerate physical effort or exercise (Rief et al., 1998a). All this tends to create a vicious cycle in which their anxiety about illness and symptoms results in physiological symptoms of anxiety, which then provide further fuel for their convictions that they are ill.

If we also consider the secondary reinforcements that individuals with hypochondriasis obtain by virtue of their disorder, we can better understand how such patterns of thought and behavior are maintained in spite of the misery these individuals often experience. Most of us learn as children that when we are sick special comforts and attention are provided and, furthermore, that we may be excused from a number of responsibilities. Barsky and colleagues (1994) found that their patients with hypochondriasis reported much childhood sickness and missing of school. People with hypochondriasis also tend to have an excessive amount of illness in their families while growing up, which may lead to strong memories of being sick or in pain (Pauli & Alpers, 2002), and perhaps also of having observed some of the secondary benefits that sick people sometimes reap (Cote et al., 1996; Kellner, 1985).

Interestingly, one study retested patients with hypochondriasis 4 to 5 years later and found that those who had remitted at follow-up had acquired significantly more (real) major medical problems than their nonremitting counterparts (Barsky et al., 1998). In other words, it appears that hypochondriacal tendencies were reduced by the occurrence of serious medical conditions. The authors suggested that having a serious medical illness "served to legitimize the patients' complaints, sanction their assumption of the sick role, and lessen the skepticism with which they had previously been regarded . . . As one noted, 'Now that I know Dr. X is paying attention to me, I can believe him if he says nothing serious is wrong'" (p. 744).

**TREATMENT OF HYPOCHONDRIASIS** More than a dozen studies on cognitive-behavioral treatment of hypochondriasis have found that it can be a very effective treatment for hypochondriasis (e.g., Barsky & Ahern, 2004; Tyrer, 2011; see also Hedman et al., 2011, for an example of Internet-based Cognitive Behavioral Therapy). The cognitive components of this treatment approach focus on assessing the patient's beliefs about illness and modifying misinterpretations of bodily sensations. The behavioral techniques include having patients

induce innocuous symptoms by intentionally focusing on parts of their body so that they can learn that selective perception of bodily sensations plays a major role in their symptoms. Sometimes they are also directed to engage in response prevention by not checking their bodies as they usually do and by stopping their constant seeking of reassurance. The treatment is relatively brief (6 to 16 sessions) and can be delivered in a group format. In these studies such treatment produced large changes in hypochondriacal symptoms and beliefs as well as in levels of anxiety and depression.

## Somatization Disorder

The *DSM-IV* diagnosis of somatization disorder is another disorder that has now been subsumed into the broader category of somatic symptom disorder in *DSM-5*. **Somatization disorder** is characterized by many different physical complaints. To qualify for the diagnosis, these had to begin before age 30, last for several years, and not be adequately explained by independent findings of physical illness or injury. They also had to have led to medical treatment or to significant life impairment. Not surprisingly, somatization disorder has long been seen most often among patients in primary medical care settings (Guerje et al., 1997; Iezzi et al., 2001). Indeed, patients with this variant of somatic symptom disorder are enormously costly to health care systems because they often have multiple unnecessary hospitalizations and surgeries (Barsky et al., 2005; Hiller et al., 2003).

The *DSM-IV-TR* (APA, 2000) criteria required that patients report a large number of symptoms across a wide range of domains (e.g., 4 pain symptoms, two gastrointestinal symptoms, one sexual symptom and one neurological-type symptom). Thus, to qualify for a diagnosis of somatization disorder, a patient had to have experienced at least 8 out of 33 specified symptoms (Rief & Barsky, 2005). Over time, the rather arbitrary nature of this became increasing apparent and the formal diagnostic criteria began to be modified by many researchers and clinicians (e.g., Rief & Broadbent, 2007). Following suit, in *DSM-5* the long and complicated symptom count is no longer required and somatization disorder is now considered to be just another variant of somatic symptom disorder.

Another advantage of the recent change in *DSM-5* is that it is no longer necessary for us to be concerned about whether somatization disorder and hypochondriasis are really two different and distinct disorders. There are indeed significant similarities between the two conditions. They also sometimes co-occur (Mai, 2004). Some years ago leading researchers in this area expressed concerns about whether somatization disorder and hypochondriasis could really be regarded as separate disorders (e.g., Creed & Barsky, 2004). Combining them both into a common category in *DSM-5* and considering them to be variants of somatic symptom disorder is probably a wise move.

The main features of somatization disorder are illustrated in the following case summary, which also involves a secondary diagnosis of depression.

→ **Not-Yet-Discovered Illness** This 38-year-old married woman, the mother of five children, reports to a mental health clinic with the chief complaint of depression, meeting diagnostic criteria for major depressive disorder . . . . Her marriage has been a chronically unhappy one; her husband is described as an alcoholic with an unstable work history, and there have been frequent arguments revolving around finances, her sexual indifference, and her complaints of pain during intercourse.

The history reveals that the patient . . . describes herself as nervous since childhood and as having been continuously sickly beginning in her youth. She experiences chest pain and reportedly has been told by doctors that she has a "nervous heart." She sees physicians frequently for abdominal pain, having been diagnosed on one occasion as having a "spastic colon." In addition to M.D. physicians, she has consulted chiropractors and osteopaths for backaches, pains in her extremities, and a feeling of anesthesia in her fingertips. She was recently admitted to a hospital following complaints of abdominal and chest pain and of vomiting, during which admission she received a hysterectomy. Following the surgery she has been troubled by spells of anxiety, fainting, vomiting, food intolerance, and weakness and fatigue. Physical examinations reveal completely negative findings.

## DEMOGRAPHICS, COMORBIDITY, AND COURSE OF

**ILLNESS** Somatization disorder usually begins in adolescence and is believed by many to be about three to ten times more common among women than among men. It also tends to occur more among less educated individuals and in lower socioeconomic classes. The lifetime prevalence has been estimated to be between 0.2 and 2.0 percent in women and less than 0.2 percent in men (APA, 2000). Somatization disorder very commonly co-occurred with several other disorders including major depression, panic disorder, phobic disorders, and generalized anxiety disorder. It has generally been considered to be a relatively chronic condition with a poor prognosis, although sometimes the disorder remits spontaneously (e.g., Creed & Barsky, 2004).

**CAUSAL FACTORS IN SOMATIZATION DISORDER** Despite its prevalence in medical settings, researchers are still not certain about the developmental course and specific etiology of somatization disorder. There is evidence that somatization disorder runs in families and that there is a familial linkage between antisocial personality disorder in men (see Chapter 10) and somatization disorder in women. That is, one possibility is that some common, underlying predisposition, probably at least partly genetically based, leads to antisocial behavior in men and to somatization disorder in women (Cale & Lilienfeld, 2002b; Guze et al., 1986; Lilienfeld, 1992). Moreover, somatic symptoms and antisocial

symptoms in women tend to co-occur (Cale & Lilienfeld, 2002b). However, we do not yet have a clear understanding of this relationship. One possibility is that the two disorders are linked through a common trait of impulsivity.

It has also become clear that people with somatization disorder selectively attend to, and show perceptual amplification of, bodily sensations. They also tend to see bodily *sensations* as somatic *symptoms* (Martin et al., 2007). Like patients with hypochondriasis, they tend to catastrophize about minor bodily complaints (taking them as signs of serious physical illness) and to think of themselves as physically weak and unable to tolerate stress or physical activity (Martin et al., 2007; Rief et al., 1998).

**TREATMENT OF SOMATIZATION DISORDER** Somatization disorder was long considered to be extremely difficult to treat, and general practitioners experienced a great deal of uncertainty and frustration in working with these patients. However, in the past 15 years some treatment research has begun to suggest that a certain type of medical management along with cognitive-behavioral treatments may be quite helpful and that general practitioners can be educated in how to better manage and treat somatization patients and be less frustrated by them (Rosendal et al., 2005; see also Edwards & Edwards, 2010). One moderately effective treatment involves identifying one physician who will integrate the patient's care by seeing the patient at regular visits (thereby trying to anticipate the appearance of new problems) and by providing physical exams focused on new complaints (thereby accepting her or his symptoms as valid). At the same time, however, the physician avoids unnecessary diagnostic testing and makes minimal use of medications or other therapies (Looper & Kirmayer, 2002; Mai, 2004). Several studies have found that these patients show substantial decreases in health care expenditures over subsequent months and sometimes an improvement in physical functioning (although not necessarily in psychological distress; e.g., Rost et al., 1994). This type of medical management can be even more effective when combined with cognitive-behavioral therapy that focuses on promoting appropriate behavior, such as better coping and personal adjustment, and discouraging inappropriate behavior such as illness behavior and preoccupation with physical symptoms (e.g., Bleichhardt et al., 2004; Mai, 2004).

### Pain Disorder

The third *DSM-IV* diagnosis subsumed into the new category of somatic symptom disorder is pain disorder. **Pain disorder** is characterized by persistent and severe pain in one or more areas of the body that is not intentionally produced or feigned. Although a medical condition may contribute to the pain, psychological factors are judged to play an important role. Indeed psychological factors play a role in all forms of pain. The pain disorder may be *acute* (duration of less than 6 months) or *chronic*

When one physician integrates a patient's care, the physical functioning of patients with somatization disorder may improve. Why should this be?

(duration of over 6 months). When working with patients with pain disorder it is very important to remember that the pain that is experienced is very real and can hurt as much as pain that comes from other sources. It is also important to note that pain is always, in part, a subjective experience that is private and cannot be objectively identified by others.

The experience of pain is always subjective and private, making pain impossible to assess with pinpoint accuracy. Pain does not always exist in perfect correlation with observable tissue damage or irritation. Psychological factors influence all forms of pain.

The prevalence of pain disorder in the general population is unknown. It is definitely quite common among patients at pain clinics. It is diagnosed more frequently in women than in men and is very frequently comorbid with anxiety or mood disorders, which may occur first or may arise later as a consequence of the pain disorder. People with pain disorder are often unable to work (they sometimes go on disability) or to perform some other usual daily activities. Their resulting inactivity (including an avoidance of physical activity) and social isolation may lead to depression and to a loss of physical strength and endurance. This fatigue and loss of strength can then exacerbate the pain in a kind of vicious cycle (Bouman et al., 1999; Flor et al., 1990). In addition, the behavioral component of pain is quite malleable in the sense that it can increase when it is reinforced by attention, sympathy, or avoidance of unwanted activities (Bouman et al., 1999). Finally, there is suggestive evidence that people who have a tendency to catastrophize about the meaning and effects of pain may be the ones most likely to progress to a state of chronic pain (Seminowicz & Davis, 2006).

**TREATMENT OF PAIN DISORDER** Perhaps because it is a less complex and multifaceted disorder than somatization disorder, pain disorder is usually easier to treat. Indeed, cognitive-behavioral techniques have been widely used in the treatment of both physical and more psychological pain syndromes. Treatment programs generally include relaxation training, support and validation that the pain is real, scheduling of daily activities, cognitive restructuring, and reinforcement of “no-pain” behaviors (Simon, 2002). Patients receiving such treatments tend to show substantial reductions in disability and distress, although changes in the intensity of their pain tend to be

smaller in magnitude. In addition, antidepressant medications (especially the tricyclic antidepressants) and certain SSRIs have been shown to reduce pain intensity in a manner independent of the effects the medications may have on mood (Aragona et al., 2005; Simon, 2002).

**ILLNESS ANXIETY DISORDER** Illness anxiety disorder is new to *DSM-5*. In this newly identified disorder, people have high anxiety about having or developing a serious illness. This anxiety is distressing and/or disruptive but there are very few (mild) somatic symptoms. (see the *DSM-5* criteria box below).

It is estimated that around 25 percent of people who would have been diagnosed with hypochondriasis in *DSM-IV* will be diagnosed with illness anxiety disorder in *DSM-5* (APA, 2013).

## Conversion Disorder (Functional Neurological Symptom Disorder)

**Conversion disorder** is one of the most intriguing and baffling patterns in psychopathology, and we still have much to learn about it. It involves a pattern in which symptoms or deficits affecting the senses or motor behavior strongly suggest that the patient has a medical or neurological condition. However, upon a thorough medical examination, it becomes apparent that the pattern of symptoms or deficits cannot be fully explained by any known medical condition. A few typical examples include partial paralysis, blindness, deafness, and pseudoseizures. The person is not intentionally producing or faking the symptoms. Rather, psychological factors are often judged to play an important role because symptoms usually

### criteria for Illness Anxiety Disorder

DSM-5

- A. Preoccupation with having or acquiring a serious illness.
- B. Somatic symptoms are not present or, if present, are only mild in intensity. If another medical condition is present or there is a high risk for developing a medical condition (e.g., strong family history is present), the preoccupation is clearly excessive or disproportionate.
- C. There is a high level of anxiety about health, and the individual is easily alarmed about personal health status.
- D. The individual performs excessive health-related behaviors (e.g., repeatedly checks his or her body for signs of illness) or exhibits maladaptive avoidance (e.g., avoids doctor appointments and hospitals).
- E. Illness preoccupation has been present for at least 6 months, but the specific illness that is feared may change over that period of time.
- F. The illness-related preoccupation is not better explained by another mental disorder, such as somatic symptom disorder, panic disorder, generalized anxiety disorder, body dysmorphic disorder, obsessive-compulsive disorder, or delusional disorder, somatic type.

either start or are exacerbated by preceding emotional or interpersonal conflicts or stressors.

Early observations dating back to Freud suggested that most people with conversion disorder showed very little of the anxiety and fear that would be expected in a person with a paralyzed arm or loss of sight. This seeming lack of concern (known as *la belle indifférence*—French for “the beautiful indifference”) in the way the patient describes what is wrong was thought for a long time to be an important diagnostic criterion for conversion disorder. However, more careful research later showed that *la belle indifférence* actually occurs in only about 20 percent of patients with conversion disorder, so it was dropped as a criterion from recent editions of the *DSM* (Stone et al., 2006, 2011).

The term *conversion disorder* is relatively recent. Historically this disorder was one of several disorders that were grouped together under the term **hysteria**.

Freud used the term *conversion hysteria* for these disorders (which were fairly common in his practice) because he believed that the symptoms were an expression of repressed sexual energy—that is, the *unconscious conflict* that a person felt about his or her repressed sexual desires. However, in Freud’s view, the repressed anxiety threatens to become conscious, so it is unconsciously *converted* into a bodily disturbance, thereby allowing the person to avoid having to deal with the conflict. For example, a person’s guilty feelings about the desire to masturbate might be solved by developing a paralyzed hand. This is not done consciously, of course, and the person is not aware of the origin or meaning of the physical symptom. Freud also thought that the reduction in anxiety and intrapsychic conflict was the “primary gain” that maintained the condition, but he noted that patients often had many sources of “secondary gain” as well, such as receiving sympathy and attention from loved ones. Authors of *DSM-5* had many suggestions for changing the name of this disorder (e.g., to psychogenic, functional, and dissociative). In the end, a conservative approach was taken and the term conversion

disorder was retained, although this is now followed in parentheses by “Functional neurological symptom disorder” (Stone et al., 2011).

### PRECIPITATING CIRCUMSTANCES, ESCAPE, AND

**SECONDARY GAINS** Freud’s theory that conversion symptoms are caused by the conversion of sexual conflicts or other psychological problems into physical symptoms is no longer accepted outside psychodynamic circles. However, many of Freud’s astute clinical observations about primary and secondary gain are still incorporated into contemporary views of conversion disorder. Although the condition is still called a conversion disorder, the physical symptoms are usually seen as serving the rather obvious function of providing a plausible bodily “excuse” enabling an individual to escape or avoid an intolerably stressful situation without having to take responsibility for doing so. Typically, it is thought that the person first experiences a traumatic event that motivates the desire to escape the unpleasant situation, but literal escape may not be feasible or socially acceptable. Moreover, although becoming sick or disabled is more socially acceptable, this is true only if the person’s motivation to do so is unconscious.

Thus, in contemporary terms, the **primary gain** for conversion symptoms is continued escape or avoidance of a stressful situation. Because this is all unconscious (i.e., the person sees no relation between the symptoms and the stressful situation), the symptoms go away only if the stressful situation has been removed or resolved. Relatedly, the term **secondary gain**, which originally referred to advantages that the symptom(s) bestow beyond the “primary gain” of neutralizing intrapsychic conflict, has also been retained. Generally, it is used to refer to any “external” circumstance, such as attention from loved ones or financial compensation, that would tend to reinforce the maintenance of disability.

Given the important role often attributed to stressful life events in precipitating the onset of conversion disorder, it is unfortunate that little is actually known about the exact nature

### Criteria for Conversion Disorder

- A. One or more symptoms of altered voluntary motor or sensory function.
- B. Clinical findings provide evidence of incompatibility between the symptom and recognized neurological or medical conditions.
- C. The symptom or deficit is not better explained by another medical or mental disorder.

- D. The symptom or deficit causes clinically significant distress or impairment in social, occupational, or other important areas of functioning or warrants medical evaluation.

**DSM-5**

and timing of these psychological stress factors (Roelofs et al., 2005). However, one study compared the frequency of stressful life events in the recent past in patients with conversion disorder and depressed controls and did not find a difference in frequency between them. Moreover, the greater the negative impact of the preceding life events, the greater the severity of the conversion disorder symptoms (Roelofs et al., 2005). Another study compared levels of a neurobiological marker of stress (lower levels of brain-derived neurotropic factor) in individuals with conversion disorder versus major depression versus no disorder. Both those with depression and those with conversion disorder showed reduced levels of this marker relative to the nondisordered controls (Deveci et al., 2007). This also provides support for the link between stress and the onset of conversion disorder.

### DECREASING PREVALENCE AND DEMOGRAPHIC

**CHARACTERISTICS** Conversion disorders were once relatively common in civilian and (especially) military life. In World War I, conversion disorder was the most frequently diagnosed psychiatric syndrome among soldiers; it was also relatively common during World War II. Conversion disorder typically occurred under highly stressful combat conditions and involved men who would ordinarily be considered stable. Here, conversion symptoms—such as paralysis of the legs—enabled a soldier to avoid an anxiety-arousing combat situation without being labeled a coward or being subject to court-martial.

Conversion disorders are found in approximately 50 percent of people referred for treatment at neurology clinics. The prevalence in the general population is unknown, but even the highest estimates have been around only 0.005 percent (APA, 2013). Interestingly, this decreased prevalence seems to be closely related to our growing sophistication about medical and psychological disorders: A conversion disorder apparently loses its defensive function if it can be readily shown to lack a medical basis. When it does occur today, it is most likely to occur in rural people from lower socioeconomic circles who are medically unsophisticated. For example, a highly unusual “outbreak” of cases of severe conversion disorder involving serious motor weakness and wasting symptoms was reported in five 9- to 13-year-old girls living in a small, poor, rural Amish community. Each of these girls had experienced substantial psychosocial stressors including behavioral problems, dysfunctional family dynamics, and significant community stress from a serious local church crisis (see Cassady et al., 2005). Fortunately, after the caregivers of these girls were educated regarding the psychological nature of the symptoms and given advice to stick with one doctor, minimize stress, and avoid reinforcement of the “sick role,” four of the five girls showed significant improvement over the next 3 months. In the fifth case, the family refused to acknowledge the psychological component of the illness, holding to the belief that the symptoms were caused by parasites.

Conversion disorders were fairly common during World War I and World War II. The disorder typically occurred in otherwise “normal” men during stressful combat conditions. The symptoms of conversion disorder (e.g., paralysis of the legs) enabled a soldier to avoid high-anxiety combat situations without being labeled a coward or being court-martialed.

Conversion disorder occurs two to three times more often in women than in men (APA 2013). It can develop at any age but most commonly occurs between early adolescence and early adulthood (Maldonado & Spiegel, 2001). It generally has a rapid onset after a significant stressor and often resolves within 2 weeks if the stressor is removed, although it commonly recurs. In many other cases, however, it has a more chronic course. Like most other somatic symptom disorders, conversion disorder frequently occurs along with other disorders, especially major depression, anxiety disorders, and other forms of somatic symptom or dissociative conditions.

**RANGE OF CONVERSION DISORDER SYMPTOMS** The range of symptoms for conversion disorder is practically as diverse as it is for physically based ailments. In describing the clinical picture in conversion disorder, it is useful to think in terms of four categories of symptoms: (1) sensory, (2) motor, (3) seizures, and (4) a mixed presentation of the first three categories (APA, 2013).

**Sensory Symptoms or Deficits** Conversion disorder can involve almost any sensory modality, and it can often be

diagnosed as a conversion disorder because symptoms in the affected area are inconsistent with how known anatomical sensory pathways operate. Today the sensory symptoms or deficits are most often in the visual system (especially blindness and tunnel vision), in the auditory system (especially deafness), or in the sensitivity to feeling (especially the anesthesias). In the *anesthesias*, the person loses her or his sense of feeling in a part of the body. One of the most common is *glove anesthesia*, in which the person cannot feel anything on the hand in the area where gloves are worn, although the loss of sensation usually makes no anatomical sense.

With conversion blindness, the person reports that he or she cannot see and yet can often navigate about a room without bumping into furniture or other objects. With conversion deafness, the person reports not being able to hear and yet orients appropriately upon “hearing” his or her own name. Such observations lead to obvious questions: In conversion blindness (and deafness), can affected people actually not see (or hear), or is the sensory information received but screened from consciousness? In general, the evidence supports the idea that the sensory input is registered but is somehow screened from explicit conscious recognition (explicit perception).

**Motor Symptoms or Deficits** Motor conversion reactions also cover a wide range of symptoms (e.g., Maldonado & Spiegel, 2001; see also Stone et al., 2010). For example, conversion paralysis is usually confined to a single limb such as an arm or a leg, and the loss of function is usually selective for certain functions. For example, a person may not be able to write but may be able to use the same muscles for scratching, or a person may not be able to walk most of the time but may be able to walk in an emergency such as a fire where escape is important. The most common speech-related conversion disturbance is *aphonia*, in which a person is able to talk only in a whisper although he or she can usually cough in a normal manner. (In true, organic laryngeal paralysis, both the cough and the voice are affected.) Another common motor symptom, called *globus hystericus*, is difficulty swallowing or the sensation of a lump in the throat (Finkenbine & Miele, 2004).

**Seizures** Conversion seizures, another relatively common form of conversion symptom, involve pseudoseizures, which resemble epileptic seizures in some ways but can usually be fairly well differentiated via modern medical technology (Bowman & Markand, 2005; Stonnington et al., 2006). For example, patients with pseudoseizures do not show any EEG abnormalities and do not show confusion and loss of memory afterward, as patients with true epileptic seizures do. Moreover, patients with conversion seizures often show excessive thrashing about and writhing not seen with true seizures, and they rarely injure themselves in falls or lose control over their bowels or bladder, as patients with true seizures frequently do.

The following case of conversion disorder clearly shows how “functional” a conversion disorder may be in the overall life

circumstances of a patient despite its exacting a certain cost in illness or disability.

→ **A Wife with “Fits”** Mrs. Chatterjee, a 26-year-old patient, attends a clinic in New Delhi, India, with complaints of “fits” for the last 4 years. The “fits” are always sudden in onset and usually last 30 to 60 minutes. A few minutes before a fit begins, she knows that it is imminent, and she usually goes to bed. During the fits she becomes unresponsive and rigid throughout her body, with bizarre and thrashing movements of the extremities. Her eyes close and her jaw is clenched, and she froths at the mouth. She frequently cries and sometimes shouts abuses. She is never incontinent of urine or feces, nor does she bite her tongue. After a “fit” she claims to have no memory of it. These episodes recur about once or twice a month. She functions well between the episodes.

Both the patient and her family believe that her “fits” are evidence of a physical illness and are not under her control. However, they recognize that the fits often occur following some stressor such as arguments with family members or friends . . . . She is described by her family as being somewhat immature but “quite social” and good company. She is self-centered, she craves attention from others, and she often reacts with irritability and anger if her wishes are not immediately fulfilled. On physical examination, Mrs. Chatterjee was found to have mild anemia but was otherwise healthy. A mental status examination did not reveal any abnormality . . . and her memory was normal. An electroencephalogram showed no seizure activity.

## IMPORTANT ISSUES IN DIAGNOSING CONVERSION DISORDER

**DISORDER** Because the symptoms in conversion disorder can simulate a variety of medical conditions, accurate diagnosis can be extremely difficult. It is crucial that a person with suspected conversion symptoms receive a thorough medical and neurological examination. Unfortunately, however, misdiagnoses can still occur. Nevertheless, as medical tests (especially brain imaging) have become increasingly sophisticated, the rate of misdiagnoses has declined substantially from in the past, with estimates of misdiagnoses in the 1990s at only 4 percent down from nearly 30 percent in the 1950s (e.g., Stone et al., 2005).

Several other criteria are also commonly used for distinguishing between conversion disorders and true neurological disturbances:

- The frequent failure of the dysfunction to conform clearly to the symptoms of the particular disease or disorder simulated. For example, little or no wasting away or atrophy of

Virtually all the symptoms of conversion disorder can be temporarily reduced or reproduced by hypnotic suggestion.

a “paralyzed” limb occurs in conversion paralyses, except in rare and long-standing cases.

- The selective nature of the dysfunction. As already noted, in conversion blindness the affected individual does not usually bump into people or objects, and “paralyzed” muscles can be used for some activities but not others.
- Under hypnosis or narcosis (a sleeplike state induced by drugs), the symptoms can usually be removed, shifted, or re-induced at the suggestion of the therapist. Similarly, a person abruptly awakened from a sound sleep may suddenly be able to use a “paralyzed” limb.

**TREATMENT OF CONVERSION DISORDER** Our knowledge of how best to treat conversion disorder is very limited because few well-controlled studies have yet been conducted (e.g., Bowman & Markand, 2005; Looper & Kirmayer, 2002). However, it is known that some hospitalized patients with motor conversion symptoms have been successfully treated with a behavioral approach in which specific exercises are prescribed in order to increase movement or walking, and

then reinforcements (e.g., praise and gaining privileges) are provided when patients show improvements. Any reinforcements of abnormal motor behaviors are removed in order to eliminate any sources of secondary gain. In one small study using this kind of treatment for 10 patients, all had regained their ability to move or walk in an average of 12 days, and for seven of the nine patients available at approximately 2-year follow-up, the improvements had been maintained (Speed, 1996). At least one study has also used cognitive-behavior therapy to successfully treat psychogenic seizures (LaFrance et al., 2009). Some studies have used hypnosis combined with other problem-solving therapies, and there are some suggestions that hypnosis, or adding hypnosis to other therapeutic techniques, can be useful (Looper & Kirmayer, 2002; Moene et al., 2003).

### Distinguishing Somatization, Pain, and Conversion Disorders from Malingering and Factitious Disorder

Earlier we mentioned that the *DSM* distinguishes between *malingering* and *factitious disorder* on the basis of the feigning person’s apparent goals. Malingering is diagnosed if the person is intentionally producing or grossly exaggerating physical symptoms and is motivated by external incentives such as avoiding work or obtaining financial compensation. Factitious disorder is diagnosed if the person intentionally produces psychological or physical symptoms, the person’s goal being simply to obtain and maintain the personal benefits that playing the “sick role” (even undergoing repeated hospitalizations) may provide, including the attention and concern of family and medical personnel. In factitious disorder, frequently these patients surreptitiously alter their own physiology—for example, by taking drugs—in order to simulate various real illnesses. Indeed, they may be at risk for serious injury or death and may even need to be committed to an institution for their own protection. The World Around Us box above describes a particularly pathological variation on this theme. In the past, severe and chronic forms of factitious

#### criteria for Factitious Disorder

DSM-5

##### Factitious Disorder Imposed on Self

- A. Falsification of physical or psychological signs or symptoms, or induction of injury or disease, associated with identified deception.
- B. The individual presents himself or herself to others as ill, impaired, or injured.

- C. The deceptive behavior is evident even in the absence of obvious external rewards.
- D. The behavior is not better explained by another mental disorder, such as delusional disorder or another psychotic disorder.

Source: Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, (Copyright 2013). American Psychiatric Association.

## Factitious Disorder Imposed on Another (Munchausen's Syndrome by Proxy)

**I**n a somewhat bizarre variant of factitious disorder called **factitious disorder imposed on another** (or *Munchausen's syndrome by proxy*), the person seeking medical help or consulting a mental health professional has intentionally produced a medical or psychiatric illness (or appearance of an illness) in another person who is under his or her care (usually a child; e.g.,

Over a period of 20 months, Jennifer, 8, shown here with her mother, Kathy Bush, was taken to the hospital more than 130 times, underwent 40 surgeries, and amassed over \$3 million in medical expenses. Doctors and nurses testified that Jennifer's condition always worsened after her mother visited her daughter at the hospital behind closed doors. In addition, Jennifer's health had significantly improved since being removed from her mother's care. The jury was convinced that Kathy Bush was responsible for causing Jennifer's illnesses. Bush was arrested and diagnosed with Munchausen's syndrome by proxy.

Pankratz, 2006). In a typical instance, a mother presents her own child for treatment of a medical condition she has deliberately caused, disclaiming any knowledge of its origin. Of course, the health of such victims is often seriously endangered by this repeated abuse, and the intervention of social service agencies or law enforcement is sometimes necessary. In as many as 10 percent of cases, this atypical form of child abuse may lead to a child's death (Hall et al., 2000).

This disorder may be indicated when the victim's clinical presentation is atypical, when lab results are inconsistent with each other or with recognized diseases, or when there are unduly frequent returns or increasingly urgent visits to the same hospital or clinic. The perpetrators (who often have extensive medical knowledge) tend to be highly resistant to admitting the truth (McCann, 1999), and it has been estimated that the average length of time to confirm the diagnosis is 14 months (Rogers, 2004). If the perpetrator senses that the medical staff is suspicious, he or she may abruptly terminate contact with that facility, only to show up at another one to begin the entire process anew. Compounding the problem of detection is the fact that health care professionals who realize they have been duped may be reluctant to acknowledge their fallibility for fear of legal action. Misdiagnosing the disorder when the parent is in fact innocent can also lead to legal difficulties for the health care professionals (McNicholas et al., 2000; Pankratz, 2006). One technique that has been used with considerable success is covert video surveillance of the mother and child during hospitalizations. In one study, 23 of 41 suspected cases were finally determined to have factitious disorder by proxy, and in 56 percent of those cases video surveillance was essential to the diagnosis (Hall et al., 2000).

disorder with physical symptoms were called "Munchausen's syndrome," where the general idea was that the person had some kind of "hospital addiction" or a "professional patient" syndrome.

It is sometimes possible to distinguish between a conversion (or other somatic symptom) disorder and malingering, or factitiously "sick-role-playing," with a fair degree of confidence, but in other cases it is more difficult to make the correct diagnosis. Persons engaged in malingering (for which there are no formal diagnostic criteria) and those who have factitious disorder are consciously perpetrating frauds by faking the symptoms of diseases or disabilities, and this fact is often reflected in their demeanor. In contrast, individuals with conversion disorders (as well as with other somatic symptom disorders) are not consciously producing their symptoms,

feel themselves to be the "victims of their symptoms," and are very willing to discuss them, often in excruciating detail (Maldonado & Spiegel, 2001, p. 109). When inconsistencies in their behaviors are pointed out, they are usually unperturbed. Any secondary gains they experience are byproducts of the conversion symptoms themselves and are not involved in motivating the symptoms. On the other hand, persons who are feigning symptoms are inclined to be defensive, evasive, and suspicious when asked about them; they are usually reluctant to be examined and slow to talk about their symptoms lest the pretense be discovered. Should inconsistencies in their behaviors be pointed out, deliberate deceivers as a rule immediately become more defensive. Thus conversion disorder and deliberate faking of illness are considered distinct patterns.

## in review

- What are the primary characteristics of hypochondriasis, and how does the cognitive-behavioral viewpoint explain their occurrence?
- What are the symptoms of somatization disorder and of pain disorder?
- What are sources of primary and secondary gains involved in conversion disorders, and how is conversion disorder distinguished from malingering and from factitious disorder?

## Dissociative Disorders

**Dissociative disorders** are a group of conditions involving disruptions in a person's normally integrated functions of consciousness, memory, identity, or perception (APA, 2013; Spiegel et al., 2013). Included here are some of the more dramatic phenomena in the entire domain of psychopathology: people who cannot recall who they are or where they may have come from, and people who have two or more distinct identities or personality states that alternately take control of the individual's behavior.

The term **dissociation** refers to the human mind's capacity to engage in complex mental activity in channels split off from, or independent of, conscious awareness (Kihlstrom, 1994, 2001, 2005). The concept of dissociation was first promoted over a century ago by the French neurologist Pierre Janet (1859–1947). We all dissociate to a degree some of the time. Mild dissociative symptoms occur when we daydream or lose track of what is going on around us, when we drive miles beyond our destination without realizing how we got there, or when we miss part of a conversation we are engaged in. As these everyday examples suggest, there is nothing inherently pathological about dissociation itself. Dissociation only becomes pathological when the dissociative symptoms are "perceived as disruptive, invoking a loss of needed information, as producing discontinuity of experience" or as "recurrent, jarring involuntary intrusions into executive functioning and sense of self" (Spiegel et al., 2011, p. E19).

Much of the mental life of all human beings involves automatic nonconscious processes that are to a large extent autonomous with respect to deliberate, self-aware direction and monitoring. Such unaware processing extends to the areas of implicit memory and implicit perception, where it can be demonstrated that all persons routinely show indirect evidence of remembering things they cannot consciously recall (**implicit memory**) and respond to sights or sounds as if they had perceived them (as in conversion blindness or deafness) even though they cannot report that they have seen or heard them (**implicit perception**; Kihlstrom, 2001, 2005; Kihlstrom et al., 1993). As we learned in Chapter 3, the general idea of unconscious mental processes has been embraced by psychodynamically oriented clinicians for many years. But only in the past 30 years has it also become a major research area in the field of cognitive psychology (though without any of the psychodynamic implications for why so much of our mental activity is unconscious).

In people with dissociative disorders, however, this normally integrated and well-coordinated multichannel quality of human cognition becomes much less coordinated and integrated. When this happens, the affected person may be unable to access information that is normally in the forefront of consciousness, such as his or her own personal identity or details of an important period of time in the recent past. That is, the normally useful capacity of maintaining ongoing mental activity outside of awareness appears to be subverted, sometimes for the purpose of managing severe psychological threat. When that happens, we observe the pathological dissociative symptoms that are the cardinal characteristic of dissociative disorders. Like somatic symptom disorders, dissociative disorders appear mainly to be ways of avoiding anxiety and stress and of managing life problems that threaten to overwhelm the person's usual coping resources. Both types of disorders also enable the individual to deny personal responsibility for his or her "unacceptable" wishes or behavior. In the case of *DSM*-defined dissociative disorders, the person avoids the stress by pathologically dissociating—in essence, by escaping from his or her own autobiographical memory or personal identity. The *DSM-5* recognizes several types of pathological dissociation. These include depersonalization/derealization disorder, dissociative amnesia, dissociative fugue (a subtype of dissociative amnesia) and dissociative identity disorder.

### Depersonalization/Derealization Disorder

Two of the more common kinds of dissociative symptoms are derealization and depersonalization. We mentioned these in Chapter 6 because they sometimes occur during panic attacks. In **derealization** one's sense of the reality of the outside world is temporarily lost, and in **depersonalization** one's sense of one's own self and one's own reality is temporarily lost. As many as 50–74 percent of us have such experiences in mild form at least once in our lives, usually during or after periods of severe stress, sleep deprivation, or sensory deprivation (e.g., Khazaal et al., 2005; Reutens et al., 2010). But when episodes of depersonalization or derealization become persistent and recurrent and interfere with normal functioning, **depersonalization/derealization disorder** may be diagnosed.

In this disorder, people have persistent or recurrent experiences of feeling detached from (and like an outside observer of) their own bodies and mental processes. They may even feel they are, for a time, floating above their physical bodies, which may suddenly feel very different—as if drastically changed or unreal. During periods of depersonalization, unlike during psychotic states, reality testing remains intact. The related experience of derealization, in which the external world is perceived as strange and new in various ways, may also occur. As one leader in the field described it, in both states "the feeling puzzles the experiencers: the changed condition is perceived as unreal, and as discontinuous with his or her previous ego-states. The object of the experience, self (in depersonalization) or world (in derealization), is commonly described as isolated, lifeless, strange,

- A. The presence of persistent or recurrent experiences of depersonalization, derealization, or both:
  - 1. **Depersonalization:** Experiences of unreality, detachment, or being an outside observer with respect to one's thoughts, feelings, sensations, body, or actions (e.g., perceptual alterations, distorted sense of time, unreal or absent self, emotional and/or physical numbing).
  - 2. **Derealization:** Experiences of unreality or detachment with respect to surroundings (e.g., individuals or objects are experienced as unreal, dreamlike, foggy, lifeless, or visually distorted).
- B. During the depersonalization or derealization experiences, reality testing remains intact.

- C. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- D. The disturbance is not attributable to the physiological effects of a substance (e.g., a drug of abuse, medication) or another medical condition (e.g., seizures).
- E. The disturbance is not better explained by another mental disorder, such as schizophrenia, panic disorder, major depressive disorder, acute stress disorder, posttraumatic stress disorder, or another dissociative disorder.

Source: Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, (Copyright 2013). American Psychiatric Association.

People with derealization symptoms experience the world as hazy and indistinct.

and unfamiliar; oneself and others are perceived as ‘automatons,’ behaving mechanically, without initiative or self-control” (Kihlstrom, 2001, p. 267). Often people also report feeling as though they are living in a dream or movie (Maldonado et al., 2002). In keeping with such reports, research has shown that emotional experiences are attenuated or reduced during depersonalization—both at the subjective level and at the level of neural and autonomic activity that normally accompanies emotional responses to threatening or unpleasant emotional stimuli (Lemche et al., 2007; Phillips & Sierra, 2003; Stein & Simeon, 2009). After viewing an emotional video clip, participants with depersonalization disorder showed higher levels of subjective and objective memory fragmentation than controls (Giesbrecht et al., 2010). Memory fragmentation is marked by difficulties forming an accurate or coherent narrative sequence of events, which is consistent with earlier research suggesting that time distortion is a key element of the experience of depersonalization (Simeon et al., 2008).

A number of researchers have noted elevated rates of comorbid anxiety and mood disorders as well as avoidant, borderline, and obsessive-compulsive personality disorders (e.g., Hunter

et al., 2003; Mula et al., 2007; Reutens et al., 2010). Another study of over 200 cases found that the disorder had an average age of onset of 23. Moreover, in nearly 80 percent of cases, the disorder has a fairly chronic course (with little or no fluctuation in intensity; Baker, Hunter, et al., 2003).

The case of the foggy student below is fairly typical.

→ **A Foggy Student** A 20-year-old male college student sought psychiatric consultation because he was worried that he might be going insane. For the past 2 years he had experienced increasingly frequent episodes of feeling “outside” himself. These episodes were accompanied by a sense of deadness in his body. In addition, during these periods he was uncertain of his balance and frequently stumbled into furniture; this was more apt to occur in public, especially if he was somewhat anxious. During these episodes he felt a lack of easy, natural control of his body, and his thoughts seemed “foggy” as well . . . .

The patient’s subjective sense of lack of control was especially troublesome, and he would fight it by shaking his head and saying “stop” to himself. This would momentarily clear his mind and restore his sense of autonomy, but only temporarily, as the feelings of deadness and of being outside himself would return. Gradually, over a period of several hours, the unpleasant experiences would fade . . . . At the time the patient came for treatment, he was experiencing these symptoms about twice a week, and each incident lasted from 3 to 4 hours. On several occasions the episodes had occurred while he was driving his car and was alone; worried that he might have an accident, he had stopped driving unless someone accompanied him.

The lifetime prevalence of depersonalization/derealization disorder is unknown but has been estimated at 1 to 2 percent of the population (Reutens et al., 2010). Moreover, occasional depersonalization/derealization symptoms are not uncommon in a variety of other disorders such as schizophrenia, borderline personality disorder, panic disorder, acute stress disorder, and posttraumatic stress disorder (PTSD) (Hunter et al., 2003). Although severe depersonalization/derealization symptoms can be quite frightening and may make the victim fear imminent mental collapse, such fears are usually unfounded. Sometimes, however, feelings of depersonalization are clearly early manifestations of impending decompensation and the development of psychotic states (Chapter 13). In either case, professional assistance in dealing with the precipitating stressors and in reducing anxiety may be helpful. Unfortunately, however, as of yet there are no clearly effective treatments—either through medication or psychotherapy.

### Dissociative Amnesia and Dissociative Fugue

*Retrograde amnesia* is the partial or total inability to recall or identify previously acquired information or past experiences; by contrast, *anterograde amnesia* is the partial or total inability to retain new information (Gilboa et al., 2006; Kapur, 1999). Persistent amnesia may occur in several disorders, such as dissociative amnesia and dissociative fugue. It may also result from traumatic brain injury or diseases of the central nervous system. If the amnesia is caused by *brain pathology*, it most often involves failure to retain new information and experiences (anterograde amnesia). That is, the information contained in experience is not registered and does not enter memory storage (Kapur, 1999).

On the other hand, **dissociative amnesia** is usually limited to a failure to recall previously stored personal information (retrograde amnesia) when that failure cannot be accounted for

by ordinary forgetting. The gaps in memory most often occur following intolerably stressful circumstances—wartime combat conditions, for example, or catastrophic events such as serious car accidents, suicide attempts, or violent outbursts (Maldonado & Spiegel, 2007; Spiegel et al., 2011). In this disorder, apparently forgotten personal information is still there beneath the level of consciousness, as sometimes becomes apparent in interviews conducted under hypnosis or narcosis (induced by sodium amyral, or so-called truth serum) and in cases where the amnesia spontaneously clears up.  Watch the Video *Sharon: Dissociative Amnesia* on MyPsychLab.

Amnesic episodes usually last between a few days and a few years. Although many people experience only one such episode, some people have multiple episodes in their lifetimes (Maldonado & Spiegel, 2007; Staniloiu & Markowitsch, 2010). In typical dissociative amnesic reactions, individuals cannot remember certain aspects of their personal life history or important facts about their identity. Yet their basic habit patterns—such as their abilities to read, talk, perform skilled work, and so on—remain intact, and they seem normal aside from the memory deficit (Kihlstrom, 2005; Kihlstrom & Schacter, 2000). Thus the only type of memory that is affected is *episodic* (pertaining to events experienced) or *autobiographical memory* (pertaining to personal events experienced). The other recognized forms of memory—semantic (pertaining to language and concepts), procedural (how to do things), and short-term storage—seem usually to remain intact, although there is very little research on this topic (Kihlstrom, 2005; Kihlstrom & Schacter, 2000). Usually there is no difficulty encoding new information (Maldonado & Spiegel, 2007).

In rare cases a person may retreat still further from real-life problems by going into an amnesic state called a **dissociative fugue**, which, as the term implies (the French word *fugue* means “flight”), is a defense by actual flight—a person is not only amnesic for some or all aspects of his or her past but also departs from home surroundings. This is accompanied by confusion

#### criteria for Dissociative Amnesia

- A. An inability to recall important autobiographical information, usually of a traumatic or stressful nature, that is inconsistent with ordinary forgetting.
- Note:** Dissociative amnesia most often consists of localized or selective amnesia for a specific event or events; or generalized amnesia for identity and life history.
- B. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- C. The disturbance is not attributable to the physiological effects of a substance (e.g., alcohol or other drug of abuse,

DSM-5

a medication) or a neurological or other medical condition (e.g., partial complex seizures, transient global amnesia, sequelae of a closed head injury/traumatic brain injury, other neurological condition).

- D. The disturbance is not better explained by dissociative identity disorder, posttraumatic stress disorder, acute stress disorder, somatic symptom disorder, or major or mild neurocognitive disorder.

Source: Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, (Copyright 2013). American Psychiatric Association.

about personal identity or even the assumption of a new identity (although the identities do not alternate as they do in dissociative identity disorder). During the fugue, such individuals are unaware of memory loss for prior stages of their life, but their memory for what happens during the fugue state itself is intact (Kihlstrom, 2005; Kihlstrom & Schacter, 2000). Their behavior during the fugue state is usually quite normal and unlikely to arouse suspicion that something is wrong. However, behavior during the fugue state often reflects a rather different lifestyle from the previous one (the rejection of which is sometimes fairly obvious). Days, weeks, or sometimes even years later, such people may suddenly emerge from the fugue state and find themselves in a strange place, working in a new occupation, with no idea how they got there. In other cases, recovery from the fugue state occurs only after repeated questioning and reminders of who they are. In either case, as the fugue state remits, their initial amnesia remits—but a new, apparently complete amnesia for their fugue period occurs. In *DSM-5* dissociative fugue is considered to be a subtype of dissociative amnesia rather than a separate disorder as it was in *DSM-IV*.

The pattern in dissociative amnesia and dissociative fugue is essentially similar to that in conversion symptoms, except that instead of avoiding some unpleasant situation by becoming physically dysfunctional, a person unconsciously avoids thoughts about the situation or, in the extreme, leaves the scene (Maldonado & Spiegel, 2007; Maldonado et al., 2002). Thus people experiencing dissociative amnesia and fugue are typically faced with extremely unpleasant situations from which they see no acceptable way to escape. Eventually the stress becomes so intolerable that large segments of their personalities and all memory of the stressful situations are suppressed.

Several of these aspects of dissociative fugue are illustrated in the following case.

### → A Middle Manager Transformed into a Short-Order Cook

**Burt Tate**, a 42-year-old short-order cook in a small-town diner, was brought to the attention of local police following a heated altercation with another man at the diner. He gave his name as Burt Tate and indicated that he had arrived in town several weeks earlier. However, he could produce no official identification and could not tell the officers where he had previously lived and worked. Burt was asked to accompany the officers to the emergency room of a local hospital so that he might be examined . . . .

Burt's physical examination was negative for evidence of recent head trauma or any other medical abnormality . . . . He was oriented as to current time and place, but manifested no recall of his personal history prior to his arrival in town. He did not seem especially concerned about his total lack of a remembered past . . . .

Meanwhile, the police . . . discovered that Burt matched the description of one Gene Saunders, a resident of a city some 200

miles away who had disappeared a month earlier. The wife of Mr. Saunders . . . confirmed the real identity of Burt, who . . . stated that he did not recognize Mrs. Saunders.

Prior to his disappearance, Gene Saunders, a middle-level manager in a large manufacturing firm, had been experiencing considerable difficulties at work and at home. A number of stressful work problems, including failure to get an expected promotion, the loss of some of his key staff, failure of his section to meet production goals, and increased criticism from his superior—all occurring within a brief time frame—had upset his normal equanimity. He had become morose and withdrawn at home and had been critical of his wife and children. Two days before he had left, he had had a violent argument with his 18-year-old son, who had declared his father a failure and had stormed out of the house to go live with friends.

### MEMORY AND INTELLECTUAL DEFICITS IN DISSOCIATIVE AMNESIA AND FUGUE

Unfortunately, very little systematic research has been conducted on individuals with dissociative amnesia and fugue. What is known comes largely from intensive studies of the memory and intellectual functioning of isolated cases with these disorders, so any conclusions should be considered tentative pending further study of larger samples with appropriate control groups. What can be gathered from a handful of such case studies is that these individuals' semantic knowledge (assessed via the vocabulary subtest of an IQ test) seems to be generally intact. The primary deficit these individuals exhibit is their compromised episodic or autobiographical memory (Kihlstrom, 2005; Kihlstrom & Schacter, 2000). Indeed, several studies using brain-imaging techniques have confirmed that when people with dissociative amnesia are presented with autobiographical memory tasks, they show reduced activation in their right frontal and temporal brain areas relative to normal controls doing the same kinds of tasks (Kihlstrom, 2005; Markowitzsch, 1999). In a recent review of nine cases of dissociative amnesia for which brain imaging data were available, the authors concluded there was evidence of significant changes in the brains of these patients, mostly centered on subtle loss of function in the right anterior hemisphere—changes similar to those seen in the brains of patients with organic memory loss (Staniloiu & Markowitzsch, 2010).

However, several cases (some nearly a century old) have suggested that *implicit memory* is generally intact. For example, Jones (1909, as cited in Kihlstrom & Schacter, 2000) studied a patient with dense amnesia and found that although he could not remember his wife's or daughter's names, when asked to guess what names might fit them, he produced their names correctly. In a more contemporary case (Lyon, 1985, as cited

in Kihlstrom & Schacter, 2000), a patient who could not retrieve any autobiographical information was asked to dial numbers on a phone randomly. Without realizing what he was doing, he dialed his mother's phone number, which then led to her identifying him. In one particularly fascinating contemporary case of dissociative fugue, Glicksman and colleagues (2004) describe a German man who had come to work in the United States several months before he had experienced a traumatic incident in which he had been robbed and shot. After the trauma, he wandered along unfamiliar streets for an unknown period of time. Finally, he stopped at a motel and asked if the police could be called because he did not know who he was (and had no ID because he'd been robbed) and could not recall any personal details of his life. He spoke English (with a German accent) but could not speak German and did not respond to instructions in German (which he denied that he spoke). In spite of his extensive loss of autobiographical memory (and the German language), when given a variety of memory tasks, he showed intact implicit memory. Especially striking was his ability to learn German–English word pairs,

which he learned much faster than did normal controls, suggesting implicit knowledge of German even though he had no conscious knowledge of it.

Some of these memory deficits in dissociative amnesia and fugue have been compared to related deficits in explicit perception that occur in conversion disorders. This has convinced many people that conversion disorder should be classified with dissociative disorders rather than with somatic symptom disorders. This issue is discussed in more detail in the Thinking Critically About *DSM-5* box below.

## Dissociative Identity Disorder (DID)

**Dissociative identity disorder (DID)**, formerly known as *multiple personality disorder* is a dramatic dissociative disorder in which a patient manifests two or more distinct identities that alternate in some way in taking control of behavior. There is also an inability to recall important personal information that cannot be explained by ordinary forgetting. Each identity may appear to have a different personal history, self-image, and

## THINKING CRITICALLY about *DSM-5*

### Where Does Conversion Disorder Belong?

**DSM-5**

Starting with Freud and Janet, and for a large portion of the twentieth century prior to the publication of *DSM-III* in 1980, conversion disorders were classified together with dissociative disorders as subtypes of hysteria. When it was determined that *DSM-III* would rely heavily on overt behavioral symptoms rather than on presumed underlying etiology (namely, repressed anxiety) for classifying disorders, the decision was made to include conversion disorder with the other somatic symptom disorders. This was because its symptoms were physical ones with no demonstrable medical basis. However, as Kihlstrom (1994, 2001, 2005) and others have pointed out, this ignores some very important differences between conversion disorders and other somatic symptom disorders. The most important overall difference is that conversion symptoms (but not those of the other somatoform disorders) are nearly always pseudoneurological in nature (blindness, paralysis, anesthesias, deafness, seizures, etc.), mimicking some true neurological syndromes, just as most of the dissociative disorders do.

The disorders we currently classify as dissociative disorders (such as dissociative amnesia and DID) involve disruptions in explicit memory for events that have occurred, or who or what one's identity is, or both. However, it is clear that events occurring during a period of amnesia or in the presence of one identity are indeed registered in the nervous system because they influence behavior indirectly even when the person cannot consciously

recollect them (i.e., *implicit memory* remains at least partially intact in dissociative disorders). Similarly, Kihlstrom and others have argued that the conversion disorders involve disruptions in *explicit perception and action*. That is, people with conversion disorders have no conscious recognition that they can see or hear or feel, or no conscious knowledge that they can walk or talk or feel. However, patients with conversion disorder *can* see, hear, feel, or move when tricked into doing so or when indirect physiological or behavioral measures are used (see Janet, 1901, 1907; Kihlstrom, 1994, 2001, 2005). Thus Kihlstrom (1994, 2001, 2005) and others made a compelling argument that in future editions, the term *conversion disorder* should be dropped and the sensory and motor types of the syndrome should be reclassified as forms of dissociative disorders. This way, the central feature of all dissociative disorders would be a disruption of the normally integrated functions of consciousness (memory, perception, and action). Such a proposal is also consistent with observations that dissociative symptoms and disorders are quite common in patients with conversion disorder (e.g., Sar et al., 2004). This proposal was seriously considered and heavily debated by the *DSM-5* task force. In the end, the proponents for moving conversion disorder into the dissociative disorders category did not succeed and in *DSM-5* conversion disorder (at least for now) is still listed as a somatic symptom disorder.

name, although there are some identities that are only partially distinct and independent from other identities. In most cases the one identity that is most frequently encountered and carries the person's real name is the **host identity**. Also in most cases, the host is not the original identity, and it may or may not be the best-adjusted identity. The **alter identities** may differ in striking ways involving gender, age, handedness, handwriting, sexual orientation, prescription for eyeglasses, predominant affect, foreign languages spoken, and general knowledge. For example, one alter may be carefree, fun-loving, and sexually provocative, and another alter quiet, studious, serious, and prudish. Needs and behaviors inhibited in the primary or host identity are usually liberally displayed by one or more alter identities. Certain roles such as a child and someone of the opposite sex are extremely common.

Much of the reason for abandoning the older diagnostic term *multiple personality disorder* in favor of DID was the growing recognition that it had misleading connotations, suggesting multiple occupancy of space, time, and people's bodies by differing, but fully organized and coherent, "personalities." In fact, alters are not in any meaningful sense personalities but rather reflect a failure to integrate various aspects of a person's identity, consciousness, and memory (Spiegel, 2006). The term *DID* better captures this. Indeed Spiegel (one prominent theorist in this area) has argued that "the problem is not having more than one personality, it is having less than one" (Spiegel, 2006, p. 567).

Alter identities take control at different points in time, and the switches typically occur very quickly (in a matter of seconds), although more gradual switches can also occur. When switches occur in people with DID, it is often easy to observe the gaps in

Chris Sizemore was the inspiration for the book and movie *Three Faces of Eve*, which explore her multiple personality disorder (now known as DID). After her recovery, Sizemore worked as an advocate for the mentally ill.

memories for things that have happened—often for things that have happened to other identities. But this amnesia is not always symmetrical; that is, some identities may know more about certain alters than do other identities. Sometimes one submerged identity gains control by producing hallucinations (such as a voice inside the head giving instructions). In sum, DID is a condition in which normally integrated aspects of memory, identity, and consciousness are no longer integrated. Additional symptoms of DID include depression, self-mutilation, frequent suicidal ideation and attempts, erratic behavior, headaches, hallucinations, posttraumatic symptoms, and other amnesia and fugue symptoms (APA, 2013; Maldonado et al., 2002). Depressive disorders, PTSD, substance-use disorders, and borderline personality disorder are the most

## criteria for Dissociative Identity Disorder

- A.** Disruption of identity characterized by two or more distinct personality states, which may be described in some cultures as an experience of possession. The disruption in identity involves marked discontinuity in sense of self and sense of agency, accompanied by related alterations in affect, behavior, consciousness, memory, perception, cognition, and/or sensory-motor functioning. These signs and symptoms may be observed by others or reported by the individual.
- B.** Recurrent gaps in the recall of everyday events, important personal information, and/ or traumatic events that are inconsistent with ordinary forgetting.
- C.** The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

- D.** The disturbance is not a normal part of a broadly accepted cultural or religious practice.
- Note:** In children, the symptoms are not better explained by imaginary playmates or other fantasy play.
- E.** The symptoms are not attributable to the physiological effects of a substance (e.g., blackouts or chaotic behavior during alcohol intoxication) or another medical condition (e.g., complex partial seizures).

DSM-5

common comorbid diagnoses (Maldonado & Spiegel, 2007). One recent study found that among patients with diagnoses of DID, the average number of comorbid diagnoses (based on structured diagnostic interviews) was five, with PTSD being the most common (Rodewald et al., 2011).

DID usually starts in childhood, although most patients are in their teens, 20s, or 30s at the time of diagnosis (Maldonado & Spiegel, 2007). Approximately three to nine times more females than males are diagnosed as having the disorder, and females tend to have a larger number of alters than do males (Maldonado & Spiegel, 2007). Some believe that this pronounced gender discrepancy is due to the much greater proportion of childhood sexual abuse among females than among males (see Chapter 12), but this is a highly controversial point.

Many of these features are illustrated in the case of Mary Kendall below.

→ **Mary and Marian** Mary, a 35-year-old divorced social worker, had . . . in her right forearm and hand . . . chronic pain. Medical management of this pain had proved problematic, and it was decided to teach her self-hypnosis as a means whereby she might control it. She proved an excellent hypnotic subject and quickly learned effective pain control techniques.

Her hypnotist/trainer, a psychiatrist, describes Mary's life in rather unappealing terms. She is said to be competent professionally but has an "arid" personal and social life . . . . She spends most of her free time doing volunteer work in a hospice . . . .

In the course of the hypnotic training, Mary's psychiatrist discovered that she seemed to have substantial gaps in her memory. One phenomenon in particular was very puzzling: She reported that she could not account for what seemed an extraordinary depletion of the gasoline in her car's tank. She would arrive home from work with a nearly full tank, and by the following morning as she began her trip to work would notice that the tank was now only half-full. When it was advised that she keep track of her odometer readings, she discovered that on many nights on which she insisted she'd remained at home the odometer showed significant accumulations of up to 100 miles. The psychiatrist, by now strongly suspecting that Mary had a dissociative disorder, also established that there were large gaps in her memories of childhood. He shifted his focus to exploring the apparently widespread dissociative difficulties.

In the course of one of the continuing hypnotic sessions, the psychiatrist again asked about "lost time," and was greeted with a response in a wholly different voice tone that said, "It's about time you knew about me." Marian, an apparently well-established alter identity, went on to describe the trips she was fond of taking at night . . . . Marian was an extraordinarily abrupt and hostile "person," the epitome in these respects of everything the compliant and self-sacrificing Mary was not. Marian regarded Mary with unmitigated contempt, and asserted that "worrying about anyone but yourself is a waste of time."

## the WORLD around us

### DID, Schizophrenia, and Split Personality: Clearing Up the Confusion

The general public has long been confused by the distinction between DID and schizophrenia. It is not uncommon for people diagnosed with schizophrenia to be referred to as having a "split personality." We have even heard people say such things as, "I'm a bit schizophrenic on this issue" to mean that they have more than one opinion about it!

Although this misuse of the term *split personality* actually began among psychiatric professionals, today it reflects the public's general misunderstanding of schizophrenia, which does not involve a "split" or "Jekyll and Hyde" personality at all. The original confusion may have stemmed from the term *schizophrenia*, which was first coined by a Swiss psychiatrist named Bleuler. *Schizien* is German for "split," and *phren* is the Greek root for "mind." The notion that schizophrenia is characterized by a split mind or personality may have arisen this way (see McNally, 2007, for a historical review of how this confusion arose).

However, this is not at all what Bleuler intended the word *schizophrenia* to mean. Rather, Bleuler was referring to the splitting of

the normally integrated associative threads of the mind—links between words, thoughts, emotions, and behavior. Splits of this kind result in thinking that is not goal-directed or efficient, which in turn leads to the host of other difficulties known to be associated with schizophrenia.

It is very important to remember that people diagnosed with schizophrenia do *not* have multiple distinct identities that alternately take control over their mind and behavior. They may have a delusion and believe they are someone else, but they do not show the changes in identity accompanied by changes in tone of voice, vocabulary, and physical appearance that are often seen when identities "switch" in DID. Furthermore, people with DID (who are probably closer to the general public's notion of "split personality") do not exhibit such characteristics of schizophrenia as disorganized behavior, hallucinations coming from outside the head, and delusions, or incoherent and loose associations (e.g., Kluft, 2005).

In due course some six other alter identities emerged . . . . There was notable competition among the alters for time spent "out," and Marian was often so provocative as to frighten some of the more timid others, which included a 6-year-old child . . . .

Mary's history, as gradually pieced together, included memories of physical and sexual abuse by her father as well as others during her childhood . . . . Her mother was described . . . as having abdicated to a large extent the maternal role, forcing Mary from a young age to assume these duties in the family.

Four years of subsequent psychotherapy resulted in only modest success in achieving a true "integration" of these diverse trends in Mary Kendall's selfhood.

---

The number of alter identities in DID varies tremendously and has increased over time (Maldonado & Spiegel, 2007). One early review of 76 classic cases reported that two-thirds of these cases had only two personalities and most of the rest had three (Taylor & Martin, 1944). More recent estimates are that about 50 percent now show over 10 identities with some respondents claiming as many as a hundred. This historical trend of increasing multiplicity suggests the operation of social factors, perhaps through the encouragement of therapists, as we discuss below (e.g., Kihlstrom, 2005; Lilienfeld et al., 1999; Piper & Merskey, 2004a, 2004b). Another recent trend is that many of the reported cases of DID now include more unusual and even bizarre identities than in the past (such as being an animal) and more highly implausible backgrounds (e.g., ritualized satanic abuse in childhood).

**PREVALENCE—WHY HAS DID BEEN INCREASING?** Owing to their dramatic nature, cases of DID receive a great deal of attention and publicity in fiction, television, and motion pictures. But in fact, until relatively recently, DID was extremely rare—or at least rarely diagnosed—in clinical practice. Prior to 1979, only about 200 cases could be found in the entire psychological and psychiatric literature worldwide. By 1999, however, over 30,000 cases had been reported in North America alone (Ross, 1999), although as we will discuss later, many researchers believe that this is a gross overestimate (e.g., Piper & Merskey, 2004b). Because their diagnosed occurrence in both clinical settings and in the general population increased enormously in recent years, prevalence estimates in the general population vary. One study of 658 people in upstate New York estimated a 1.5 percent prevalence (Johnson et al., 2006), but it is possible that no such estimates are valid, given how hard it is to make this diagnosis reliably. (For example, recall that Mary's DID was uncovered only in the course of hypnotic sessions for pain management.)

Many factors probably have contributed to the drastic increase in the reported prevalence of DID (although in an absolute sense it is still very rare, and most practicing

psychotherapists never see a person with DID in their entire careers). For example, the number of cases began to rise in the 1970s after the publication of Flora Rhea Schreiber's *Sybil* (1973). This increased public awareness of the condition. (Ironically, however, the case has now been thoroughly discredited (see Borch-Jacobsen, 1997; Paris, 2012; Rieber, 1999). At about the same time, the diagnostic criteria for DID (then called multiple personality disorder) were clearly specified for the first time with the publication of *DSM-III* in 1980. This seems to have led to increased acceptance of the diagnosis by clinicians, which may have encouraged reporting of it in the literature. Clinicians were traditionally (and often still are today) somewhat skeptical of the astonishing behavior these patients often display.

Another reason why the diagnosis was made more frequently after 1980 is that the diagnostic criteria for schizophrenia were tightened in *DSM-III*. People who had perhaps been inappropriately diagnosed with schizophrenia could now receive the more appropriate diagnosis of multiple personality disorder. In addition, beginning in about 1980, prior scattered reports of instances of childhood abuse in the histories of adult patients began building into what would become a crescendo. As we will see later, many controversies arose regarding how to interpret such findings, but it is definitely true that these reports of abuse in patients with DID drew a great deal of attention to this disorder, which in turn may have increased the rate at which it was being diagnosed.

Finally, it is almost certain that some of the increase in the prevalence of DID is *artifactual* and has occurred because some therapists looking for evidence of DID in certain patients may suggest the existence of alter identities (especially when the person is under hypnosis and very suggestible; e.g., Kihlstrom, 2005; Piper & Merskey, 2004b). The therapist may also subtly reinforce the emergence of new identities by showing great interest in these new identities. Nevertheless, such factors cannot account for all cases of diagnosed DID, which has been observed in most parts of the world, even where there is virtually no personal or professional knowledge of DID, including rural Turkey (Akyuz et al., 1999; see also Maldonado & Spiegel, 2007) and Shanghai, China (Xiao et al., 2006).

**EXPERIMENTAL STUDIES OF DID** Much of what is known about DID comes from patients' self-reports and from therapists' or researchers' clinical observations. Indeed, only a small number of experimental studies of people with DID have been conducted to corroborate clinical observations. Moreover, most of these studies have been conducted on only one or a few cases, although very recently a few larger studies have been done that include appropriate control groups (e.g., Dorahy et al., 2005; Huntjens et al., 2003, 2007). In spite of such shortcomings, most of the findings from these studies are generally consistent with one another and reveal some very interesting features of DID.

The primary focus of these studies has been to determine the nature of the amnesia that exists between different identities.

As we have already noted, most people with DID have at least some identities that seem completely unaware of the existence and experiences of certain alter identities, although other identities may be only partially amnesic of some alters (e.g., Elzinga et al., 2003; Huntjens et al., 2003). This feature of DID has been corroborated by studies showing that when one identity (Identity 1) is asked to learn a list of word pairs, and an alter identity (Identity 2) is later asked to recall the second word in each pair using the first word as a cue, there seems to be no transfer to Identity 2 of what was learned by Identity 1. This interpersonality amnesia with regard to conscious recall of the activities and experiences of at least some other identities has generally been considered a fundamental characteristic of DID (Kihlstrom, 2001, 2005; Kihlstrom & Schacter, 2000). Nevertheless, several interesting recent studies, each with about 20 DID patients, have challenged any idea that this interpersonality amnesia is complete, instead sometimes finding partial transfer of explicit memory across identities in certain tasks (Huntjens et al., 2003, 2007, 2012; see also Dorahy & Huntjens, 2007, for a review).

As noted earlier, there are kinds of memory other than simply what can be brought to awareness (*explicit memory*). As with dissociative amnesia and fugue, there is evidence that Identity 2 has some *implicit memory* of things that Identity 1 learned. That is, although Identity 2 may not be able to recall consciously the things learned by Identity 1, these apparently forgotten events may influence Identity 2's experiences, thoughts, and behaviors unconsciously (Kihlstrom, 2001, 2005). This might be reflected in a test asking Identity 2 to learn the list of words previously learned by Identity 1. Even though Identity 2 could not consciously recall the list of words, Identity 2 would learn that list more rapidly than a brand-new list of words, an outcome that suggests the operation of implicit memory (e.g., Eich et al., 1997; Elzinga et al., 2003; see Kihlstrom, 2001, 2005, for reviews).

Related studies on implicit transfer of memories have shown that emotional reactions learned by one identity often transfer across identities, too. Thus, even though Identity 2 may not be able to recall an emotional event that happened to Identity 1, a visual or auditory reminder of the event (a conditioned stimulus) administered to Identity 2 may elicit an emotional reaction even though Identity 2 has no knowledge of why it did so (e.g., Ludwig et al., 1972; Prince, 1910). Moreover, one study by Huntjens and colleagues (2005) had 22 DID patients in Identity 1 learn to reevaluate a neutral word in a positive or negative manner through a simple evaluative conditioning procedure in which neutral words are simply paired with positive or negative words; the neutral words then come to take on positive or negative connotations. When Identity 2 was later asked to emerge, he or she also categorized the formerly neutral word in the same positive or negative manner as learned by Identity 1, showing implicit memory for the reevaluation of the word learned by Identity 1 (although complete subjective amnesia was reported by Identity 2). Nevertheless, other sophisticated studies have made it

clear that implicit memory transfer across personalities does not always occur, particularly with certain kinds of implicit memory tasks where memory performance may be strongly influenced by the identity currently being tested (e.g., Dorahy, 2001; Eich et al., 1997; Nissen et al., 1988). However, the results that do show implicit memory transfer are very important because they demonstrate that explicit amnesia across identities cannot occur simply because one identity is trying actively to suppress any evidence of memory transfer. If this were possible, there would be no leakage of implicit memories across identities (Dorahy, 2001; Eich et al., 1997).

An even smaller number of experimental studies have examined differences in brain activity when individuals with DID are tested with different identities at the forefront of consciousness. For example, in an early classic study, Putnam (1984) investigated EEG activity in 11 DID patients during different identities, and in 10 control subjects who were simulating different personality states, in order to determine whether there were different patterns of brain wave activity during different identities (real or simulated), as would be found if separate individuals were assessed. The study found that there were indeed differences in brain wave activity when the patients with DID were in different personality states and that these differences were greater than those found in the simulating subjects (see Kihlstrom et al., 1993; Putnam, 1997).

One particularly interesting study by Reinders and colleagues (2006) examined subjective and cardiovascular activation patterns to both neutral and traumatic memories in 11 people diagnosed with DID. Each patient had one alter with a neutral identity such as the one active when they were functioning in everyday life, and each had another alter with a traumatic identity who had access to traumatic memories. As expected, when exposed to a script of neutral personal memories neither identity displayed much subjective or cardiovascular reactivity. However, when exposed to a script of personal memories of traumatizing events, responding differed in the two identity states. Specifically, the traumatic identity state (but not the neutral identity state) showed subjective and cardiovascular reactivity reflecting emotional distress to the personal traumatic memory. Such results could be seen as providing support for the idea that one function of certain alters is to protect the person from traumatic memories that a traumatic identity state has access to.

## CAUSAL FACTORS AND CONTROVERSIES ABOUT DID

There are at least four serious, interrelated controversies surrounding DID and how it develops. First, some have been concerned with whether DID is a real disorder or is faked, and whether, even if it is real, it can be faked. The second major controversy is about how DID develops. Specifically, is DID caused by early childhood trauma, or does the development of DID involve some kind of social enactment of multiple different roles that have been inadvertently encouraged by careless clinicians? Third, those who maintain that DID is caused by childhood

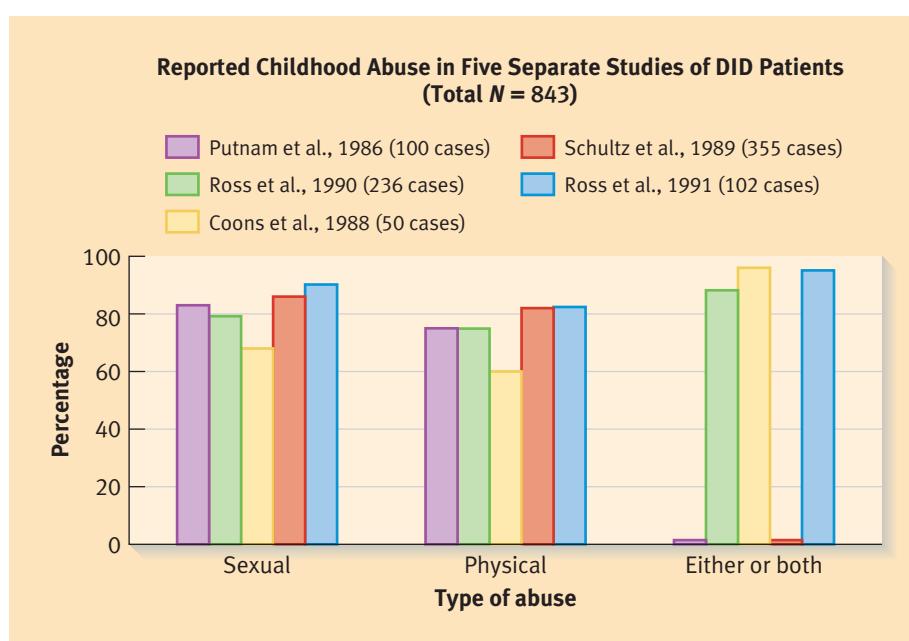

trauma cite mounting evidence that the vast majority of individuals diagnosed with DID report memories of an early history of abuse. But are these memories of early abuse real or false? Finally, if abuse has occurred in most individuals with DID, did the abuse play a *causal role*, or was something else correlated with the abuse actually the cause?

**DID: Real or Faked?** The issue of possible factitious or malingering origins of DID has dogged the diagnosis of DID for at least a century. One obvious situation in which this issue becomes critical is when it has been used by defendants and their attorneys to try to escape punishment for crimes (“My other personality did it”). For example, this defense was used, ultimately unsuccessfully, in the famous case of the Hillside Strangler, Kenneth Bianchi (Orne et al., 1984), but it has probably been used successfully in other cases that we are unaware of (unaware because the person is not sent to prison but rather to a mental hospital in most cases). Bianchi was accused of brutally raping and murdering 10 young women in the Los Angeles area. Although there was a great deal of evidence that he had committed these crimes, he steadfastly denied it, and some lawyers thought perhaps he had DID. He was subsequently interviewed by a clinical psychologist, and under hypnosis a second personality, “Steve,” emerged. Steve confessed to the crimes, thereby creating the basis for a plea of “not guilty by reason of insanity” (see Chapter 17). However, Bianchi was later examined even more closely by a renowned psychologist and psychiatrist specializing in this area, the late Martin Orne. Upon closer examination, Orne determined that Bianchi was faking the condition. Orne drew this conclusion in part because when he suggested to Bianchi that most people with DID have more than two identities, Bianchi suddenly produced a third (Orne et al., 1984). Moreover, there was no evidence of multiple identities exist-

ing prior to the trial. When Bianchi’s faking the disorder was discovered, he was convicted of the murders. In other words, some cases of DID may involve complete fabrication orchestrated by criminal or other unscrupulous persons seeking unfair advantages, and not all prosecutors have as clever and knowledgeable an expert witness as Martin Orne to help detect this. Nevertheless, most researchers think that factitious and malingering cases of DID (such as the Bianchi case or cases in which the person has a need to be a patient) are relatively rare.

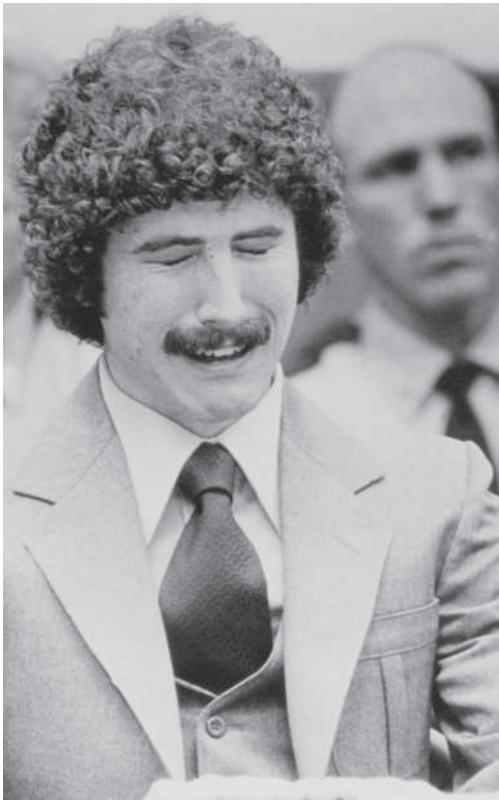

### If DID Is Not Faked, How Does It Develop: Posttraumatic

**Theory or Sociocognitive Theory?** Many professionals acknowledge that, in most cases, DID is a real syndrome (not consciously faked), but there is marked disagreement about how it develops and how it is maintained. In the contemporary literature, the original major theory of how DID develops is **posttraumatic theory** (Gleaves, 1996; Maldonado & Spiegel, 2007; Ross, 1997, 1999). The vast majority of patients with DID (over 95 percent by some estimates) report memories of severe and horrific abuse as children (see Figure 8.1 below). According to this view, DID starts from the child’s attempt to cope with an overwhelming sense of hopelessness and powerlessness in the face of repeated traumatic abuse. Lacking other resources or routes of escape, the child may dissociate and escape into a fantasy, becoming someone else. This escape may occur through a process like self-hypnosis (Butler et al., 1996), and if it helps to alleviate some of the pain caused by the abuse it will be reinforced and occur again in the future. This notion is consistent with recent evidence that inducing a dissociative state in research participants can lead to decreased pain sensitivity (Ludascher et al., 2009). Sometimes the child simply imagines the abuse is happening to someone else. If the child is fantasy prone, and continues to stay fantasy prone over time, the child may unknowingly create different selves at different points

**FIGURE 8.1**

Reported childhood abuse in five separate studies of DID patients (Total  $n = 843$ ).

Kenneth Bianchi, known as the "Hillside Strangler," brutally raped and murdered 10 women in the Los Angeles area. Hoping to create a plea of "not guilty by reason of insanity," Bianchi fabricated a second personality—"Steve"—who "emerged" while Kenneth was under hypnosis. A psychologist and psychiatrist specializing in DID determined he was faking the diagnosis, and Bianchi was subsequently convicted of the murders.

in time, possibly laying the foundation for multiple dissociated identities.

But only a subset of children who undergo traumatic experiences are prone to fantasy or self-hypnosis, which leads to the idea that a diathesis-stress model may be appropriate here. That is, children who are prone to fantasy and those who are easily hypnotizable may have a diathesis for developing DID (or other dissociative disorders) when severe abuse occurs (e.g., Butler et al., 1996; Kihlstrom et al., 1993). However, it should also be emphasized that there is nothing inherently pathological about being prone to fantasy or readily hypnotizable (Kihlstrom et al., 1994).

Increasingly, those who view childhood abuse as playing a critical role in the development of DID are beginning to see DID as perhaps a complex and chronic variant of posttraumatic stress disorder, which by definition is caused by exposure to some kind of highly traumatic event(s), including abuse (e.g., Brown, 1994; Maldonado & Spiegel, 2007; Maldonado et al., 2002). Anxiety symptoms are more prominent in PTSD than in DID, and dissociative symptoms are more prominent in DID than in PTSD. Nevertheless, both kinds of symptoms are present in both disorders (Putnam, 1997). Moreover, some (but not all) investigators have estimated that a very high percentage of individuals diagnosed with DID have a comorbid diagnosis of PTSD, suggesting the

likelihood of some important common causal factors (Vermetten et al., 2006; see also Rodewald et al., 2011).

At the other extreme from posttraumatic theory is **sociocognitive theory**, which claims that DID develops when a highly suggestible person learns to adopt and enact the roles of multiple identities, mostly because clinicians have inadvertently suggested, legitimized, and reinforced them and because these different identities are geared to the individual's own personal goals (Lilienfeld & Lynn, 2003; Lilienfeld et al., 1999; Spanos, 1994, 1996). It is important to realize that at the present time, the sociocognitive perspective maintains that this is not done intentionally or consciously by the afflicted individual but, rather, occurs spontaneously with little or no awareness (Lilienfeld et al., 1999). The suspicion is that overzealous clinicians, through fascination with the clinical phenomenon of DID and unwise use of such techniques as hypnosis, are themselves largely responsible for eliciting this disorder in highly suggestible, fantasy-prone patients (e.g., Giesbrecht et al., 2008; Piper, Merskey, 2004a, 2004b; Spanos, 1996).

Consistent with the sociocognitive hypothesis, Spanos et al. (1985) demonstrated that normal college students can be induced by suggestion under hypnosis to exhibit some of the phenomena seen in DID, including the adoption of a second identity with a different name that shows a different profile on a personality inventory. Thus people can enact a second identity when situational forces encourage it. Related situational forces that may affect the individual outside the therapist's office include memories of one's past behavior (e.g., as a child), observations of other people's behavior (e.g., others being assertive and independent, or sexy and flirtatious), and media portrayals of DID (Lilienfeld et al., 1999; Piper & Merskey, 2004b; Spanos, 1994).

Sociocognitive theory is also consistent with evidence that most DID patients do not show unambiguous signs of the disorder before they enter therapy and with evidence that the number of alter identities often increases (sometimes dramatically) with time spent in therapy (Piper & Merskey, 2004b). It is also consistent with the increased prevalence of DID since the 1970s, when the first popular accounts of DID reached the general public, and since 1980, when therapist awareness of the condition increased as well (Lilienfeld et al., 1999; Piper & Merskey, 2004a).

However, there are also many criticisms of sociocognitive theory. For example, Spanos and colleagues' demonstration of role-playing in hypnotized college students is interesting, but it does not show that this is the way DID is actually caused in real life. For example, someone might be able to give a convincing portrayal of a person with a broken leg, but this would not establish how legs are usually broken. Moreover, the hypnotized participants in this and other experiments showed only a few of the most obvious symptoms of DID (such as more than one identity) and showed them only under short-lived, contrived laboratory conditions. No studies have shown that other symptoms such as depersonalization, memory lapses for prolonged periods, or auditory hallucinations can occur under similar laboratory

Former Georgia football star Herschel Walker has written a book, *Breaking Free: My Life with Dissociative Identity Disorder* (2008), in which he tells about his struggle with this disorder.

conditions. Thus, although some of the *symptoms* of DID could be created by social enactment, there is no evidence that the *disorder* can be created this way (e.g., Gleaves, 1996).

**Are Recovered Memories of Abuse in DID Real or False?** Case reports of the cruelty and torture that some DID patients suffered as children are gut-wrenching to read or hear. However, the accuracy and trustworthiness of these reports of widespread sexual and other forms of childhood abuse in DID have become a matter of major controversy. Critics (who are often proponents of sociocognitive theory) argue that many of these reports of DID patients, which generally come up in the course of therapy, may be the result of false memories, which are in turn a product of highly leading questions and suggestive techniques applied by well-meaning but inadequately skilled and careless psychotherapists (Lilienfeld et al., 1999; Loftus & Davis, 2006; Yapko, 1994). It seems quite clear to many investigators that this sort of thing has happened, often with tragic consequences. Innocent family members have been falsely accused by DID patients and have sometimes been convicted and imprisoned. But it is also true that brutal abuse of children occurs far too often and that it can have very adverse effects on development, perhaps encouraging pathological dissociation (e.g., Maldonado & Spiegel, 2007; Nash et al., 1993). In such cases, prosecution of the perpetrators of the abuse is indeed appropriate. Of course, the real difficulty here is in determining when the recovered memories of abuse are real and when they are false (or some combination of the two). This bitter controversy about the issue of false memory is more extensively considered in the Unresolved Issues section at the end of this chapter.

One way to document that particular recovered memories are real might be if some reliable physiological test could be developed to distinguish between them. Thus, some researchers are currently trying to determine whether there are different neural correlates of real and false memories that could be used to make this determination reliably. Another somewhat easier way to document whether a particular recovered memory is real would be to have independent verification that the abuse had actually occurred, such as through physician, hospital, and police records. A number of studies have indeed reported that they have confirmed the reported cases of abuse, but critics have shown

that the criteria used for corroborating evidence are almost invariably very loose and suspect as to their validity. For example, Chu and colleagues (1999) simply asked their subjects, “Have you had anyone confirm these events?” (p. 751) but did not specify what constituted confirmation and had no way of determining if subjects were exaggerating or distorting the information they provided as confirming evidence (Loftus & Davis, 2006; Piper & Merskey, 2004a). In another example of a flawed study, Lewis and colleagues (1997) studied 12 convicted murderers and then confirmed through medical, social service, and prison records that all 12 had been severely abused as children. Unfortunately, this study did not include a control group of otherwise comparable murderers who did not exhibit DID symptoms. Hence we cannot be certain that the childhood abuse of these subjects is not as much (or more) associated with violence or conviction for murder as with the development of DID specifically. Moreover, Lewis and colleagues should have carefully assessed for the possibility that some of the murderers might have been malingering (i.e., faking DID; Lilienfeld et al., 1999). Thus, although this study may have been one of the most impressive attempts yet to document abuse independently in people with DID, it was significantly flawed and therefore highly inconclusive.

**If Abuse Has Occurred, Does It Play a Causal Role in DID?** Let us put the previous controversy about the reality of recovered memories of abuse aside for a moment and assume that severe abuse has occurred in the early childhood backgrounds of many people with DID. How can we determine whether this abuse has played a critical *causal role* in the development of DID (e.g., Piper & Merskey, 2004a)? Unfortunately, many difficulties arise in answering this question. For example, child abuse usually happens in family environments plagued by many other sources of adversity and trauma (e.g., various forms of psychopathology and extreme neglect and poverty). One or more of these other, correlated sources of adversity could actually be playing the causal role (e.g., Lilienfeld et al., 1999; Nash et al., 1993). Another difficulty of determining the role of abuse is that people who have experienced child abuse as well as symptoms of DID may be more likely to seek treatment than people with symptoms of DID who did not experience abuse. Thus the individuals in most studies on the prevalence of child abuse in DID may not be representative of the population of all people who suffer from DID. Finally, childhood abuse has been claimed by some to lead to many different forms of psychopathology including depression, PTSD, eating disorders, somatic symptom disorders, and borderline personality disorder, to name just a few. Perhaps the most we will ever be able to say is that childhood abuse may play a *nonspecific* role for many disorders, with other, more specific factors determining which disorder develops (see Chapters 10 and 12).

**Comments on a Few of These Controversies About DID** As we have seen, numerous studies indicate that the separate identities harbored by DID patients are somewhat physi-

ologically and cognitively distinct. For example, EEG activity of various alters may be quite different. Because such differences cannot in any obvious way be simulated (e.g., Eich et al., 1997), it seems that DID must, in at least some cases, involve more than simply the social enactment of roles. Moreover, this should not be too surprising, given the widespread evidence of separate (dissociated) memory subsystems and nonconscious active mental processing, which indicates that much highly organized mental activity is normally carried on in all of us in the background, outside of awareness (e.g., Kihlstrom, 2005). Moreover, some people seem to be especially prone to pathological variants of these dissociative processes (Waller et al., 1996; Waller & Ross, 1997).

We should also note that each of these controversies has usually been stated in a dichotomous way: Is DID real or faked? What causes DID—spontaneous social enactment of roles or repeated childhood trauma? Are recovered memories of abuse real or false? If abuse occurs, does it play a primary causal role? Unfortunately, however, such dichotomously stated questions encourage oversimplified answers. The human mind does not seem to operate in these dichotomous ways, and we need to address the complex and multifaceted nature of the dissociated mental processes that these often miserable and severely stressed patients are experiencing. Fortunately, theorists on both sides have begun to soften their positions a little, acknowledging that multiple different causal pathways are likely to be involved. For example, Ross (1997, 1999), a long-time advocate for a strong version of posttraumatic theory, later acknowledged that some cases are faked and that some may be inadvertently caused by unskilled therapists in the course of treatment. In addition, other advocates of posttraumatic theory have recently acknowledged that both real and false memories do occur in these patients, noting that it is critical that a method for determining which is which be developed (e.g., Gleaves & Williams, 2005; Gleaves et al., 2004). From the other side, Lilienfeld et al., 1999, who have been vocal advocates for Spanos' sociocognitive theory since his death in 1994, have acknowledged that some people with DID may have undergone real abuse, although they believe it occurs far less often, and is less likely to play a real causal role, than the trauma theorists maintain (see also Kihlstrom, 2005).

## Sociocultural Factors in Dissociative Disorders

There seems little doubt that the prevalence of dissociative disorders, especially their more dramatic forms such as DID, is influenced by the degree to which such phenomena are accepted or tolerated either as normal or as legitimate mental disorders by the surrounding cultural context. Indeed, in our own society, the acceptance and tolerance of DID as a legitimate disorder have varied tremendously over time. Compared to relatively high reported rates of DID in Western cultures, a recent study of 893 patients diagnosed with some type of dissociative disorder over 10 years at a psychiatric hospital in India found no cases of DID (Chaturvedi et al., 2010). Nevertheless, although its prevalence varies, DID has now been identified in all racial groups, socioeconomic classes, and

cultures where it has been studied. For example, outside North America it has been found in countries ranging from Nigeria and Ethiopia to Turkey, India, China, Australia, and the Caribbean, to name a few (Maldonado et al., 2002; Xiao et al., 2006).

Many seemingly related phenomena, such as spirit possession and dissociative trances, occur very frequently in many different parts of the world where the local culture sanctions them (Krippner, 1994; Spiegel et al., 2011). When entered into voluntarily, trance and possession states are not considered pathological and should not be construed as mental disorders. But some people who enter into these states voluntarily because of cultural norms develop distress and impairment. In *DSM-5*, the diagnostic criteria for DID have been modified to that they now include certain phenomena associated with possession. A *trance* is said to occur when someone experiences a temporary marked alteration in state of consciousness or identity (but with no replacement by an alternative identity). It is usually associated with either a narrowing of awareness of the immediate surroundings, or stereotyped behaviors or movements that are experienced as beyond one's control. A *possession trance* is similar except that the alteration of consciousness or identity is replaced by a new identity that is attributed to the influence of a spirit, deity, or other power. In both cases there is typically amnesia for the trance state. One study of 58 individuals from Singapore with this diagnosis, as well as 58 individuals with a diagnosis of major depression, found that conflicts over religious or cultural issues, prior exposure to trance states, and being a spiritual healer or healer's helper were most predictive of who had dissociative trance disorder relative to major depression (Ng & Chan, 2004). A recent review of 402 cases of dissociative trance and possession disorders indicates that migration and struggles with acculturation are associated with these disorders (During et al., 2011).

There are also cross-cultural variants on dissociative disorders, such as *Amok*, which is often thought of as a rage disorder. *Amok* occurs when a dissociative episode leads to violent, aggressive, or homicidal behavior directed at other people and objects. It occurs mostly in men and is often precipitated by a perceived slight or insult. The person often has ideas of persecution, anger, and amnesia, often followed by a period of exhaustion and depression. *Amok* is found in places such as Malaysia, Laos, the Philippines, Papua New Guinea, and Puerto Rico and among Navajo Indians.

## Treatment and Outcomes in Dissociative Disorders

Unfortunately, virtually no systematic, controlled research has been conducted on treatment of depersonalization disorder, dissociative amnesia, and dissociative fugue, and so very little is known about how to treat them successfully. Numerous case histories, sometimes presented in small sets of cases, are available, but without control groups who are assessed at the same time or

who receive nonspecific treatments it is impossible to know the effectiveness of the varied treatments that have been attempted (Kihlstrom, 2005).

As noted earlier depersonalization/derealization disorder is generally thought to be resistant to treatment (e.g., Simeon et al., 1997), although treatment may be useful for associated psychopathology such as anxiety and depressive disorders. Some think that hypnosis, including training in self-hypnosis techniques, may be useful because patients with depersonalization disorder can learn to dissociate and then “reassociate,” thereby gaining some sense of control over their depersonalization and derealization experiences (Maldonado & Spiegel, 2007; Maldonado et al., 2002). Many types of antidepressant, antianxiety, and antipsychotic drugs have also been tried and sometimes have modest effects. However, one randomized controlled study showed no difference between treatment with Prozac versus with placebo (Simeon et al., 2004). One recent treatment showing some promise for the treatment of dissociative disorders involves administering rTMS (repetitive transcranial magnetic stimulation) to the temporo-parietal junction, an area of the brain highly involved in the experience of a unified self and body (Mantovani et al., 2011). After three weeks of treatment, half of the subjects showed significant reductions in depersonalization, with nonresponders showing symptom reduction after an additional three weeks of treatment. In dissociative amnesia and fugue, it is important for the person to be in a safe environment, and simply removing her or him from what he or she perceives as a threatening situation sometimes allows for spontaneous recovery of memory. Hypnosis, as well as drugs such as benzodiazepines, barbiturates, sodium pentobarbital, and sodium amobarbital, is often used to facilitate recall of repressed and dissociated memories (Maldonado & Spiegel, 2007; Maldonado et al., 2002). After memories are recalled, it is important for the patient to work through the memories with the therapist so that the experiences can be reframed in new ways. However, unless the memories can be independently corroborated, they should not be taken at their face value (Kihlstrom, 2005).

For DID patients, most current therapeutic approaches are based on the assumption of posttraumatic theory that the disorder was caused by abuse (Kihlstrom, 2005). Most therapists set integration of the previously separate alters, together with their collective merging into the host personality, as the ultimate goal of treatment (e.g., Maldonado & Spiegel, 2007). There is often considerable resistance to this process by the DID patients, who often consider dissociation as a protective device (e.g., “I knew my father could get some of me, but he couldn’t get all of me”; Maldonado & Spiegel, 2007, p. 781). If successful integration occurs, the patient eventually develops a unified personality, although it is not uncommon for only partial integration to be achieved. But it is also very important to assess whether improvement in other symptoms of DID and associated disorders has occurred. Indeed, it seems that treatment is more likely to produce symptom improvement, as well as associated improvements

in functioning, than to achieve full and stable integration of the different alter identities (Maldonado & Spiegel, 2007; Maldonado et al., 2002).

Typically the treatment for DID is psychodynamic and insight-oriented, focused on uncovering and working through the trauma and other conflicts that are thought to have led to the disorder (Kihlstrom, 2005). One of the primary techniques used in most treatments of DID is hypnosis (e.g., Kluft, 1993; Maldonado & Spiegel, 2007; Maldonado et al., 2002). Most DID patients are hypnotizable and when hypnotized are often able to recover past unconscious and frequently traumatic memories, often from childhood. Then these memories can be processed, and the patient can become aware that the dangers once present are no longer there. (One problem here is that such patients are suggestible under hypnosis, so much of what is recalled may not be accurate; see Kihlstrom, 2005; Loftus & Davis, 2006). Through the use of hypnosis, therapists are often able to make contact with different identities and reestablish connections between distinct, seemingly separate identity states. An important goal is to integrate the personalities into one identity that is better able to cope with current stressors. Clearly, successful negotiation of this critical phase of treatment requires therapeutic skills of the highest order; that is, the therapist must be strongly committed as well as professionally competent. Regrettably, not all therapists are.

Most reports in the literature are treatment summaries of single cases, and reports of successful cases should always be considered with caution, especially given the large bias in favor of publishing positive rather than negative results. Treatment outcome data for large groups of DID patients have been reported in only four studies we are aware of, and none of these included a control group, although it is clear that DID does not spontaneously remit simply with the passage of time, nor if a therapist chooses to ignore DID-related issues (Kluft, 1999; Maldonado et al., 2002). For example, Ellason and Ross (1997) reported on a 2-year postdischarge follow-up of DID patients originally treated in a specialized inpatient unit. Of the original 135 such patients, 54 were located and systematically assessed. All these patients, and especially those who had achieved full integration, generally showed marked improvements in various aspects of their lives. However, only 12 of the 54 had achieved full integration of their identities. Such results are promising, but we must wonder about the clinical status of the 81 “lost” patients who may likely have done less well. Another 10-year follow-up study reported similar results in a smaller sample of 25 treated DID patients. Only 12 were located 10 years later; of these, six had achieved full integration, but two of those had partially relapsed (Coons & Bowman, 2001). In general it has been found that (1) for treatment to be successful, it must be prolonged, often lasting many years, and (2) the more severe the case, the longer that treatment is needed (Maldonado & Spiegel, 2007; Maldonado et al., 2002).

## in review

- Describe the symptoms known as depersonalization and derealization, and indicate which disorder is primarily characterized by their appearance.
- Describe dissociative amnesia and dissociative fugue, and indicate what aspects of memory are affected.

- What are the primary symptoms of dissociative identity disorder (DID), and why is its prevalence thought to have increased?
- Review the four major controversies surrounding DID that were discussed in this chapter.

## UNRESOLVED issues

### DID and the Reality of “Recovered Memories”

**A**s we have seen in this chapter, many controversies surround the nature and origins of DID. None have been more bitter than those related to the truth value of “recovered” memories of childhood abuse, particularly sexual abuse, which posttraumatic theorists assert is the major causal factor in the development of DID. Indeed, a virtual chasm has developed between the “believers” (mostly but not exclusively private practitioners who treat people with DID) and the “disbelievers” (mostly but not exclusively the more academic and science-oriented mental health professionals). The disbelievers are very sympathetic to people suffering DID symptoms, but they have tended to doubt that the disorder is usually caused by childhood abuse and have challenged the validity or accuracy of recovered memories of abuse (see Loftus & Davis, 2006, for a review of the recovered memory debate).

For 20 years, these controversies have moved beyond professional debate and have become major public issues, leading to countless legal proceedings. DID patients who recover memories of abuse (often in therapy) have often sued their parents for having inflicted abuse. But ironically, therapists and institutions have also been sued for implanting memories of abuse that they later came to believe had not actually occurred. Some parents, asserting they had been falsely accused, formed an international support organization—the False Memory Syndrome Foundation—and have sometimes sued therapists for damages, alleging that the therapists induced false memories of parental abuse in their child. Many families have been torn apart in the fallout from this remarkable climate of suspicion, accusation, litigation, and unrelenting hostility.

Whether DID originates in childhood abuse and whether recovered memories of abuse are accurate are basically separate issues, but they have tended to become fused in the course of the debate. Hence those who doubt the validity of memories of abuse are also likely to regard the phenomenon of DID as stemming from the social enactment of roles encouraged or induced—like the memories of abuse themselves—by misguided therapy (e.g., see Bjorklund, 2000; Lilienfeld et al., 1999; Lynn et al., 2004; Piper & Merskey, 2004a, 2004b). Believers, on the other hand, have usually taken both DID and the idea that abuse is its cause to be established beyond doubt (e.g., see Gleaves, 1996; Gleaves et al., 2001; Ross, 1997, 1999).

Much of the controversy about the validity of recovered memories is rooted in disagreements about the nature, reliability, and malleability of human autobiographical memory. With some exceptions, evidence for childhood abuse as a cause of DID is restricted to the “recovered memories” (memories not originally accessible) of adults being treated for dissociative experiences. Believers argue that before treatment such memories had been “repressed” because of their traumatic nature or had been available only to certain alter identities that the host identity was generally not aware of. Treatment, according to this view of believers, dismantles the repressive defense and thus makes available to awareness an essentially accurate memory recording of the past abuse.

Disbelievers counter with several scientifically well-supported arguments. For example, scientific evidence in support of the repression concept is quite weak (e.g., Kihlstrom, 2005; Loftus & Davis, 2006; Piper, 1998). In many alleged cases of repression, the event may have been lost to memory in the course of ordinary forgetting rather than repression, or it may have occurred in the first 3 to 4 years of life, before memories can be recorded for retrieval in adulthood. In many other cases, evidence for repression has been claimed in studies where people may simply have failed to report a previously remembered event, often because they were never asked or were reluctant to disclose such very personal information (Kihlstrom, 2005; Loftus & Davis, 2006; Pope et al., 1998).

Even if memories can be repressed, there are very serious questions about the accuracy of recovered memories. Human memory of past events does not operate in a computer-like manner, retrieving with perfect accuracy an unadulterated record of information previously stored and then repressed. Rather, human memory is malleable, constructive, and very much subject to modification on the basis of events happening after any original memory trace is established (Loftus & Bernstein, 2005; Loftus & Davis, 2006; Schacter et al., 2000).

Indeed, there is now good evidence that in certain circumstances, people are sometimes very prone to the development of false memories (see Wade et al., 2007, for a review). For example, a number of studies have now shown that when normal adult subjects are asked to imagine repeatedly events that they

are quite sure had not happened to them before age 10, they later increase their estimate of the likelihood that these events actually had happened to them (Tsai et al., 2000). Moreover, even in a relatively short time frame, adult subjects sometimes come to believe they have performed somewhat bizarre acts (e.g., kissing a magnifying glass), as well as common acts (e.g., flipping a coin), after simply having imagined they had engaged in these acts several times 2 weeks earlier (Thomas & Loftus, 2002). These and other studies clearly show that repeated imagining of certain events (even somewhat bizarre events) can lead people to have false memories of events that never happened (Loftus & Bernstein, 2005; Loftus & Davis, 2006). In addition, an experimental study by McNally and colleagues (2005) looked at individuals who reported either repressed or recovered memories of childhood sexual abuse and found some evidence that they had greater difficulty on at least some measures than normal controls in distinguishing between words that they had seen versus words that they had only imagined. This suggests that people with repressed or recovered memories of abuse may have greater difficulty distinguishing between what has actually happened to them and what they have imagined happened to them. However, a different study found that those who report recovered memories of childhood sexual abuse did not show increased difficulty retrieving non-abuse-related autobiographic memories compared to those who reported continuous

memories of childhood sexual abuse or a control group reporting no childhood sexual abuse (Raymaekers et al., 2010).

One fascinating study compared a group of people who had continuous memories of childhood abuse with two groups who had recovered memories of abuse. In one of the latter groups the memories had been recovered during therapy and in the other the memories had been recovered out of therapy. The researchers then attempted to corroborate these recovered memories, and found corroborative evidence for over half of those who had recovered memories outside of therapy and for none in the group who recovered their memories during therapy (Geraerts et al., 2007).

Recently, McNally and Geraerts (2009) offered a different perspective on recovered memories, one that attempts to bridge the gap between the conviction that repression underlies recovered memories and the alternate conviction that all recovered memories are false. Their third perspective suggests that some recovered memories are genuine but were never actually repressed. Instead, some abuse victims may simply not have thought about their abuse for a long period of time, have been deliberately attempting to forget the abuse (suppression rather than repression), or may have forgotten prior instances when they did recall the abuse, resulting in the false impression that a recently surfaced memory had been repressed for years.

# 8 summary

## 8.1 What are somatic symptom disorders?

- Somatic symptom disorders lie at the interface of abnormal psychology and medicine. These are disorders in which psychological problems are manifested in physical symptoms. In response to the symptoms the person also experiences abnormal thoughts, feelings, and behaviors.
- Somatic symptom disorder occurs in individuals who have had multiple somatic complaints lasting at least 6 months. Even if the symptoms do not seem to have a medical explanation, the person's suffering is regarded as authentic.

## 8.2 What is illness anxiety disorder?

- Illness anxiety occurs in individuals who are very anxious about having an illness even though there are no apparent symptoms.

## 8.3 What is conversion disorder (functional neurological symptom disorder)?

- Conversion disorder involves patterns of symptoms or deficits affecting sensory or voluntary motor functions leading one to think there is a medical or neurological condition, even though medical examination reveals no physical basis for the symptoms.

## 8.4 What is the difference between a factitious disorder and malingering?

- Individuals with factitious disorder intentionally produce medical or psychological symptoms (or both). They do this in the absence of external rewards in order to take on an illness role.
- Malingering involves the intentional production of symptoms or the exaggeration of symptoms. This is motivated by external factors such as a wish to claim insurance money, avoid work or military service, or to get leniency in a criminal prosecution.

## 8.5 What are the primary features of dissociative disorders?

- Dissociative disorders occur when the processes that normally regulate awareness and the multichannel capacities of the mind apparently become disorganized, leading to various anomalies of consciousness and personal identity.

### **8.6 What is depersonalization/derealization disorder?**

- Depersonalization/derealization disorder occurs in people who experience persistent and recurrent episodes of derealization (losing one's sense of reality of the outside world) and/or depersonalization (losing one's sense of oneself and one's own reality).

### **8.7 What is dissociative amnesia?**

- Dissociative amnesia involves an inability to recall previously stored information that cannot be accounted for by ordinary forgetting and seems to be a common initial reaction to highly

stressful circumstances. The memory loss is primarily for episodic or autobiographical memory.

### **8.8 What is dissociative identity disorder?**

- In dissociative identity disorder, the person manifests at least two or more distinct identities that alternate in some way in taking control of behavior. Alter identities may differ in many ways from the host identity.

How do we define obesity and why is it a worldwide problem?

### 9.5

Who is most at risk for obesity

### 9.6

How is obesity treated?

Weighing a mere 88 pounds on her 5-foot-8 frame, Brazilian model Ana Carolina Reston succumbed to a generalized infection on November 15, 2006, while battling anorexia nervosa. She was 21 years old. Having modeled for Armani and Versace and in numerous countries around the world, Carolina was initially hospitalized for kidney failure. Ana Carolina's anorexia nervosa apparently began after she was criticized for being "too fat" during a casting call in China. At the height of her illness her diet consisted only of tomatoes and apples. Her death highlights the health risks associated with eating disorders.

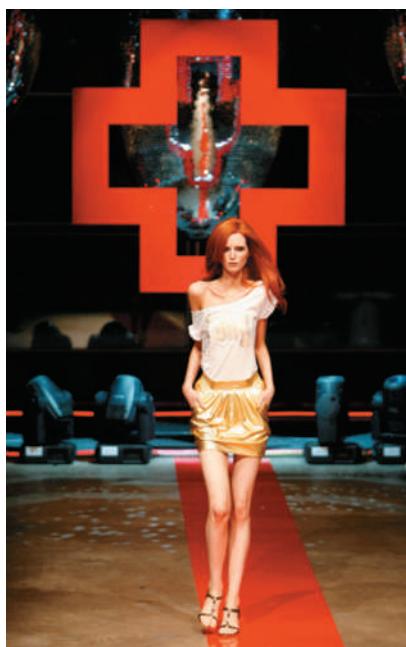

This model's struggles with anorexia nervosa also reveal the extent to which ideals of beauty are intertwined with thinness. Looking good often means being slim, especially for those in the public eye. Not surprisingly, many celebrities, including Nicole Richie, Mary-Kate Olsen, Victoria Beckham, and the late Princess Diana, have also struggled with eating disorders.

After the death in 2006 of Luisel Ramos, a model from Uruguay, some steps were taken by the fashion industry to try to address the situation. The organizers of the Madrid Fashion Week decided to ban models who did not have a body mass index

(a measure of a person's weight relative to height) in the healthy range. In 2010, Victoria Beckham reportedly deemed 23 models "too skinny" and refused to have them be part of her New York Fashion Week runway show. And in France, legislation has been proposed to prohibit media that encourage emaciation, or extreme thinness. What do you think? Should models be required to get a certificate of health from their doctors before being allowed on the catwalks? Should we expect the fashion industry to police itself, or should legislation be involved? Are you ready to see healthier-looking models in the pages of *Vogue*, or does ultrathin still mean ultrafashionable to you?

According to the *DSM-5* (APA, 2013), **eating disorders** are characterized by a persistent disturbance in eating behavior. No doubt you have heard about anorexia nervosa and bulimia nervosa. Within the *DSM* these are considered to be separate syndromes, and they reflect two types of adult eating disorders. However, disordered eating is not their only striking feature. At the heart of both disorders is an intense fear of becoming overweight and fat and an accompanying pursuit of thinness. This pursuit is relentless and sometimes deadly.

In this chapter we focus on both of these disorders. We also examine obesity. Obesity is not considered to be an eating disorder or a psychiatric condition in the *DSM*; however, its prevalence is rising at an alarming rate. Obesity also accounts for more morbidity and mortality than all other eating disorders combined. Because obesity clearly involves disordered eating patterns, we discuss it in detail in this chapter.

Model Ana Carolina Reston weighed just 88 pounds when she died from medical complications of anorexia nervosa.

The late Princess Diana's courage in discussing her own struggles with bulimia nervosa helped many other individuals with the same problem to seek treatment.

# Clinical Aspects of Eating Disorders

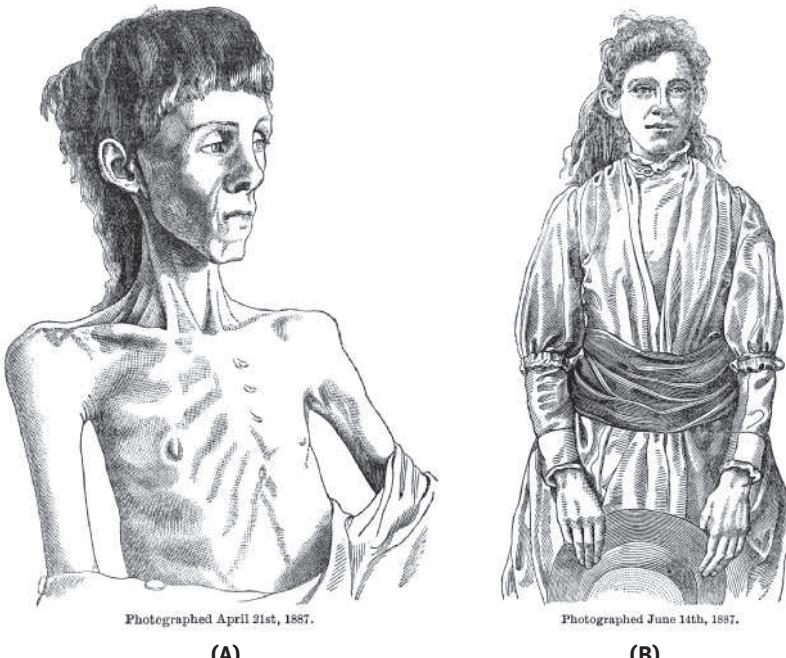

## Anorexia Nervosa

The term *anorexia nervosa* literally means “lack of appetite induced by nervousness.” This definition is something of a misnomer, however, as a lack of appetite is neither the core difficulty nor necessarily even true. At the heart of **anorexia nervosa** is an intense fear of gaining weight or becoming fat, combined with behaviors that result in a significantly low body weight. The *DSM-5* criteria for anorexia nervosa are shown in the *DSM* criteria box. An important change from *DSM-IV* to *DSM-5* is that in *DSM-5* amenorrhea (cessation of menstruation) is no longer required for a person to be given the diagnosis. Studies have suggested that women who continue to menstruate but meet all the other diagnostic criteria for anorexia nervosa are very similar psychologically to women who have amenorrhea and have ceased menstruating (Attia & Roberto, 2009). Amenorrhea is also not a criterion that can be used for males, nor can it be assessed in prepubescent girls or in women who use hormonal contraceptives.

 Watch the Video *Natasha: Anorexia* on MyPsychLab

Although we may think of anorexia nervosa as a modern problem, it is centuries old. Descriptions of extreme fasting that were probably signs of anorexia nervosa can be found in early religious literature (Vandereycken, 2002). The first known medical account of anorexia nervosa, however, was published in 1689 by Richard Morton (see Silverman, 1997, for a good general historical overview). Morton described two patients, an

**FIGURE 9.1**

Gull's patient with anorexia nervosa. (A) Before treatment. (B) After treatment.

**criteria for**  
**Anorexia Nervosa**

**DSM-5**

A. Restriction of energy intake relative to requirements, leading to a significantly low body weight in the context of age, sex, developmental trajectory, and physical health. *Significantly low weight* is defined as a weight that is less than minimally normal or, for children and adolescents, less than that minimally expected.

B. Intense fear of gaining weight or of becoming fat, or persistent behavior that interferes with weight gain, even though at a significantly low weight.

C. Disturbance in the way in which one's body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or persistent lack of recognition of the seriousness of the current low body weight.

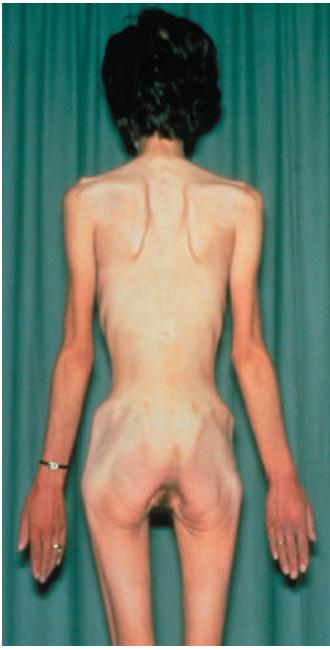

Source: Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, (Copyright 2013). American Psychiatric Association.

18-year-old girl and a 16-year-old boy, who suffered from a “nervous consumption” that resulted in wasting of body tissue. The female patient eventually died because she refused treatment.

The disorder did not receive its current name until 1873, when Charles Lasègue in Paris and Sir William Gull in London independently described the clinical syndrome. In his last publication on the condition, Gull (1888) described a 14-year-old girl who began “without apparent cause, to evince a repugnance to food; and soon afterwards declined to take any whatever, except half a cup of tea or coffee.” After being prescribed to eat light food every few hours, the patient made a good recovery. Gull’s illustrations of the patient before and after treatment appear in Figure 9.1.

Even though they may look painfully thin or even emaciated, many patients with anorexia nervosa deny having any problem. Indeed, they may come to feel fulfilled by their weight loss. Despite this quiet satisfaction, however, they may feel ambivalent about their weight. Efforts may be made to conceal their thinness by wearing baggy clothes or carrying hidden bulky objects so that they will weigh more when measured by others. Patients with anorexia nervosa may even resort to drinking large amounts of water to increase their weight temporarily.

There are two types of anorexia nervosa: the restricting type and the binge-eating/purging type. The central difference

Patients with anorexia nervosa may be emaciated while still denying that they have any problems with their weight. They will go to great lengths to conceal their thinness by wearing baggy clothes, or by drinking massive amounts of water prior to being weighed (in a hospital setting, for instance).

**TABLE 9.1**  
**Distorted Thinking in Anorexia Nervosa**

"I have a rule when I weigh myself. If I've gained then I starve the rest of the day. But if I've lost, then I starve too."

"Bones define who we really are, let them show."

"An imperfect body reflects an imperfect person."

"Anorexia is not a self-inflicted disease, it's a self-controlled lifestyle."

"It's not deprivation, it's liberation."

between these two subtypes concerns the way in which patients maintain their very low weight. In the restricting type, every effort is made to limit the quantity of food consumed. Caloric intake is tightly controlled. Patients often try to avoid eating in the presence of other people. When they are at the table, they may eat excessively slowly, cut their food into very small pieces, or dispose of food secretly (Beaumont, 2002).

The relentless restriction of food intake is not possible for all patients with anorexia nervosa. Patients with the binge-eating/purging type of anorexia nervosa differ from patients with restricting anorexia nervosa because they either binge, purge, or binge and purge. A **binge** involves an out-of-control consumption of an amount of food that is far greater than what most people would eat in the same amount of time and under the same circumstances. These binges may be followed by efforts to **purge**, or remove from their bodies, the food they have eaten. Methods of purging commonly include self-induced vomiting or misusing laxatives, diuretics, and enemas. Other compensatory behaviors that do not involve purging are excessive exercise or fasting. Even purging strategies, however, do not prevent the absorption of all calories from food.

Indicative of the distorted values of eating-disordered patients, (see Table 9.1 for personal comments that provide examples of this) those with the restricting type of anorexia nervosa are often greatly admired by others with eating disorders. One patient reported that she had not been "successful" in her anorexia nervosa because of her failure to reach an extremely low weight. Her belief was that the hallmark of a truly successful person with anorexia nervosa was death from starvation, and that patients who were able to accomplish this should somehow be revered (see Bulik & Kendler, 2000).

In the example that follows, we describe the case of Tim, who is suffering from the restricting type of anorexia nervosa. Tim's

case reminds us that eating disorders can occur in young children as well as in boys. It further highlights the high comorbidity between eating disorders and obsessive-compulsive symptoms and personality traits, which we will subsequently discuss. In fact, Tim warrants an additional diagnosis of obsessive-compulsive disorder.

→ **Tim: Obsessed With His Weight** Tim is 8 years old. He is extremely concerned about his weight and weighs himself daily. Tim complains that he is too fat, and if he does not lose weight, he cuts back on food. He has lost 10 pounds in the past year and still feels that he is too fat. However, it is clear that he is underweight. In desperation, his parents have removed the scales from the house; as a result, Tim is keeping a record of the calories that he eats daily. He spends an excessive amount of time on these calculations, checking and rechecking that he has done it just right.

In addition, Tim is described as being obsessed with cleanliness and neatness. Currently, he has no friends because he refuses to visit them, feeling that their houses are "dirty." He becomes upset when another child touches him. He is always checking whether he is doing things the way they "should" be done. He often feels very agitated and anxious about this. Each day, he has to wake up at least 2 hours before leaving for school in order to allow himself sufficient time to get ready. Recently, he woke up at 1:30 A.M. to prepare for school.

Because the artistic standards of their profession emphasize a slender physique, ballet dancers are at an especially high risk for eating disorders (see the case study of Ms. R. on p. 297). Gelsey Kirkland, who developed an eating disorder while she was a premier ballerina with the New York City Ballet, described the existence of a "concentration camp aesthetic" within the company. This was no doubt fostered by the famous choreographer George Balanchine, who, as described by Kirkland in her autobiography, tapped her on the ribs and sternum after one event and exhorted that he "must see the bones" (Kirkland, 1986, pp. 55–56).

Ballet dancers are at very high risk for developing eating disorders. According to Gelsey Kirkland, once the premier ballerina at the New York City Ballet, the value placed on being thin can create a "concentration camp aesthetic" supported and encouraged by the dance company.

→ **Ms. R.: Going to Extremes** Ms. R. is a very thin, 19-year-old, single ballet student who comes in at the insistence of her parents for a consultation concerning her eating behavior. Ms. R. has had a lifelong interest in ballet. She began to attend classes at age 5 and by age 8 was recognized by her teachers as having impressive talent. Since the age of 14 she has been a member of a national ballet company.

Ms. R. has had difficulties with eating since age 15 when, for reasons she is unable to explain, she began to induce vomiting after what she felt was overeating. The vomiting was preceded by many years of persistent dieting, which began with the encouragement of her ballet teacher. Over the past 3 years, Ms. R.'s binges have occurred once a day in the evening and have been routinely followed by self-induced vomiting. The binges consist of dozens of rice cakes or, more rarely, half a gallon of ice cream. Ms. R. consumes this food late at night after her parents have gone to bed. For some time, Ms. R.'s parents have been concerned that their daughter has a problem with her eating, but she consistently denied difficulties until about a month before this consultation.

Ms. R. reached her full height of 5 feet 8 inches at age 15. Her greatest weight was 120 pounds at age 16, which she describes as being fat. For the past 3 years, her weight has been reasonably stable in the range of 100 to 104 pounds. She exercises regularly as part of her profession, and she denies using laxatives, diuretics, or diet pills as a means of weight control. Except when she is binge eating, she avoids the consumption of foods high in fat or sugar.

Since age 15, she has been a strict vegetarian and consumes no meat or eggs and little cheese. For the past 3 or 4 years, Ms. R. has been uncomfortable eating in front of other people and

goes to great lengths to avoid such situations. This places great limitations on her social life.

## Bulimia Nervosa

**Bulimia nervosa** is characterized by uncontrollable binge eating and efforts to prevent resulting weight gain by using inappropriate behaviors such as self-induced vomiting and excessive exercise. Bulimia nervosa was recognized as a psychiatric syndrome relatively recently. The British psychiatrist G. F. M. Russell (1997) proposed the term in 1979, and it was adopted into the *DSM* in 1987. The word bulimia comes from the Greek *bous* (which means "ox"), and *limos* ("hunger"). It is meant to denote a hunger of such proportions that the person "could eat an ox."

The *DSM-5* criteria for bulimia nervosa are shown in the *DSM* box below. Compared to *DSM-IV*, the diagnostic criteria for bulimia nervosa have been relaxed. Binge eating and purging now have to occur on average once a week (instead of twice a week) over a 3-month period. This change was made after research showed that people with sub-threshold bulimia nervosa were remarkably similar to those who had the full syndrome (Eddy, Doyle, et al., 2008; Fairburn et al., 2007).

### criteria for Bulimia Nervosa

**DSM-5**

- A. Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:
  - 1. Eating, in a discrete period of time (e.g., within any 2-hour period), an amount of food that is definitely larger than what most individuals would eat in a similar period of time under similar circumstances.
  - 2. A sense of lack of control over eating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating).
- B. Recurrent inappropriate compensatory behaviors in order to prevent weight gain, such as self-induced vomiting; misuse of laxatives, diuretics, or other medications; fasting; or excessive exercise.
- C. The binge eating and inappropriate compensatory behaviors both occur, on average, at least once a week for 3 months.
- D. Self-evaluation is unduly influenced by body shape and weight.
- E. The disturbance does not occur exclusively during episodes of anorexia nervosa.

Source: Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, (Copyright 2013). American Psychiatric Association.

The clinical picture of the binge-eating/purging type of anorexia nervosa has much in common with bulimia nervosa. Indeed, some researchers have argued that the bulimic type of anorexia nervosa should really be considered another form of bulimia nervosa. The difference between a person with bulimia nervosa and a person with the binge-eating/purging type of anorexia nervosa is weight. By definition, the person with anorexia nervosa is severely underweight. This is not true of the person with bulimia nervosa.

Consequently, if the person who binges or purges also meets criteria for anorexia nervosa, the diagnosis is anorexia nervosa (binge-eating/purging type) and not bulimia nervosa. In other words, the anorexia nervosa diagnosis “trumps” the bulimia nervosa diagnosis. This is because there is a far greater mortality rate associated with anorexia nervosa than with bulimia nervosa. Recognizing this, the *DSM* requires that the more severe form of eating pathology take precedence diagnostically.

People with anorexia nervosa and bulimia nervosa share a common fear of being or becoming fat. However, unlike patients with anorexia nervosa, those with bulimia nervosa are typically of normal weight or sometimes even slightly overweight. The fear of becoming fat helps explain the development of bulimia nervosa. Bulimia typically begins with restricted eating motivated by the desire to be slender. During these early stages, the person diets and eats low-calorie foods. Over time, however, the early resolve to restrict gradually erodes, and the person starts to eat “forbidden foods” such as potato chips, pizza, cake, ice cream, and chocolate. Of course, some patients binge on whatever food is available, including such things as raw cookie dough. During an average binge, someone with bulimia nervosa may consume as many as 4,800 calories (Johnson et al., 1982). After the binge, in an effort to manage the breakdown of self-control, the person begins to vomit, fast, exercise excessively, or abuse laxatives. This pattern then persists because, even though those with bulimia nervosa are disgusted by their behavior, the purging alleviates the fear of gaining weight that comes from eating.

Whereas people with anorexia nervosa often deny the seriousness of their disorder and are surprised by the shock and concern with which others view their emaciated conditions, those with bulimia nervosa are often preoccupied with shame, guilt, and self-deprecation. They make efforts to conceal their behavior as they struggle (often unsuccessfully) to master their urges to binge. The case described below depicts a typical pattern.

→ **Catherine: Distressed by Her Weight** Catherine is 20 years old. Catherine has been concerned about her weight and shape for several years. As a teenager she felt plump and was frequently on a diet, even though she was within the normal weight range for her age and height. As she became older, these concerns became more serious. She severely restricted her food intake and started punishing exercise regimens. At one stage she became significantly underweight. Medical help led to weight gain, which was quickly followed by more dieting and, for the

first time, she started binge eating. Distressed by the increase in her weight and by increasingly frequent binge eating, Catherine began vomiting in a desperate attempt to lose weight.

Over the last six months Catherine has skipped breakfast and lunch, eaten a normal evening meal with her family, but gone on to binge eat in the late evening usually two or three times a week. She binges in response to feeling upset and worried. In a recent typical binge she ate four slices of toast with butter and jam, six packets of potato chips, three large bars of chocolate, half a box of cereal and a large bowl of ice cream. She had been feeling rejected by a friend. Catherine drinks large quantities of water to help her induce vomiting after bingeing. More recently she has started to take 30 to 40 laxatives, as well as vomiting. She has a strenuous exercise regime, including 500 daily sit-ups and an aerobic workout. Food is divided rigidly into good and bad categories; food in the bad category (such as cookies, chocolate, and cheese) is not allowed.

Catherine has become increasingly self-conscious. She refuses to weigh herself, has given up swimming (she used to swim on her school team) and if she goes shopping she will not try on clothes unless she has privacy. Catherine dislikes her body. She is preoccupied with her shape and reports that a little voice in her head constantly says, “You’re fat and ugly, I can’t stand the way you look.” Catherine worries that her friends will think less of her if she does not lose weight (when out with friends she avoids eating and sucks her tummy in to the point of pain in order to appear thinner). She feels very bad about herself if she thinks she has gained weight.

## Binge Eating Disorder

A new addition to *DSM-5* is the diagnosis of **binge eating disorder (BED)**. Previously, in *DSM-IV*, binge eating was given provisional status. This encouraged researchers to study it. Research has now supported the idea that BED is a distinct clinical syndrome (Wonderlich et al., 2009). It has therefore entered the *DSM* as a new formal diagnosis.  Watch the [Video Stacy: Binge Eating Disorder on MyPsychLab](#)

Although BED has some clinical features in common with bulimia nervosa, there is an important difference.

After a binge (which may be at a level comparable to that of a patient with bulimia nervosa), the person with BED does not engage in any form of inappropriate “compensatory” behavior. This might include purging, using laxatives, or even exercising to limit weight gain (Table 9.2 summarizes the similarities and differences between different types of eating disorders). There is also much less dietary restraint in BED than is typical of either bulimia nervosa or anorexia nervosa (Wilfley et al., 2000). Not surprisingly, binge-eating disorder is associated with being overweight or even obese (Hudson et al., 2007; Pike et al., 2001),

TABLE 9.2

## Comparing Anorexia Nervosa, Bulimia Nervosa, and Binge Eating Disorder

Symptom	Anorexia Nervosa		Bulimia Nervosa		Binge Eating Disorder
	Restricting	Binge/Purge	Purging	Nonpurging	
Body weight	Markedly low	Markedly low	Normal weight or slightly overweight	Normal weight or slightly overweight	Typically overweight or obese
Fear of weight gain, becoming fat	yes	yes	yes	yes	no
Body image	Distorted perception	Distorted perception	Overconcerned with weight	Overconcerned with weight	May be unhappy with body and weight
Binge eating	no	yes	yes	yes	yes
Purging	no	yes	yes	no	no
Use of nonpurging methods to avoid weight gain	yes	yes	yes	yes	no
Feeling of lack of control over eating	no	During binges	yes	yes	yes

criteria for  
Binge-Eating Disorder

DSM-5

- A. Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:
1. Eating, in a discrete period of time (e.g., within any 2-hour period), an amount of food that is definitely larger than what most people would eat in a similar period of time under similar circumstances.
  2. A sense of lack of control over eating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating).
- B. The binge-eating episodes are associated with three (or more) of the following:
1. Eating much more rapidly than normal.
  2. Eating until feeling uncomfortably full.
  3. Eating large amounts of food when not feeling physically hungry.
  4. Eating alone because of feeling embarrassed by how much one is eating.
  5. Feeling disgusted with oneself, depressed, or very guilty afterward.
- C. Marked distress regarding binge eating is present.
- D. The binge eating occurs, on average, at least once a week for 3 months.
- E. The binge eating is not associated with the recurrent use of inappropriate compensatory behavior as in bulimia nervosa and does not occur exclusively during the course of bulimia nervosa or anorexia nervosa.

although weight is not a factor involved in making the diagnosis. Interestingly, individuals with binge-eating disorder are more likely to have overvalued ideas about the importance of weight and shape than overweight or obese patients who do not have binge-eating disorder. In this respect, they also resemble people with bulimia nervosa (Allison et al., 2005).

→ **Ms. A.: Feeling Out of Control** Ms. A. was a 38-year-old African American woman who was single, lived alone, and was employed as a personnel manager at a hotel in New York. Her height was 6 feet, and she weighed 292 pounds ( $BMI = 39.6$ ; see Table 9.4 on p. 310) when she was initially seen at the eating disorders clinic. Her chief reason for going to the clinic was that she felt her eating was out of control and, as a result, she had gained approximately 80 pounds over the previous year.

Ms. A. reported a lifetime history of obesity and a history of binge eating beginning at approximately age 11. At her intake session, she described her eating. She felt out of control and ate large amounts of food nearly every day, typically in the evenings when she was on her way home from work or alone at home. She tended to feel out of control throughout the day, which contributed to her daily snacking on three or four regular candy bars or three or four medium cookies and one ice cream bar. Ms. A. would consequently feel that a binge episode was inevitable.

A typical binge episode consisted of two pieces of chicken, one small bowl of salad, two servings of mashed potatoes, one hamburger, one large serving of french fries, one fast-food serving of apple pie, one large chocolate shake, one large bag of potato chips, and 15 to 20 small cookies—all within a 2-hour period. During her binge episodes, Ms. A. ate much more rapidly than usual until she felt uncomfortably full, ate large amounts of food when she didn't feel physically hungry, ate alone because she was embarrassed by the quantity

of food she ate, and felt disgusted with herself and very guilty after eating. She was also extremely distressed about her weight. She sadly acknowledged that her weight and shape were the most important factors in determining her feelings about herself.

## Age of Onset and Gender Differences

Eating disorders are often considered to be “modern” disorders, yet pathological patterns of eating date back several centuries (Silverman, 1997). St. Catherine of Sienna began to starve herself when she was around 16 years of age. She died in 1380 (at the age of 32 or 33) because she refused to consume either food or water (Keel & Klump, 2003). Moreover, as far back as the second century, the Greek physician Galen referred to a syndrome characterized by overeating, vomiting, and fainting, which he termed *bulimia* (see Ziolko, 1996). It was not until the 1970s and 1980s, however, that eating disorders began to attract significant attention. Clinicians began seeing more and more patients with pathological eating patterns. It soon became apparent that this was an important clinical problem.

Anorexia nervosa and bulimia nervosa do not occur in appreciable numbers before adolescence. Children as young as 7, though, have been known to develop eating disorders, especially anorexia nervosa (Bryant-Waugh & Lask, 2002). Anorexia nervosa is most likely to develop in 15- to 19-year-olds. For bulimia nervosa, the age group at highest risk is young women falling in the age range of 20 to 24 (Hoek & van Hoecken, 2003). Most patients with binge-eating disorder are older than those with anorexia nervosa or bulimia nervosa, generally between 30 and 50 years of age.

Eating disorders have long been regarded as occurring primarily in women. Although in the past it was thought that the gender ratio was as high as 10:1, more recent estimates suggest that there are three females for every male with an eating disorder (Jones & Morgan, 2010). This downward revision of the gender ratio reflects the fact that eating disorders in men may have been

Competitive eating contests, such as the hot dog eating contest that is held every year in Coney Island, New York, attract many spectators. During a 10-minute time span, some competitors are able to eat 60 or more hot dogs. Do you think this is a healthy sport? What messages does it send about food? In what ways is competitive eating different from binge eating disorder?

underdiagnosed in the past because of the stereotype that they are female disorders. Another reason for the underdiagnosis of eating disorders in men is the gender bias in the *DSM* criteria. These emphasize the type of weight and shape concerns (e.g., desire to be thin) and methods of weight control (dieting) that are more typical of women. For men, body dissatisfaction often involves a wish to be more muscular. Over-exercising as a means of weight control is also more common in men. As a result, men are less likely to recognize that they have an eating disorder, are more likely to be misdiagnosed when they do, and are less likely to receive specialist treatment (Jones & Morgan, 2010).

One established risk factor for eating disorders in men is homosexuality. Gay and bisexual men have higher rates of eating disorders than heterosexual men do (Feldman & Meyer, 2007). Gay men (like heterosexual men) value attractiveness and youth in their romantic partners. Because gay men (like women) are seeking to be sexually attractive to men, body dissatisfaction may therefore be more of an issue for gay men than it is for heterosexual men. In support of this idea, Smith and colleagues (2011) found that gay men were more dissatisfied with their bodies and had higher levels

## THINKING CRITICALLY about DSM-5

### Other Forms of Eating Disorders

DSM-5

In addition to anorexia nervosa, bulimia nervosa, and binge eating disorder, the *DSM-5* also includes a new category that is used to diagnose other clinically significant problems involving feeding and eating. Purging disorder (which involves purging in normal weight people who have not eaten large amounts of food) is one example of this. Gone from the *DSM* is the diagnosis of eating disorder not otherwise specified (EDNOS). Prior to

*DSM-5*, the diagnosis of EDNOS was given to around 60 percent of adolescents and adults who sought treatment in outpatient settings (Eddy, Doyle, et al., 2008; Fairburn & Bohn, 2005). Changes to the diagnostic criteria for anorexia nervosa and bulimia nervosa in *DSM-5* as well as the inclusion of BED as a new diagnosis are expected to make EDNOS a less meaningful and necessary diagnosis. As a result it has been removed.

Men are now experiencing socio-cultural pressures to have toned and muscular bodies. For many men, body dissatisfaction takes the form of wanting to have a more muscular upper torso.

of disordered eating than heterosexual men did. Moreover, gay men tended to believe that a potential mate would want them to be leaner than they themselves wanted to be. Other specific subgroups of men who are at higher risk of eating disorders are wrestlers and jockeys, who need to “make weight” in order to compete or work (Carlat et al., 1997).

### Prevalence of Eating Disorders

The most common form of eating disorder is binge-eating disorder. Worldwide, and based on the most recent data, the lifetime prevalence of binge eating disorder is around 2 percent (Kessler et al., 2013). In the United States, community-based estimates from the National Comorbidity Survey indicate a lifetime prevalence of around 3.5 percent in women and 2 percent in men (Hudson et al., 2007). It is also worth noting that the prevalence of binge-eating disorder is higher in obese people and in the range of 6.5 to 8 percent (Grilo, 2002; Sansone et al., 2008).

Worldwide, the prevalence of bulimia nervosa is estimated at 1 percent (Kessler et al., 2013). Data from the National Comorbidity Survey further show that the lifetime prevalence of bulimia nervosa in the United States is around 1.5 percent for women and 0.5 percent for men (Hudson et al., 2007). Somewhat less frequent is anorexia nervosa. Estimates from the United States suggest that this disorder has a lifetime prevalence of 0.9 percent in women and 0.3 percent in men (Hudson et al., 2007). These figures are comparable to prevalence estimates from Sweden, where the rate of anorexia nervosa is 1.2 percent in women and 0.29 percent in men (Bulik et al., 2006). Although anorexia nervosa is sometimes viewed as a very rare disorder, in its severe form it is about as common as schizophrenia.

The risk of developing anorexia nervosa seemed to increase during the twentieth century. In one study, lifetime rates of this disorder were higher in people born after 1945 than before this time (Klump et al., 2007). This is true for both males and females. This increase is not fully explained by increased awareness of the

disorder and better detection by clinicians. There was also a rise in the number of new cases of bulimia nervosa from 1970 to 1993 (Keel & Klump, 2003). However, much of this increase may have occurred in the time period up to 1982. A more recent analysis has indicated that the prevalence of bulimia nervosa decreased from 1982 to 1992 and remained stable from 1992 to 2002 (Keel et al., 2006). Stable rates of bulimia nervosa from 1990 to 2004 have also been reported (Crowther et al., 2008).

Despite the encouraging news of a decrease in the prevalence of bulimia nervosa over the last few decades, many young people, particularly girls and young women in their adolescence and early adulthood, show some evidence of disturbed eating patterns or have distorted self-perceptions about their bodies. For example, in a sample of 4,746 middle and high school students, 41.5 percent of girls and 24.9 percent of boys reported problems with body image, and more than a third of the girls and almost a quarter of the boys said they placed a lot of importance on weight and shape with regard to their self-esteem (Ackard et al., 2007). Questionnaire studies further suggest that up to 19 percent of students report some bulimic symptoms (Hoek, 2002). Also of concern are findings from a survey of adults in Australia showing a twofold increase in binge eating, purging, and strict dieting or fasting in the period from 1995 to 2005 (Hay et al., 2008). Disordered eating behaviors that do not meet criteria for an eating disorder diagnosis are of concern because, in some cases, they may worsen over time, eventually leading to clinically significant problems. Table 9.3 shows some sample items from the Eating Disorders Inventory, a questionnaire measure that is often used in research.

### Medical Complications of Eating Disorders

The tragic death of Ana Carolina Reston from kidney failure serves as a sad reminder of just how lethal a disorder anorexia nervosa is. In fact, anorexia nervosa has the highest mortality rate of any psychiatric disorder. The mortality rate for females with anorexia nervosa is more than 12 times higher than the mortality rate for females aged 15 to 24 in the general U.S. population (Sullivan, 1995, 2002). When patients with this disorder die, it

**TABLE 9.3**

Garner, PhD, Copyright 1984, 1991, 2004, by Psychological Assessment Resources, Inc. (PAR). Further reproduction is prohibited without permission of PAR.

is most often because of medical complications. Overall, approximately 3 percent of people with anorexia nervosa die from the consequences of their self-imposed starvation (Signorini et al., 2007).

Malnutrition also takes its toll in other ways (see Mitchell & Crow, 2010). Many patients with anorexia nervosa disorder look extremely unwell. Their hair on the scalp thins and becomes brittle, as do their nails. Their skin becomes very dry, and downy hair (called “lanugo”) starts to grow on the face, neck, arms, back, and legs. Many patients also develop a yellowish tinge to their skin, especially on the palms of their hands and bottoms of their feet. Some of these problems are illustrated in Figure 9.2.

Because they are so undernourished, people with this disorder have a difficult time coping with cold temperatures. Their hands and feet are often cold to the touch and have a purplish-blue tinge due to problems with temperature regulation and lack of oxygen to the extremities. As a consequence of chronically low blood pressure, patients often feel tired, weak, dizzy, and faint. Thiamin (vitamin B1) deficiency may also be present; this could account for some of the depression and cognitive changes documented in low-weight anorexia patients (Winston et al., 2000). Although many of these problems resolve when patients gain weight, anorexia nervosa may result in increased risk for osteoporosis in later life. This is because peak bone density is normally attained during the years of early adulthood. The failure to eat healthily during this time may result in more brittle and fragile bones forever (Attia & Walsh, 2007).

People with anorexia nervosa can die from heart arrhythmias (irregular heartbeats). Sometimes this is caused by major imbalances

in key electrolytes such as potassium (Mitchell & Crow, 2010). Chronically low levels of potassium (hypokalemia) can also result in kidney damage and renal failure severe enough to require dialysis.

Abuse of laxatives, which occurs in 10 to 60 percent of patients with eating disorders (Roerrig et al., 2010) makes all of these problems much worse. Laxatives are used to induce diarrhea so that the person feels thinner or to remove unwanted calories from the body. Laxative abuse can lead to dehydration, electrolyte imbalances, and kidney disease as well as damage to the bowels and gastrointestinal tract.

Bulimia nervosa is much less lethal than anorexia nervosa, although it is still associated with a mortality rate that is approximately twice that found in people of comparable age in the general population (Arcelus et al., 2011). Bulimia nervosa also creates a number of medical concerns (Mitchell & Crow, 2010). Purging can cause electrolyte imbalances and low potassium, which, as we have already mentioned, puts the patient at risk for heart abnormalities. Another complication is damage to the heart muscle, which may be due to using ipecac syrup (a poison that causes vomiting). More typically, however, patients develop calluses on their hands from sticking their fingers down their throats to make themselves sick. In extreme cases, where objects such as a toothbrush are used to induce vomiting, tears to the throat can occur.

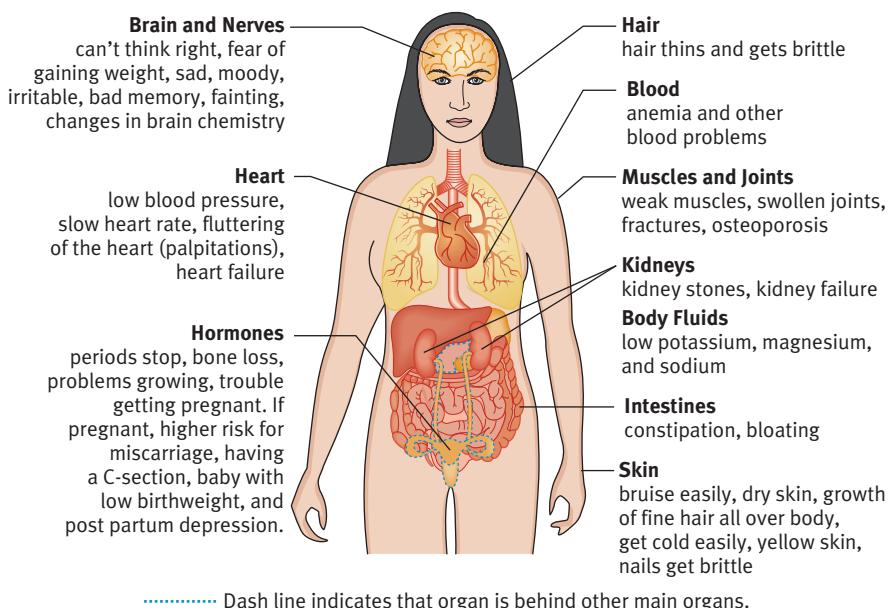

Because the contents of the stomach are acidic, patients damage their teeth when they throw up repeatedly. Brushing teeth immediately after vomiting damages them even more. Mouth ulcers and dental cavities are a common consequence of repeated purging, as are small red dots around the eyes that are caused by the

pressure of throwing up. Finally, patients with bulimia very often have swollen parotid (salivary) glands caused by repeatedly vomiting. These are known as “puffy cheeks” or “chipmunk cheeks” by many bulimia sufferers. Although such swellings are not painful, they are often quite noticeable to others.

## Course and Outcome

We begin this section with a sobering statistic. After medical complications, the second most common cause of death in those who suffer from anorexia nervosa is suicide. Recent estimates suggest that one out of five deaths in individuals with anorexia nervosa is the result of suicide (Arcelus et al., 2011). Somewhere between 3 and 23 percent of patients with anorexia will make a suicide attempt, and rates of completed suicide are 50 times greater than they are in the general population (Franko & Keel, 2006; Keel et al., 2003). It has been suggested that patients who have lost their ability to maintain an “emotionally protective” low body weight are at particularly high risk of suicide (Crisp et al., 2006). Patients who are older when they first receive clinical attention for their disorder are also more likely to have a premature

### Anorexia affects your whole body

**FIGURE 9.2**

Anorexia nervosa takes its toll on the body and causes many medical problems. When starved, the body turns on itself in an effort to provide energy. Fat is burned first, then muscle. Eventually, organs are destroyed in the body's struggle to find fuel. [Watch](#)  
the [Video Eating Disorders](#) on [MyPsychLab](#)

death (Arcelus et al., 2011). Bulimia nervosa is not associated with increased risk of completed suicide, although suicide attempts are made in 25 to 30 percent of cases (Franko & Keel, 2006).

Although the clinical outcome for some patients is tragic, over the very long term recovery is possible. Löwe and colleagues (2001) examined what happened to patients with anorexia nervosa 21 years after they had first sought treatment. Reflecting the high morbidity associated with anorexia nervosa, 16 percent of the patients (all of whom were women) were no longer alive, having died primarily from complications of starvation or from suicide. Another 10 percent were still suffering from the disorder, and a further 21 percent had partially recovered. On the positive side, however, 51 percent of the individuals were fully recovered at the time of the follow-up. In another 6-year follow-up study, 52.1 percent of patients who had received outpatient cognitive behavioral therapy for their anorexia nervosa eventually recovered (Castellini et al., 2011). These findings provide grounds for optimism for those who suffer from this disorder. They indicate that even after a series of treatment failures it is still possible for women with anorexia nervosa to become well again.

With regard to bulimia nervosa, in the long term, prognosis tends to be quite good. Two outcome studies have shown that around 70 percent of women initially diagnosed with this disorder will be in remission and will no longer meet diagnostic criteria for any eating disorder by the end of an 11- to 12-year follow-up (Keel et al., 1999; Fichter & Quadflieg, 2007). The remaining 30 percent, however, will continue to experience significant difficulties with their eating. Substance-abuse problems, more frequent binges, more shape concerns, as well as a longer duration of illness predict worse outcomes over time (Castellini et al., 2011; Keel et al., 1999).

Finally, like patients with bulimia nervosa, patients with binge-eating disorder also have high rates of clinical remission. Following a period of intensive treatment, two-thirds of a sample of 60 patients no longer had any form of eating disorder (Fichter & Quadflieg, 2007). In a larger study involving 137 Italian patients who received individual cognitive-behavior therapy, 60 percent were found to be recovered when they were assessed 6 years after the end of treatment (Castellini et al., 2011).

It is worth noting that, even when well, many individuals who recover from anorexia nervosa and bulimia nervosa still harbor residual food issues. They may be excessively concerned about shape and weight, restrict their dietary intakes, and overeat and purge in response to negative mood states (Sullivan, 2002). In other words, the idea of recovery is relative. Someone who no longer meets all of the diagnostic criteria for an eating disorder may still have issues with food and body image.

## Diagnostic Crossover

One way in which eating disorders differ from other types of disorders is that there is a lot of diagnostic crossover. What this means is that it is quite common for someone who is diagnosed

with one form of eating disorder to be later diagnosed with another eating disorder. Over a 7-year period, Eddy and colleagues (2008) report that the majority of women in their study experienced diagnostic crossover. Bidirectional transitions between the two subtypes of anorexia nervosa (restricting and binge-purging) were especially common.

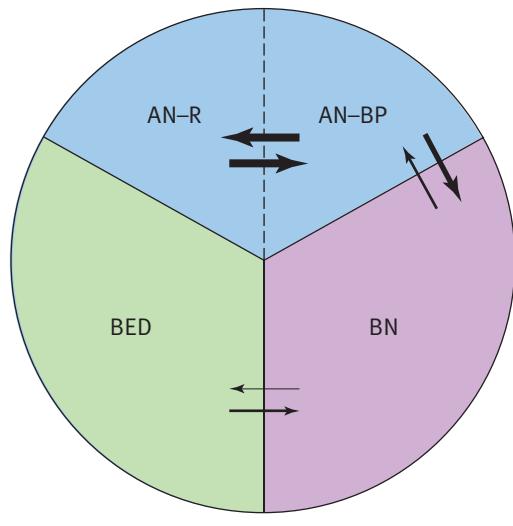

Shifts from anorexia nervosa to bulimia nervosa also occurred in about a third of patients. Interestingly, however, there were no cases of direct transition from the restricting type of anorexia nervosa directly into bulimia nervosa. Instead, the transition to bulimia nervosa seems to occur after an earlier transition to the binge-purging subtype of anorexia nervosa. You may also recall that the main difference between patients with the binge-purging subtype of anorexia nervosa and bulimia nervosa is weight (and associated amenorrhea). So if someone with anorexia nervosa (binge-purge subtype) gains weight, the diagnosis will change to bulimia nervosa to reflect this fact, even though there may not be a big clinical change in the illness itself. Moreover, even after they have crossed over into bulimia nervosa, these women remain vulnerable to relapsing back into anorexia nervosa. This suggests that clinicians should pay attention to a past history of anorexia nervosa even when patients no longer meet the low-weight criterion necessary for its diagnosis.

Only a minority of patients with bulimia nervosa transition into anorexia nervosa. In one study the figure was 14 percent (Eddy, Dorer, et al., 2008). In another it was 9.2 percent (Castellini et al., 2011). Crossovers from the restricting subtype of anorexia nervosa into binge-eating disorder do not seem to occur at all. Diagnostic crossover from bulimia nervosa into binge-eating disorder occurs in about 10.9 percent of cases (Castellini et al., 2011).

Finally, we note that binge-eating disorder and anorexia nervosa appear to be quite distinct disorders. Over the course of a 12-year follow-up, no patient with binge-eating disorder developed anorexia nervosa and no patient with anorexia nervosa developed binge-eating disorder (Fichter & Quadflieg, 2007). In other words, there was no diagnostic crossover between these diagnoses. However, around 10 percent of patients who previously had binge-eating disorder transitioned into bulimia nervosa during this time. Figure 9.3 on p. 304 illustrates some of these trends.

## Association of Eating Disorders With Other Forms of Psychopathology

Eating disorder diagnoses are commonly associated with other diagnosable psychiatric conditions. In fact, comorbidity is the rule rather than the exception (Hudson et al., 2007). For instance, approximately 68 percent of patients with anorexia nervosa, 63 percent of patients with bulimia nervosa, and almost 50 percent of people with binge-eating disorder are also diagnosed with depression (Brewerton et al., 1995; Halmi, et al., 1991; Hudson et al., 2007; O'Brien & Vincent, 2003). Obsessive-compulsive disorder is often found in patients with anorexia nervosa and bulimia nervosa (Kaye et al., 2004; Milos et al., 2002;

- AN-R = Anorexia nervosa-restricting subtype  
 AN-BP = Anorexia nervosa-binge-purge subtype  
 BN = Bulimia nervosa  
 BED = Binge eating disorder

**FIGURE 9.3**

**Diagnostic Crossover in Eating Disorders.** Diagnostic crossover is common in eating disorders with transitions between the two subtypes of anorexia nervosa being very common. Transitions from the binge-purge subtype of anorexia nervosa to bulimia nervosa also often occur. In the figure, the width of the arrow denotes the relative likelihood of any transition. (Adapted from Fichter & Quadflieg, 2007, and Eddy, Dorer, et al., 2008.)

O'Brien & Vincent, 2003). In addition, there is frequent co-occurrence of substance-abuse disorders in the binge-purging subtype of anorexia nervosa as well as in bulimia nervosa. The restrictive type of anorexia nervosa, however, tends not to be associated with higher rates of substance abuse (Halmi, 2010).

Comorbid personality disorders are frequently diagnosed in people with eating disorders (Rø et al., 2005; see Chapter 10). Those with the restrictive type of anorexia nervosa are inclined toward personality disorders in the anxious-avoidant cluster (Cluster C; Skodol et al., 1993). In contrast, eating disorders that involve binge/purge syndromes (both anorexia nervosa and bulimia nervosa) are more likely to be associated with dramatic, emotional, or erratic (Cluster B) problems, especially borderline personality disorder (Halmi, 2010).

Consistent with this, more than a third of patients with eating disorders have engaged in the kinds of self-harming behaviors (cutting or burning themselves, for example) that are symptomatic of borderline personality disorder (Paul et al., 2002). Personality disorders are similarly reported in patients with BED, although no clear pattern has emerged (Wilfley et al., 2000). People with BED also have high rates of anxiety disorders (65%), mood disorders (46%), and substance use disorders (23%; see Hudson et al., 2007).

One problem with simple examinations of personality disorders in patients with eating disorders is that some of the disturbances found in these patients could reflect the consequences of malnourishment. Starvation is known to increase both irritability

and obsessionalism (Keys et al., 1950). We must therefore be cautious in our conclusions.

Even though the physiological consequences of eating disorders may exacerbate personality disturbances, they may only be enhancing traits that were present prior to the development of the illness. Research suggests that some personality traits in eating-disordered patients might both predate the onset of the disorder and remain even when the eating disorder remits and the patient has recovered (Kaye et al., 2004; Klump et al., 2004). Consistent with this, around two-thirds of a sample of patients with anorexia nervosa reported that they were rigid and perfectionistic, even as children (Anderluh et al., 2003).

### Eating Disorders Across Cultures

Although the majority of research on eating disorders is conducted in the United States and Europe, eating disorders are not confined to these areas. Widespread eating disorder difficulties have been reported among both Caucasian and black South African college students (le Grange et al., 1998). Anorexia nervosa and bulimia nervosa are also clinical problems in Japan, Hong Kong, Taiwan, Singapore, and Korea (Lee & Katzman, 2002).

Cases of eating disorders have also been documented in India and Africa. The prevalence of eating disorders in Iran is comparable to that in the United States (Nobakht & Dezhkam, 2000). And a few years ago, the first published report of five men in central China who were diagnosed with eating disorders appeared (Tong et al., 2005). Far from being confined to industrialized Western countries, eating disorders are becoming a problem worldwide.

Being Caucasian, however, does appear to be associated with subclinical problems that may place individuals at higher risk for developing eating disorders. Examples of such problems include body dissatisfaction, dietary restraint, and a drive for thinness. A **meta-analysis** involving a total of 17,781 participants has shown that such attitudes and behaviors are significantly more prevalent in whites than in nonwhites (Wildes et al., 2001).

Although Asian women exhibit levels of pathological eating similar to those of white women (Wildes et al., 2001), it has long

### research CLOSE-UP

#### Meta-analysis

A meta-analysis is a statistical method used to combine the results of a number of similar research studies. The data from each separate study are transformed into a common metric called the effect size. Doing this allows data from the various studies to be combined and then analyzed. You can think of a meta-analysis as being just like the research with which you are already familiar, except that the "participants" are individual research studies, not individual people!

been held that African Americans are less susceptible to subclinical types of eating problems and body image concerns than Caucasians are. For example, in one sample of 1,061 black women, no case of anorexia nervosa was found. In contrast, out of a sample of 985 white women, 15 (1.5%) met clinical criteria for this disorder. Fewer black than white women also had bulimia nervosa (0.4% versus 2.3%; see Striegel-Moore et al., 2003).

However, as minorities become more and more integrated and internalize white, middle-class societal values about the desirability of thinness, we should expect to see increases in the rates of eating disorders. As an example of this, Alegria and colleagues (2007) have demonstrated that rates of eating disorders were higher in Latinos who were born in the United States compared with those who were not. In The World Around Us box below we discuss the protective role of ethnic identity in African American women.

A select number of the clinical features of diagnosed forms of eating disorders may also vary according to culture. For instance, about 58 percent of anorexia nervosa patients in Hong Kong are not excessively concerned about fatness. The reason they give for refusing food is fear of stomach bloating (Lee et al., 1993). Anorexia nervosa patients who were living in

Britain but who had South Asian (Indian, Pakistani, Bangladeshi) ethnic origins also were less likely than patients with English ethnic origins to show evidence of fat phobia (Tareen et al., 2005).

In yet another study, young women in Ghana who had anorexia nervosa were also not especially concerned about their weight or shape. Rather, they emphasized religious ideas of self-control and denial of hunger as the motivation for their self-starvation (Bennett et al., 2004). In a final example, Japanese women with eating disorders reported significantly lower levels of perfectionism and less of a drive for thinness than did American women with eating disorders (Pike & Mizushima, 2005). Findings such as these highlight the considerable role played by culture in the clinical presentation of eating disorders.

Cases of anorexia nervosa have been reported throughout history. They have furthermore been shown to occur all over the world. In light of this reality, Keel and Klump (2003) have concluded that anorexia nervosa is not a culture-bound syndrome. Of course, as we have just noted, culture may influence the disorder's clinical manifestation. The more important point, however, is that anorexia nervosa is not a disorder that occurs simply because of exposure to Western ideals and the

## the WORLD around us

### Ethnic Identity and Disordered Eating

In contrast to young white, Asian American, and Hispanic girls, black adolescent girls seem less inclined to use weight and appearance to fuel their sense of identity and self-worth (Grabe & Hyde, 2006; Polivy et al., 2005). This may provide them with some protection from the development of eating disorders. However, any protection afforded to black women seems to be linked to how strongly they identify with their ethnic group and how much they receive culturally consistent messages that value what their bodies naturally look like and support who they are.

In a study of 322 African American female college students, Rogers and colleagues (2010) found that women who had stronger ethnic identities were less likely to have internalized U.S. societal beauty ideals about the importance of being thin and attractive. This is an important finding because, in the same study, internalization of these ideals was found to be linked to disordered eating. An important factor in the ethnic distribution and occurrence of eating disorders is therefore the extent to which minority women are both exposed to and willing to internalize the same kind of white, middle-class values that have been linked to increased risk for eating disorders. There is already some evidence that the body dissatisfaction difference between blacks and whites is getting smaller over time (Grabe & Hyde, 2006).

This highlights the importance of healthy role models for young black girls. Without these, black women will no longer remain unique among American ethnic groups in their lower levels of body dissatisfaction.

African American women who have a strong identification with their ethnicity and cultural heritage have less risk of developing eating disorders than African American women who have internalized white middle-class values about the desirability of thinness.

modern emphasis on thinness. In contrast, bulimia nervosa does seem to be a culture-bound syndrome. More specifically, it seems to occur in people who have had some exposure to Western ideals about thinness, who have access to large amounts of food, and who, because of modern plumbing, can purge in private (Keel, 2010).

### in review

- What are the major clinical differences between patients with anorexia nervosa and patients with bulimia nervosa? What clinical features do these two forms of eating disorders have in common?
- How do the prevalence rates for eating disorders vary according to gender, sexual orientation, and ethnicity?
- What kinds of medical problems do patients with eating disorders suffer from?
- What is the long-term outcome for patients with anorexia nervosa? In what ways is the clinical outcome of patients with anorexia nervosa different from the clinical outcome of patients with bulimia nervosa?
- Why is bulimia nervosa viewed as a culture-bound syndrome when anorexia nervosa is not?

## Risk and Causal Factors in Eating Disorders

There is no single cause of eating disorders. In all probability, they reflect the complex interaction between genetic and environmental factors. Biological, sociocultural, family, and individual variables likely all play a role. However, it is important not to regard these areas as distinct and in competition with each other. The question of whether eating disorders are caused by biological factors or by cultural pressures is not an appropriate one. Biological and cultural explanations are interlinked. For example, being exposed to cultural attitudes that emphasize thinness is significant in the development of eating disorders. However, only a small number of people who are exposed to such attitudes actually develop eating disorders. Genetic factors may give rise to individual differences that help explain why certain people are more sensitive than others to cultural attitudes and other environmental risk factors. In other words, eating disorders are best conceptualized in terms of the diathesis-stress model, where genes render some people more susceptible to environmental pressures and hence to the development of problematic eating attitudes and behaviors.

### Biological Factors

**GENETICS** Much research attention is now being devoted to the study of genetic factors in eating disorders. This is because the tendency to develop an eating disorder has been shown to run in families (Wade, 2010). The biological relatives of people with anorexia nervosa or bulimia nervosa have elevated rates of

anorexia nervosa and bulimia nervosa themselves. In one large family study of eating disorders, the risk of anorexia nervosa for the relatives of individuals with anorexia nervosa was 11.4 times greater than for the relatives of the healthy controls (Strober et al., 2000).

For the relatives of people with bulimia nervosa, the risk of bulimia nervosa was 3.7 times higher than it was for the relatives of the healthy controls (Strober et al., 2000). It is of additional interest that the relatives of patients with eating disorders are more likely to suffer from a variety of other disorders as well as eating disorders. For example, high rates of major depressive disorder are found in the relatives of patients with anorexia nervosa, bulimia nervosa, and binge-eating disorder (Lilenfeld et al., 1998; Lilenfeld et al., 2006; Mangweth et al., 2003). The relatives of people suffering from bulimia nervosa also have an increased likelihood of having problems with alcohol and drug dependence, while the relatives of those diagnosed with anorexia nervosa are at increased risk of obsessive-compulsive disorder and obsessive-compulsive personality disorder (Lilenfeld et al., 1998).

As you know, family studies do not allow for the untangling of the different contributions of genetic and environmental influences. These kinds of questions are best resolved by twin and adoption studies. Presently, we have none of the latter. Fortunately, a number of twin studies do exist. Considered together, these studies suggest that both anorexia nervosa and bulimia nervosa are heritable disorders (Fairburn & Harrison, 2003; Wade, 2010). Indeed, it has been suggested that the contribution of genetic factors to the development of eating disorders may be about as strong as the contribution of genetic factors to bipolar disorder and schizophrenia (Kaye, 2008).

There is provocative evidence for a gene (or genes) on chromosome 1 that might be linked to susceptibility to the restrictive type of anorexia nervosa (Grice et al., 2002). However, a recent study failed to find any links between 182 different candidate genes and various aspects of eating disorders such as lowest body mass index, drive for thinness, or body dissatisfaction (Root et al., 2011). These disappointing findings highlight the challenges associated with trying to identify the genetic basis of anorexia nervosa. Evidence has also suggested that susceptibility to bulimia nervosa, particularly self-induced vomiting, may be linked to chromosome 10 (Bulik, Devlin, et al., 2003). Of course, until these findings are widely replicated, they must be viewed as preliminary.

Eating disorders have additionally been linked to genes that are involved in the regulation of the neurotransmitter serotonin (Wade, 2010). This makes sense, given the role that serotonin is known to play in the regulation of eating behavior. Furthermore, serotonin is known to be involved in mood. With this in mind, it is interesting to note that mood disorders and eating disorders often cluster together in families (Halmi, 2010).

At present, researchers are still some distance away from understanding the precise role genes play in the development of eating disorders. Given the high degree of overlap between anorexia nervosa and bulimia nervosa (many women with

anorexia nervosa later develop bulimia nervosa and many women with bulimia nervosa report histories of anorexia nervosa), it is likely that these two eating disorders may have some genetic factors in common (Helder & Collier, 2010). There is also reason to believe that genetic factors may play more of a role after puberty than before it (Klump et al., 2007). In other words, the magnitude of genetic influences may increase over the course of development. This could be because genetic factors may determine how different individuals respond to the psychosocial risk factors (pressure to be thin, family conflict) that may develop or become more important during the adolescent years.

**BRAIN ABNORMALITIES** An area of the brain that plays an important role in eating is the **hypothalamus**. Animal studies have demonstrated that when the lateral hypothalamus (the side areas of the hypothalamus) is stimulated electrically the animal will start to eat, even if it has eaten very recently. During stimulation of the lateral hypothalamus, animals will also tolerate shock and other unpleasant stimuli in order to gain access to food.

There is no good evidence that abnormalities in the hypothalamus play a central role in eating disorders, however. Uher and Treasure (2005) review a series of case reports of patients with tumors in the hypothalamus. Although these were sometimes associated with an increase or loss of appetite, there was no evidence that they resulted in specific eating disorders. In contrast, damage to the frontal and the temporal cortex did seem to be linked to the development of anorexia nervosa in some cases and bulimia nervosa in others. This is interesting because the temporal cortex is known to be involved in body image perception. Parts of the frontal cortex (particularly an area called the orbitofrontal cortex) also play a role in monitoring the pleasantness of stimuli such as smell and taste (van Kuyck et al., 2009).

Although very speculative at this time, it is possible that the lateral hypothalamus acts as a site that integrates information relevant for regulating food intake. The lateral hypothalamus receives information from many parts of the brain, including the frontal cortex and the amygdala (which is a part of the brain involved in emotion and fear learning). Animal research suggests that a network involving these (and other) brain areas may be important not only for overeating in response to environmental cues but for suppressing eating in response to fear (Petrovich, 2011). As research progresses we will learn more about how the pieces of the puzzle fit together to result in different types of eating disorders.

**SET POINTS** There is a well-established tendency for our bodies to resist marked variation from some sort of biologically determined **set point** or weight that our individual bodies try to “defend” (Garner, 1997). Anyone intent on achieving and maintaining a significant decrease in body mass below his or her individual set point may be trying to do this in the face of internal physiologic opposition, which is aimed at trying to get the body back close to its original set-point weight.

One important kind of physiologic opposition designed to prevent us from moving far from our set point is hunger. As we lose more and more weight, hunger may rise to extreme levels, encouraging eating, weight gain, and a return to a state of equilibrium. Far from having little or no appetite, patients with anorexia nervosa may think about food constantly and make intense efforts to suppress their increasing hunger. Accordingly, chronic dieting may well enhance the likelihood that a person will encounter periods of seemingly irresistible impulses to gorge on large amounts of high-calorie food. For patients with bulimia nervosa, these hunger-driven impulses may escalate into uncontrollable binge eating.

**SEROTONIN** Serotonin is a neurotransmitter that has been implicated in obsessionality, mood disorders, and impulsivity. It also modulates appetite and feeding behavior. Because many patients with eating disorders respond well to treatment with antidepressants (which target serotonin), some researchers have concluded that eating disorders involve a disruption in the serotonergic system (Bailer & Kaye, 2011).

Serotonin is made from an essential amino acid called tryptophan. This can only be obtained from food. After tryptophan is consumed, it is converted to serotonin via a series of chemical reactions. People with anorexia nervosa have low levels of 5-HIAA, which is a major metabolite of serotonin. This may be because they are eating so little food. In contrast, levels of 5-HIAA are normal in people with bulimia nervosa. What is interesting is that, after recovery, both of these patient groups have higher levels of 5-HIAA than control women do; they also have higher levels of 5-HIAA than they had when they were in the ill state (Kaye, 2008). Although the finding of higher levels of 5-HIAA in recovered patients compared to controls seems counterintuitive, it has been suggested that resuming normal eating makes it possible to detect abnormalities in the serotonin system (such as higher levels of serotonin in several different brain areas) that might be involved in risk for eating disorders. Kaye and colleagues have further suggested that people with serotonin overactivity may use dieting as a way to regulate this by decreasing the amount of tryptophan that is available to make serotonin (Bailer & Kaye, 2010).

Of course, it is important to remember that neurotransmitters like serotonin do not work in isolation. A change in the serotonin system will have implications for other neurotransmitter systems too (e.g., dopamine, norepinephrine). So the situation is undoubtedly complex. Nonetheless, investigating the role of serotonin in eating disorders is still an active area of research.

## Sociocultural Factors

What is the ideal body shape for women in Western culture? Next time you glance at a glossy fashion magazine, take a moment to consider the messages contained in its pages. The overall body size of the models that appear on the covers of such magazines as *Vogue* and *Cosopolitan* has become increasingly

thinner over the years (Sypeck et al., 2004). Young women are avid consumers of such magazines and are bombarded with images of unrealistically thin models. These magazines are also widely available all over the world. *British Vogue* is published in 40 or more countries and can be found in India, Argentina, and Kenya among other places (see Gordon, 2000). Moreover, social pressures toward thinness may be particularly powerful in higher socioeconomic backgrounds, from which a majority of girls and women with anorexia nervosa appear to come (McClelland & Crisp, 2001).

It is likely that thinness became deeply rooted as a cultural ideal in the 1960s, although prior to this time women had certainly been concerned with their weight and appearance. However, the type of body that was regarded as glamorous and attractive (e.g., Marilyn Monroe) was more curvaceous. One landmark event was the arrival of Twiggy on the fashion scene. Twiggy was the first superthin supermodel. Although her appearance was initially regarded as shocking, it did not take long for the fashion industry to embrace the look she exemplified.

The emphasis on thinness in the fashion industry continues. Although, as we noted earlier, some efforts are being made to exclude excessively thin models from the runways, these changes are still being resisted by many designers. In an example of the glamorization of anorexia, British supermodel Kate Moss has even made up a new word to describe herself. The word is “rexy,” a hybrid term that combines “anorexic” and “sexy.”

A provocative illustration of the importance of the media in creating pressures to be thin comes from a now classic study that was done by Anne Becker and her colleagues (2002). When Becker first began conducting research in Fiji in the 1990s, she was struck by the considerable percentage of Fijians (especially women) who were overweight with respect to their Western counterparts. From a cultural perspective, however, this made sense. Within Fijian culture, being fat was associated

British supermodel Kate Moss has said that one of her mottos is “Nothing tastes as good as skinny feels.”

with qualities that were highly valued such as being strong, able to work, and kind and generous. Being thin, in contrast, was regarded negatively because it was thought to reflect being sickly, incompetent, or having somehow received poor treatment. Culturally, fatness was preferred over thinness, and dieting was viewed as offensive. What was also striking was the total absence of any condition that could be considered an eating disorder.

After television came to Fiji, however, the cultural climate changed. Not only were Fijians able to see programs such as *Beverly Hills 90210* and *Melrose Place* that were popular at that time, but many young women also began to express concerns about their weight and dislike of their bodies. For the first time, women in Fiji started to diet in earnest. The young Fijian women studied by Becker also made comments that suggested that their body dissatisfaction and wish to lose weight were motivated by a desire to emulate the actors they had seen on television.

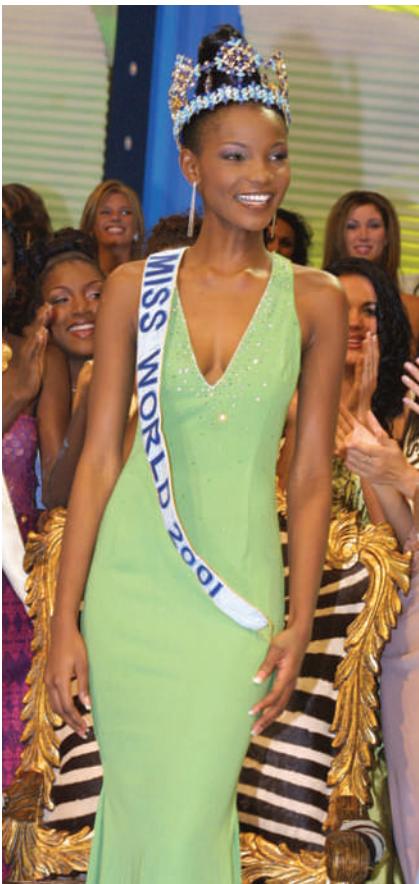

Although Becker did not collect information about eating disorders themselves (she measured attitudes toward eating), this “natural experiment” provides us with some anecdotal information as to the way in which Western values about thinness may begin to infest themselves into foreign cultural environments. In another reflection of this, after 51 years of Nigeria being unsuccessful in the Miss World beauty pageant, a 19-year-old Nigerian contestant finally won the coveted crown in 2001. Her success was later attributed to the fact that, for the first time, Nigerians had selected a contestant to represent them who was not considered to be beautiful by local standards on account of being too thin (Onishi, 2002).

British model Twiggy was the first superthin model to achieve international fame.

## Family Influences

Clinicians have long been aware that certain problems seem to regularly characterize the families of patients with anorexia nervosa, prompting many clinicians to advocate a family therapy approach to treatment intervention (Lock et al., 2001). Echoing this sentiment, more than one-third of patients with anorexia

In her home country of Nigeria, Agbani Darego was considered too thin to be beautiful. Nonetheless, she was selected to represent the country in the 2001 Miss World contest and won the coveted crown.

individual with an eating disorder in the family is likely to affect family functioning in a negative way. That is, the causal connection, if any, might be in the other direction. In fact, recent longitudinal data from a twin study suggest that disordered eating attitudes may predate parent–child conflict (Spanos et al., 2010). If this finding is replicated in future studies, we may need to reconsider the role of family conflict as a risk factor for the development of eating problems.

### Individual Risk Factors

Not everyone who lives in a society that places excessive emphasis on being thin goes on to develop an eating disorder. If that were the case, eating disorders would be much more prevalent than they are. There must be other factors that increase a given person's susceptibility to the development of disordered eating. As we noted earlier, some of these factors may be biological, while others may be more psychological in nature. In a further reflection of gene–environment interaction, genetic factors may actually influence some of the traits (e.g., perfectionism, obsessiveness, anxiety) that may make some people more likely to respond to cultural pressures with disturbed eating patterns.

**GENDER** As you have already learned, eating disorders are much more frequently found in women than in men. Being female is a strong risk factor for developing eating disorders, particularly anorexia nervosa and bulimia nervosa (Jacobi et al., 2004). Moreover, the greatest period of risk for these disorders occurs in adolescence. Binge-eating disorder does not follow this pattern, however. The onset of binge-eating disorder is typically well after adolescence. Binge-eating disorder is also much more likely to be found in males as well as in females.

For men (but not for women) sexual orientation is a risk factor for disordered eating. As we noted earlier, this may be because gay and bisexual men are trying to be attractive to men, who (regardless of sexual orientation) typically place great emphasis on physical appearance. However, being in a relationship may moderate the risk for disordered eating. Brown and Keel (2012a) have recently shown that gay and bisexual men in their 30s and 40s who were in relationships reported less of a drive for thinness and dieted less frequently than men of the same age who were single and without a partner.

**INTERNALIZING THE THIN IDEAL** The Duchess of Windsor once said that you could never be too rich or too thin. Clearly she had internalized the thin ideal, buying into the notion that being thin is highly desirable. Think for a moment about the extent to which you think this way. Do you regard thin people as unhealthy and weak? Or do you associate being thin with feeling attractive, being popular, and being happy? The extent to which people internalize the thin ideal is associated with a range of problems that are thought to be risk factors for eating disorders. These include body dissatisfaction, dieting, and negative affect (Stice, 2002). In fact, there is empirical evidence to suggest that

nervosa reported that family dysfunction was a factor that contributed to the development of their eating disorder (Tozzi et al., 2003). Patients with anorexia nervosa perceive their families as more rigid, less cohesive, and as having poorer communication than healthy control participants do (Vidovic et al., 2005).

In addition, many of the parents of patients with eating disorders have long-standing preoccupations regarding the desirability of thinness, dieting, and good physical appearance (Garner & Garfinkel, 1997). Like their children, they have perfectionistic tendencies (Woodside et al., 2002).

Family factors have also been studied in connection with bulimia nervosa. Both white and ethnic minority (black, Hispanic, and biracial) adolescents with bulimia nervosa perceive their families to be less cohesive than their parents do (Hoste et al., 2007). Fairburn and colleagues (1997) have also noted that women with bulimia nervosa could be differentiated from both a general psychiatric control group and a healthy control group on such risk factors as high parental expectations, other family members' dieting, and degree of critical comments from other family members about shape, weight, or eating. In a large sample of college-age women, the strongest predictor of bulimic symptoms was the extent to which family members made disparaging comments about the woman's appearance and focused on her need to diet (Crowther et al., 2002).

Still, when attempting to depict family characteristics associated with eating disorders, we must remember that having an

internalizing the thin ideal may be an early component of the causal chain that culminates in disordered eating (McKnight Investigators, 2003; Stice, 2001).

**PERFECTIONISM** **Perfectionism** (defined as the pursuit of unattainably high standards combined with an intolerance of mistakes) has long been regarded as an important risk factor for eating disorders (Bruch, 1973). This is because people who are perfectionistic may be much more likely to subscribe to the thin ideal and relentlessly pursue the “perfect body.” It has also been suggested that perfectionism helps maintain bulimic pathology through the rigid adherence to dieting that then drives the binge/purge cycle (Fairburn et al., 1997).

Research supports the association of perfectionism and eating disorders (Bardone-Cone et al., 2007). This is especially true for anorexia nervosa. In a study of 322 women, Halmi and colleagues (2000) found that women with anorexia nervosa scored higher on a measure of perfectionism than did a sample of controls without an eating disorder. The women with anorexia nervosa scored higher on perfectionism regardless of whether they had the restricting subtype of anorexia nervosa or subtypes that involved either purging or binge eating and purging. A large proportion of bulimia nervosa patients also demonstrate a long-standing pattern of excessive perfectionism (Anderluh et al., 2003; Garner & Garfinkel, 1997).

Of course, any personality characteristics found in eating-disordered patients could be the result of the eating disorder itself rather than contributory in a causal sense. But if this were the case, recovery from anorexia nervosa would be followed by a reduction in perfectionism. Yet this does not seem to happen (Bardone-Cone et al. 2007). Perfectionism also seems to predate disordered eating in those with anorexia nervosa (Halmi et al., 2012) again suggesting that perfectionism is not a simple correlate of eating problems. Overall, the research findings support the idea that perfectionism is an enduring personality trait that places people at higher risk for the development of eating disorders (Lilenfeld et al., 2006; Stice, 2002). Perfectionism may also have a genetic basis. In a twin study, high levels of perfectionism were found in the twins with anorexia nervosa, as expected. However, high levels of perfectionism were also found in the co-twins, who did not suffer from eating disorders (Wade et al., 2008).

Interestingly, men with eating disorders are less perfectionistic than are women with eating disorders (Woodside et al., 2004). If men are generally less perfectionistic than women, this might help them avoid having some of the weight and shape concerns that seem to be a stepping stone to the development of eating disorders.

**NEGATIVE BODY IMAGE** One consequence of sociocultural pressure to be thin is that some young girls and women develop highly intrusive and pervasive perceptual biases regarding how “fat” they are (e.g., Fallon & Rozin, 1985; Rodin, 1993; Wiseman et al., 1992; Zellner et al., 1989). In sharp contrast, young Amish people (who live radically separated from the modern

Body dissatisfaction is a risk factor for disordered eating.

world) do not display such body image distortions (Platte et al., 2000). This supports the notion that sociocultural influences are implicated in the discrepancy between the way many young girls and women perceive their own bodies and the “ideal” female form as represented in the media. Such perceptual biases lead girls and women to believe that men prefer more slender shapes than they in fact do. Many women also feel evaluated by other women, believing that their female peers have even more stringent standards of weight and shape than they do themselves.

It would be one thing if women had a reasonable chance of attaining their “ideal” bodies simply by not exceeding an average caloric intake or by maintaining a healthy weight. Quite simply, this is not possible for most people. In fact, as pointed out by Garner (1997), the average body weight of young American women has been increasing over the past four decades at least, probably as a consequence of general improvements in nutrition, pediatric health care, and other factors as well (e.g., the widespread availability of high-calorie foods). Yet, as women’s average weight has been increasing since the late 1950s, the weight of such cultural icons of attractiveness as *Playboy* centerfolds and Miss America contestants has decreased at a roughly comparable rate. It has been calculated that 70 percent of *Playboy* centerfolds have a body mass index (see Table 9.4) below 18.5 (Katzmarzyk & Davis, 2001).

**TABLE 9.4**  
**Calculating Body Mass Index**

	$\frac{\text{weight (lb.)}}{\text{height (in.)}^2} \times 703 = \text{BMI}$
Healthy	18.5–24.9
Overweight	25–29.9
Obese	30–39.9
Morbidly obese	40

Even children's toys promote unrealistically slender ideals. Consider, for instance, the size and shape of the Barbie doll. For an average woman to achieve Barbie's proportions she would have to be 7 feet 2 inches tall, lose 10 inches from her waist, and add 12 inches to her bust (Moser, 1989).

The research literature strongly implicates body dissatisfaction as an important risk factor for pathological eating (McKnight Investigators, 2003). Indeed, in a recent prospective longitudinal study, body dissatisfaction emerged as the most powerful predictor of the onset of eating disorders in a sample of almost 500 adolescent girls (Stice et al., 2011). Body dissatisfaction is also associated with dieting and with negative affect. Pointedly, if we don't like how we look, we are likely to feel bad about ourselves. We may also try to lose weight in order to look better.

**DIETING** When people wish to be thinner, they typically go on a diet. Nearly all instances of eating disorders begin with the "normal" dieting that is routine in our culture. Have you ever dieted? Most people have, at some point in their lives (Jeffrey et al., 1991). Estimates are that, at any one time, approximately 39 percent of women and 21 percent of men are trying to lose weight (Hill, 2002).

Dieting is a risk factor for the development or worsening of eating disorders (Jacobi et al., 2004; Striegel-Moore & Bulik, 2007). In a large sample of adolescent girls, body dissatisfaction and dieting predicted symptoms of bulimia nervosa at a 1-year follow-up (Johnson & Wardle, 2005). In another large-scale longitudinal study, it was found that the majority of adolescent girls who went on to develop anorexia nervosa had been dieters (Patton et al., 1990).

As we all know, however, not everyone who diets develops an eating disorder. And in some cases diets can be helpful. For example, when overweight women were randomly assigned to either a low-calorie diet or a waiting list control group (that did not involve a diet), those who received the diet lost weight and showed a decrease in bulimic symptoms (Presnell & Stice, 2003). So why has dieting been linked to eating disorders?

Dieting is a risk factor for the development or worsening of eating disorders

As Stice (2002) notes in his comprehensive review of this topic, when our efforts to diet fall short, it is almost inevitable that we will feel bad about ourselves (see also Ackard et al., 2002). Dieting itself may therefore not be the real problem (which is good news for people who are obese and who need to lose weight). Rather, it may be the case that the people who often report that they are trying to lose weight are the people who are most unhappy with their bodies and who are most inclined to feel negatively about themselves when they fail to stick to their diet plans. Other factors, such as perfectionism, may also play a role. Those who have the highest expectations of themselves may be the people who are most likely to feel bad when they fail to meet their own self-imposed high standards.

**NEGATIVE EMOTIONALITY Negative affect** (feeling bad) is a causal risk factor for body dissatisfaction (Stice, 2002). When we feel bad, we tend to become very self-critical. We may focus on our limitations and shortcomings while magnifying our flaws and defects. This seems to be especially true of individuals with eating disorders, who, like people with depression, tend to show distorted ways of thinking and of processing information received from the environment (e.g., Butow et al., 1993; Garner et al., 1997). In many cases, there is widespread negative self-evaluation (e.g., Fairburn et al., 1997). These cognitive distortions ("I'm fat; I'm a failure; I'm useless") have the potential to make people feel even worse about themselves.

Longitudinal studies have confirmed that depression and general negative affect are predictive of a high risk for later developing an eating disorder (Johnson, Cohen, et al., 2002; Leon et al., 1997). Moreover, evidence suggests that negative affect may work to maintain binge eating (see Stice, 2002). Patients often report that they engage in binges when they feel stressed, down, or bad about themselves. They further indicate that in the very short term, eating provides much needed comfort. These reports are highly consistent with affect-regulation models that view binge eating as a distraction from negative feelings (see Vögele & Gibson, 2010). Of course, a major problem is that after binges patients feel disappointed or even disgusted with themselves. In short, a difficult situation leads to behavior that makes circumstances even worse.

**CHILDHOOD SEXUAL ABUSE** Childhood sexual abuse has been implicated in the development of eating disorders (Jacobi et al., 2004). However, there is some debate about whether sexual abuse is truly a risk factor for eating disorders (see Stice, 2002). In one prospective study, Vogeltanz-Holm and colleagues (2000) failed to find that early sexual abuse predicted the later onset of binge eating. However, another prospective study found that children who had been sexually abused or physically neglected had higher rates of eating disorders and eating problems in adolescence and adulthood (Johnson, Cohen, et al., 2002). A meta-analysis of 53 studies also revealed a weak—but positive—association between childhood sexual abuse and eating pathology (Smolak & Murnen, 2002).

This suggests that the two variables are linked in some way, although the precise nature of the link is not yet clear. One possibility is that being sexually abused increases the risk of developing other known risk factors for eating disorders, such as having a negative body image or high levels of negative affect. In other words, the causal pathway from early abuse to later eating disorder may be an indirect one (rather than a direct one) that involves an array of other intervening variables.

### in review

- What evidence suggests that genetic factors may play a role in the development of eating disorders?
- What brain areas are implicated in eating and eating disorders?
- What neurotransmitter has been implicated (and most well studied) in eating disorders?
- What individual characteristics are associated with increased risk for eating disorders?
- How might a diathesis-stress model be used to explain the development of eating disorders?

## Treatment of Eating Disorders

Patients with eating disorders are often very conflicted about getting well. Approximately 17 percent of patients with severe eating disorders have to be committed to a hospital for treatment against their will (Watson, Bowers, & Andersen, 2000). Suicide attempts are often made, and clinicians need to be mindful of this risk, even when patients have received a great deal of treatment (Franko et al., 2004).

This ambivalence toward recovery is apparent in the behavior of individuals admitted to inpatient units. Hospitalization also often means that those with anorexia nervosa will be exposed to other patients who are thinner and more experienced than they are. This can lead to competitive pressure to be the “best anorexic” patient on the unit (Wilson, Grilo, & Vitousek, 2007).

Some “pro-ana” (short for “pro-anorexia”) or “pro-mia” (“pro-bulima”) websites actively support anorexic or bulimic behavior, creating much concern in the treatment community. These sites are often visited by young people (Custers & Van den Bulck, 2009). An experimental study has also shown that exposure to the material on these websites has significant negative consequences for young women. After viewing material on a pro-anorexia website, undergraduate participants reported more negative affect and felt less positive about themselves and their bodies than did participants assigned to view other websites that concerned fashion or home décor (Bardone-Cone & Cass, 2007).

### Treatment of Anorexia Nervosa

Individuals with anorexia nervosa view the disorder as a chronic condition and are generally pessimistic about their potential for recovery (Holliday et al., 2005). They have a high dropout rate from therapy, and patients with the binge-purging subtype of

anorexia nervosa are especially likely to terminate inpatient treatment prematurely (Steinhagen, 2002; Woodside et al., 2004). Making the situation even worse, there have been surprisingly few controlled studies on which to base an informed judgment about which treatment modality will work best (le Grange & Lock, 2005; Wilson, Grilo, & Vitousek, 2007). In part, this is due to the fact that the disorder is rare. However, patients who suffer from anorexia nervosa are also often extremely reluctant to seek treatment. And when they do, taking part in research studies is unlikely to be a priority for them. These factors combine to make treatment research extremely difficult.

The most immediate concern with patients who have anorexia nervosa is to restore their weight to a level that is no longer life threatening. In severe cases, this requires hospitalization and extreme measures such as intravenous feeding. This is followed by rigorous control of the patient’s caloric intake so as to progress toward a targeted range of weight gain (Andersen et al., 1997). Normally, this short-term effort is successful. However, without treatment designed to address the psychological issues that fuel the anorexic behavior, any weight gain will be temporary and the patient will soon need medical attention again. In some cases aggressive treatment efforts can backfire (Strober, 2004).

**MEDICATIONS** Antidepressants are sometimes used in the treatment of anorexia nervosa, although there is no evidence that they are especially effective (Brown & Keel, 2012b). In contrast, research suggests that treatment with an antipsychotic medication called olanzapine may be beneficial. Antipsychotic medications (which help with disturbed thinking) are routinely used in the treatment of schizophrenia (see Chapter 13). These medications also provide benefits in the treatment of anorexia nervosa, which is characterized by distorted beliefs about body shape and size. More importantly, one side effect of olanzapine is weight gain. Although this is a problem for patients with schizophrenia, in the treatment of anorexia nervosa weight gain is obviously much more desirable.

**FAMILY THERAPY** For adolescents with anorexia nervosa, family therapy is considered to be the treatment of choice. The best-studied approach, which (very importantly) blames neither the parents nor the child for the anorexia nervosa, is known as the Maudsley model (le Grange & Lock, 2005). A typical treatment program involves 10 to 20 sessions spaced over 6 to 12 months. The treatment has three phases. In the refeeding phase, the therapist works with the parents and supports their efforts to help their child (typically a daughter) to eat healthily once more. Family meals are observed by the therapist, and efforts are made to guide the parents as a functioning support team for their daughter’s recovery. After the patient starts to gain weight, the negotiations for a new pattern of relationships phase begins, and family issues and problems begin to be addressed. Later, in the termination phase of treatment, the focus is on the development of more healthy relationships between the patient and her parents (see Lock et al., 2001).

**Randomized controlled trials** have shown that patients treated with family therapy for 1 year do better than patients who are assigned to a control treatment (where they receive supportive counseling on an individual basis). Five years after treatment, 75 to 90 percent of patients show full recovery (le Grange & Lock, 2005). In a more recent study, 121 adolescents were randomly assigned to receive either family-based treatment or individual therapy. Both treatments involved a total of 24 hours of treatment spaced over the course of a year. At the end of treatment, 42 percent of patients who received family treatment were in full remission. For those who received individual therapy, the corresponding figure was 23 percent. When followed up another year later, 49 percent of the patients who had received family-based therapy were well, compared with 23 percent of those who had been treated with individual therapy (Lock et al., 2010). What is encouraging about these findings is that that overwhelming majority of adolescents completed the treatments and did not drop out. This suggests that, although individual therapy (which encouraged weight gain, the development of autonomy, and accepting responsibility for food-related issues) was slightly less efficacious overall than family treatment, it was still very acceptable to the adolescents who received it and it still provided some benefit. This is good news, especially for adolescents whose family members are unable or unwilling to participate in family treatment.

Not surprisingly, family treatment is more helpful for some patients than it is for others. Patients who develop anorexia nervosa before age 19 and have been ill for fewer than 3 years seem

Family therapy is now regarded as the treatment of choice for adolescents with anorexia nervosa. The therapy is most effective for those in the earlier stages of the illness.

## research CLOSE-UP

### Randomized Controlled Trials

A randomized controlled trial involves a specific treatment group (which is the group the researchers are most interested in) as well as a control treatment group (against which the treatment group will be compared). Participants have an equal chance of being placed in either group because which group they go into is randomly determined.

to do better than patients who have been ill for longer or who have bulimia nervosa (Dare & Eisler, 2002). This highlights the importance of early treatment, which may save some patients from a lifetime of suffering. For patients who are older or who have a long history of anorexia nervosa, the Maudsley approach unfortunately provides little clinical benefit (Wilson, Grilo, & Vitousek, 2007).

**COGNITIVE-BEHAVIORAL THERAPY** **Cognitive-Behavioral Therapy (CBT)**, which involves changing behavior and maladaptive styles of thinking, has proved to be very effective in treating bulimia nervosa. Because anorexia nervosa shares many features with bulimia nervosa, CBT is often used with anorexia nervosa patients as well (Vitousek, 2002). The recommended length of treatment is 1 to 2 years. A major focus of the treatment involves modifying distorted beliefs concerning weight and food, as well as distorted beliefs about the self that may have contributed to the disorder (e.g., “People will reject me unless I am thin”).

Pike and colleagues (2003) treated a sample of 33 women who had anorexia nervosa, after they had been discharged from the hospital. Over the course of 1 year, the women received either 50 sessions of CBT or nutritional counseling. Despite this, only 17 percent of patients who received CBT showed full recovery. None of the women who received nutritional counseling was fully well (i.e., normal weight, no binge eating or purging, and with eating attitudes and concerns about weight within normal limits) at the end of treatment. The limited success of CBT for patients with anorexia nervosa may be due to the extreme cognitive rigidity that is characteristic of those with this disorder (Brown & Keel, 2012a). There is clearly a need for new treatment developments, particularly for older patients with more long-standing problems.

### Treatment of Bulimia Nervosa

**MEDICATIONS** It is quite common for patients with bulimia nervosa to be treated with antidepressant medications. Researchers became interested in using these medications after it became clear that many patients with bulimia nervosa also suffer from mood disorders. Generally speaking (and in contrast to patients

with anorexia nervosa), patients taking antidepressants do better than patients who are given inert, placebo medications. A positive response is usually apparent within the first 3 weeks. People who do not show early improvement are unlikely to benefit from further treatment with the same medication (Sysko et al., 2010). Perhaps surprisingly, antidepressants seem to decrease the frequency of binges as well as improve patients' mood and preoccupation with shape and weight (McElroy et al., 2010).

**COGNITIVE-BEHAVIORAL THERAPY** The leading treatment for bulimia nervosa is CBT. Most of the current treatment approaches are based on the work of Fairburn and colleagues in Oxford, England. Multiple controlled studies that include post-treatment and long-term follow-up outcomes attest to the clinical benefits of CBT for bulimia (Fairburn, Jones et al., 1993; Wilson, 2010). Such studies have included comparisons with medication therapy (chiefly antidepressants) and with interpersonal psychotherapy (IPT; see Agras et al., 2000). They generally reveal CBT to be superior. In fact, combining CBT and medications produces only a modest increment in effectiveness over that attainable with CBT alone.

The "behavioral" component of CBT for bulimia nervosa focuses on normalizing eating patterns. This includes meal planning, nutritional education, and ending bingeing and purging cycles by teaching the person to eat small amounts of food more regularly. The "cognitive" element of the treatment is aimed at

changing the cognitions and behaviors that initiate or perpetuate a binge cycle. This is accomplished by challenging the dysfunctional thought patterns typically present in bulimia nervosa, such as the "all-or-nothing" or dichotomous thinking described earlier. For instance, CBT challenges the tendency to divide all foods into "good" and "bad" categories. This is done by providing factual information, as well as by arranging for the patients to demonstrate to themselves that ingesting "bad" food does not inevitably lead to a total loss of control over eating. Figure 9.4 shows a cognitive worksheet that was completed by a patient. It provides a good example of the kind of "hot thought" that can facilitate a binge.

Treatment with CBT clearly helps to reduce the severity of symptoms in patients with bulimia nervosa. Still, patients with the disorder are rarely entirely well at the end of treatment (Lundgren et al., 2004). Bingeing and purging is eliminated in around 30 to 50 percent of cases (Wilson, 2010). Even after treatment, weight and shape concerns may remain. In an effort to improve treatment efficacy, new approaches such as dialectical behavior therapy (which is a treatment for borderline personality disorder; see Chapter 10) are now being explored, with some success (Safer et al., 2001; Chen & Safer, 2010). Another promising development involves using more individualized cognitive-behavior therapy approaches that are specifically tailored to the needs of the patient as opposed to a more standardized treatment format (Ghaderi, 2006).

Emma's completed worksheet: Identifying permissive thoughts		
Situation	Feelings and sensations	Permissive thoughts
Friday, at college, alone, had a free period, thinking about my assignment (how difficult it was going to be). Ate a bar of chocolate, knew I was going to binge. Got on the bus to town, went to Burger King—had a burger, two portions off fries, a milkshake, one big bar of chocolate, another smaller bar of chocolate.	Anxious Heavy Blank	I might as well keep eating now I've started.  I can make myself sick afterwards—so it doesn't matter—I can have what I want and I won't gain weight.
<ul style="list-style-type: none"> <li>• When was it?</li> <li>• Where were you?</li> <li>• Who were you with?</li> <li>• What were you doing?</li> <li>• What were you thinking about?</li> </ul>	<ul style="list-style-type: none"> <li>• What feelings did you have?</li> <li>• What body sensations did you notice?</li> </ul>	<ul style="list-style-type: none"> <li>• What were you saying to yourself that made it easier to keep eating?</li> <li>• Identify and circle the hot thought. This is the thought that makes it most likely that you will binge.</li> </ul>

One of the newest developments in the treatment of eating disorders is to adopt a transdiagnostic approach to treatment. As we have already mentioned, the majority of patients with eating disorders have a mixed clinical picture. What this means is that they show some symptoms of anorexia and some symptoms of bulimia, combined in a variety of ways. Fairburn and colleagues (2009) have reformulated cognitive behavior therapy for bulimia nervosa so that it is now a relevant treatment for pathological eating, no matter what the diagnosis is. One form of the treatment is quite focused, targeting eating issues as well as concerns about shape and weight, extreme dieting, purging, and binge eating. The other form of the treatment is broader and also addresses such things as perfectionism, low self-esteem, and relationship problems.

Results from a randomized control trial show that patients who receive these treatments do much better than those assigned to a waiting list condition. At the end of both treatments, regardless of their initial diagnosis, more than half of the sample had responded well. There were also some hints that patients who had more problems did a little better when they received the broader treatment, whereas for more straightforward cases the focused form of treatment was very successful. It is important to mention that very-low-weight patients with anorexia were excluded from this study. Overall, however, the results suggest that the form of the treatment that a patient receives may not need to be tailored to a very specific *DSM* diagnosis. Rather, “transdiagnostic” treatments may have a lot of promise for patients with eating disorders, broadly defined.

## Treatment of Binge Eating Disorder

BED has attracted a lot of attention from researchers, and a number of different treatment approaches have been suggested. Due to the high level of comorbidity between binge-eating disorder and depression, antidepressant medications are sometimes used to treat this disorder. Other categories of medications, such as appetite suppressants and anticonvulsant medications, have also been a focus of interest (McElroy et al., 2010). Sibutramine, a medication that inhibits the reuptake of serotonin and norepinephrine, has been shown to reduce the frequency of binges and to be associated with more weight loss than a placebo medication in a one clinical trial (Wilfley et al., 2008).

In one of the largest and most scientifically rigorous studies to date, Wilson and colleagues (2010) randomly assigned 205 overweight or obese men and women who met diagnostic criteria for BED to one of three different treatments. Some people received interpersonal psychotherapy (IPT), which is a therapy sometimes used in the treatment of depression (see Chapter 7). Others received CBT in the form of a self-help book (*Overcoming Binge Eating*, Fairburn, 1995), guided by a therapist. People in the third group were assigned to a behavioral weight loss treatment that involved exercise and moderate restriction of calories. So how did everyone do? At the end of 6 months of treatment,

there were no significant differences between the groups with regard to remission from binge eating. However, at 2-year follow up, people who had received either IPT or guided CBT were doing better than those in the behavioral weight loss group. What is also noteworthy is that the dropout rate was much lower for people in the IPT group (7% dropped out) than it was in the guided CBT (30%) or behavioral weight loss groups (28%). This is important because, overall, the dropout rate for minorities in this study was very high (approximately one-third). The findings therefore suggest that for racial and ethnic minorities with BED, interpersonal psychotherapy might be a particularly suitable treatment approach.

## in review

- What factors make eating disorders (especially anorexia nervosa) so difficult to treat?
- Describe the main features of the Maudsley approach for the treatment of anorexia nervosa. For what kind of patients does this approach yield better results?
- What treatment approaches have been shown to be helpful for binge eating disorder?
- Why do you think cognitive-behavioral therapy is so beneficial for patients with bulimia nervosa?
- What is a transdiagnostic treatment approach?

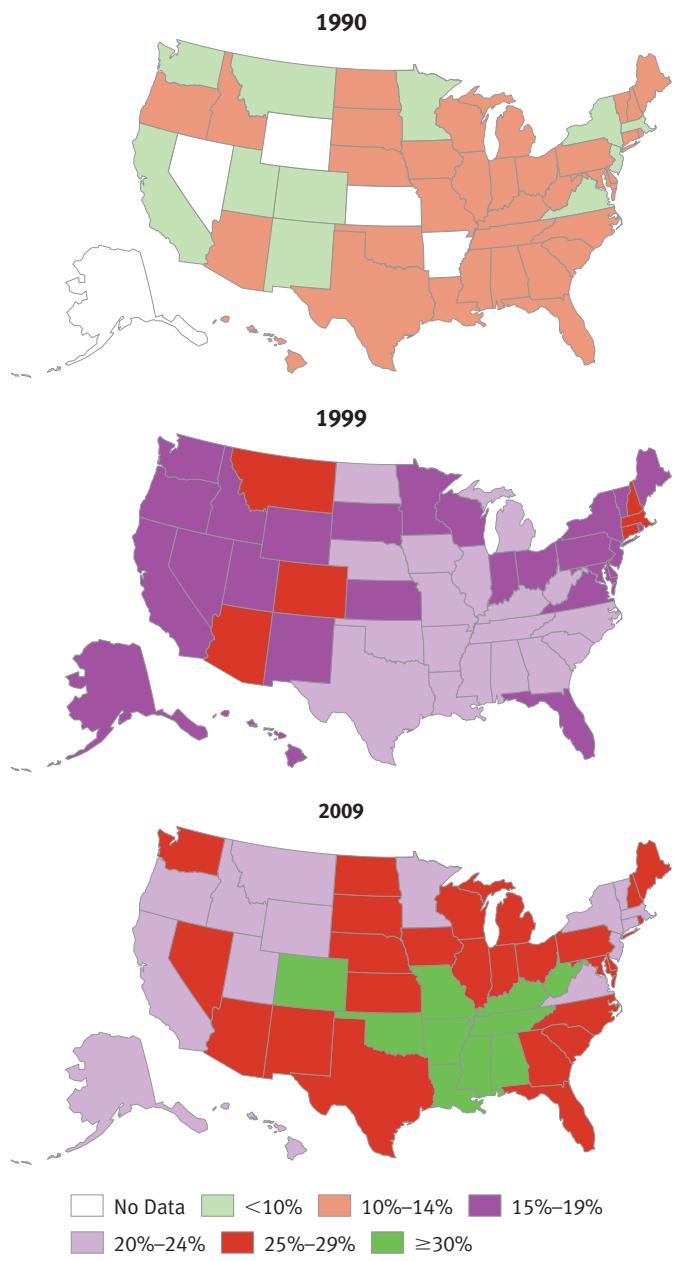

## The Problem of Obesity

Humans have evolved to be able to store surplus energy as fat. This has obvious advantages: It serves as a hedge against periods of food shortage and makes survival more likely during times of famine. But in our modern world, access to food is no longer a problem for millions of people. The food supply is stable, and large amounts of energy-dense foods are readily available. Not surprisingly, most of us are getting heavier. For some people, the problem becomes even more extreme and results in obesity. Considered in this way, obesity can be regarded as a state of excessive, chronic fat storage (Berthoud & Morrison, 2008).

Worldwide, obesity is now a major public health problem. From 1980 to 2002 the prevalence of obesity almost tripled in adults in the United Kingdom. In China, rates of obesity in preschool children were 1.5 percent in 1989 and 12.6 percent just 9 years later (Flegal et al., 2002). The most recent estimates show that one-third of adults in the United States are obese (Flegal et al., 2010). Figure 9.5 on page 316 shows how much more prevalent obesity has become in the past two decades.

## Medical Issues

Obesity brings with it increased risk for many health problems. These include high cholesterol, hypertension, heart disease, arthritis, diabetes, and cancer (Malnick & Knobler, 2006). It has been estimated that, by 2030, the cost of treating these problems in the United States alone will exceed 850 billion dollars

**FIGURE 9.5**

Obesity has increased dramatically in the United States over the past 20 years.

Source: [CDC.gov/obesity/trends.html](http://CDC.gov/obesity/trends.html)

annually (Wang et al., 2008). In addition, people who are obese have a reduced life expectancy of 5 to 20 years (Fontaine et al., 2003). It should therefore come as no surprise that the World Health Organization has recognized obesity as one of the top 10 global health problems.

### Definition and Prevalence

**Obesity** is defined on the basis of a statistic called the **body mass index (BMI)**. This is a measure of a person's weight relative to height and is calculated using the formula shown in Table 9.4 on page 310. Generally speaking, people with a BMI below 18.5

are considered underweight; 18.5 to 24.9 is considered normal; 25.0 to 29.9 is overweight; and obesity is defined as having a BMI above 30. Having a BMI above 40 or being more than 100 pounds overweight is called morbid obesity. This is the point at which excess weight begins to interfere with basic activities such as walking and creates many health problems.

Table 9.5 shows current prevalence rates of overweight and obesity for different groups of adults in the United States. As you can see, the majority of us (68.3%) weigh more than we should. But ethnicity is also very important. Obesity is more prevalent in ethnic minorities. In general, rates of obesity are slightly higher in men than they are in women. The notable exception here involves African Americans. One in every two black women is obese. This is the highest rate of obesity found for any group (Flegal et al., 2010).

Another demographic variable linked to obesity is social class, although again gender and ethnicity are important. Higher income women are much less likely to be obese than lower income women. For black and Mexican American men, however, the opposite is true; men with higher incomes are more likely to be obese.

### Weight Stigma

People who are obese are often judged harshly by others. They are routinely ridiculed, discriminated against, and stigmatized (Carr & Friedman, 2005). A powerful source of this is the media, which perpetuates weight-based stereotypes and often depicts overweight or obese people in a very negative light. Compared to thin television characters, those who are overweight or obese are more likely to be shown when eating, are less likely to be depicted as being involved in romantic relationships, and are more likely to be the target of derisive comments (see Schvey et al., 2011). Audiences also laugh more when negative comments are directed toward overweight characters, especially female ones. Weight bias is even found in health care professionals who may blame obese patients for being overweight and having weight-related health problems (Mold & Forbes, 2011). The *World Around Us* box describes

**TABLE 9.5**  
**Prevalence (%) of Overweight and Obesity in U.S. Adults**

Group	Overweight	Obese
All	68.3	33.9
White	67.5	32.8
Hispanic	76.9	37.9
Mexican American	77.5	39.3
Black	73.7	44.1

Note: Figures based on BMI of 25 or above for overweight and 30 or above for obesity.

Source: Flegal et al. (2010).

## Do Negative Messages About Being Overweight Encourage Overweight People to Eat More or Less?

In our society many people still consider it acceptable to make fun of those who are overweight or obese. But what effect does this have on the people who receive such stigmatizing messages? To address this question Schvey and colleagues (2011) asked overweight and normal weight women to view one of two videos. One video depicted clips from neutral scenes such as insurance commercials. The other video contained clips from televisions shows and movies that depicted overweight and obese women in negative ways (e.g., as clumsy, lazy, and loud). After watching the videos, all the women were given questionnaires to complete in private. The room also contained three different bowls of snack foods, which the women were invited to eat.

The variable that the researchers were most interested in was how much the women ate after being exposed to the different

types of films. After seeing the stigmatizing videos the overweight women consumed 303 calories of snack food. This is more than three times as much as the 89 calories consumed by the overweight women who had watched the neutral film. The overweight women who had watched the stigmatizing videos also ate significantly more calories than the normal-weight women who watched either type of film.

Television is a powerful source of weight-based stereotypes. The average American watches around 150 hours of television a month. Far from motivating overweight and obese people to lose weight, the negatively biased portrayals of obesity that we routinely see on TV may actually lead people to eat more rather than less.

some of the consequences that stigma has on people who are overweight.

But being obese may not be the personal choice that many people believe it is. The more research progresses, the more we are learning about how important genes and other biological factors are in determining the drive to eat and the way our bodies respond when we eat less. We are also learning how powerful environmental factors can be. In short, the idea that we can simply decide to control our weight by eating less and exercising more does not always fit with the scientific facts.

### Obesity and the DSM

From a diagnostic perspective, obesity is not an eating disorder, and it is not included in *DSM-5*. However, Volkow and O'Brien (2007) suggest that some forms of obesity are driven by an excessive motivational desire for food. They liken such symptoms as the compulsive consumption of food and the inability to restrain eating despite the wish to do so to symptoms of substance abuse and drug dependence. This parallels the view, offered by some, that obesity is a "food addiction" (see Cota et al., 2006). It has also been suggested that obesity and addiction may both concern problems in key brain regions involved in motivation, reward, and inhibitory control. Of course, the idea that obesity is a brain disorder is very controversial. Nonetheless, it does illustrate how much ideas about obesity are beginning to change.

### in review

- Why is the increase in the prevalence of obesity such a public health concern?
- Explain the importance of the body mass index in the definition of obesity.

- How are ethnicity, gender, and social class related to rates of obesity?
- How do the media portray people who are overweight and obese? What are some of the consequences of this?
- On what grounds is the argument being made that obesity might be a brain disorder? What effect might this have on stigma?

## Risk and Causal Factors in Obesity

### The Role of Genes

Are you the kind of person who can eat high-calorie foods without significant weight gain? Or does it seem as though you need only to look at a piece of chocolate cake to gain a few pounds? In all probability our genetic makeup plays an important role in determining how predisposed we are to becoming obese in the modern environment of increased food availability. Some of the genes that may, in our ancestral past, have been advantageous and helped us survive in times of famine may predispose those who carry them to readily gain weight when food is plentiful. Interestingly, population groups that were most susceptible to starvation throughout history (e.g., Pima Indians, Pacific Islanders) are those that are most inclined to become obese when they have a sedentary lifestyle and a Western diet (see Friedman, 2003).

Thinness seems to run in families (Bulik & Allison, 2002). Genes associated with thinness and leanness have been found in certain animals, and a special type of rat has now been bred that does not become obese even when fed a high-fat diet. Twin studies further suggest that genes play a role both in the development of obesity and in the tendency to binge (Bulik et al., 2003; Javaras et al., 2008).

Indeed, a genetic mutation has been discovered that is specifically associated with binge eating (Branson et al., 2003). Although this mutation was found only in a minority (5%) of the obese people in the study, all of the obese people with the gene reported problems with binge eating. In contrast, only 14 percent of obese people who did not have the genetic mutation displayed a pattern of binge eating.

## Hormones Involved in Appetite and Weight Regulation

In the course of a year, the average person will consume 1 million calories or more and yet keep a reasonably stable weight. How do we accomplish this? The answers lie in the remarkable ability of our bodies to regulate the daily quantity of food consumed and to balance this with our energy output over the longer term. This is relevant to the concept of set point that we described earlier. Remarkably, we are able to regulate our energy balance with a precision of more than 99.5 percent. This is far in excess of what we could monitor in any conscious or mindful way (Friedman, 2004).

One key element of this homeostatic system is a hormone called **leptin**. Leptin is produced by fat cells, and it acts to reduce our intake of food. Increased body fat leads to increased levels of leptin, which leads to decreased food intake. When body fat levels decrease, leptin production decreases and food intake is stimulated. Rare genetic mutations that result in an inability to produce leptin cause people to have an insatiable appetite and result in morbid obesity. One 9-year-old girl in England weighed 200 pounds. She could hardly walk because of her extreme weight. When it was discovered that she was lacking leptin, she was treated with injections of the hormone, and her weight consequently returned to normal (Farooqi et al., 2002; Montague et al., 1997).

Unfortunately, when leptin is given to overweight individuals, in the majority of cases it has little effect. People who are overweight generally have high levels of leptin in their bloodstream. The problem is that they are resistant to its effects. In fact, it has been suggested that obesity may result from a person's being resistant to leptin (Friedman, 2004). Despite this complication, the leptin system is still a major focus of interest in the search for antiobesity drugs.

Why do we get hungry at regular times during the day even if we do not even see or smell food? The reason may lie in a hormone called **ghrelin**. Ghrelin (the name comes from a Hindu word meaning "growth") is a hormone that is produced by the stomach. It is a powerful appetite stimulator. Under normal circumstances, ghrelin levels rise before a meal and fall after we have eaten. When ghrelin is injected into human volunteers, it makes them very hungry. This suggests that ghrelin is a key contributor to the appetite control system.

People with a rare condition called Prader–Willi syndrome have chromosomal abnormalities that create many problems, one

This woman suffers from Prader–Willi syndrome, a rare genetic disorder that makes people insatiably hungry. After a year in a group home with rigid dietary rules, she lost 80 pounds.

of which is very high levels of ghrelin. Sufferers are extremely obese and often die before age 30 from obesity-related causes. The food cravings experienced by Prader–Willi sufferers can be so extreme that food has to be kept locked away so that they cannot binge. Although this genetic disorder is very unusual, findings such as this highlight the role of genetics in the regulation of eating behavior and weight. They also illustrate how the biological drive to eat can be so powerful that willpower is no match for it.

## Sociocultural Influences

The examples of Prader–Willi syndrome and mutations of the leptin gene tell us that genes alone can sometimes explain why people differ in their weight and eating patterns. However, in most cases environmental factors also play an important role. As with other disorders we have discussed in this book, a diathesis-stress perspective is most appropriate. Some of us, by virtue of our genetic makeup and personality, are likely to experience more weight-related problems from living in a culture that provides ready access to high-fat, high-sugar (junk) foods, encourages overconsumption, and makes it easy to avoid exercise.

Consider your own lifestyle issues. How often do you eat fast food? Are you more likely to take the stairs or the elevator? Even when we have good intentions, we sometimes make poor food choices or get too little exercise. A major culprit is time pressure. Because we are so chronically short of time, we drive rather than walk. We put food into our mouths far too quickly, outpacking our natural feelings of fullness. This leads us to keep eating. Finally, as the pace of life gets faster, we have less time to prepare food. So we eat out more often or buy more prepackaged or fast food. Which of these behaviors do you recognize in yourself?

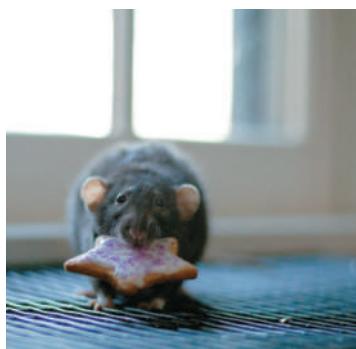

As Brownell and his colleagues (Brownell, 2003; Gearhardt et al., 2011) have pointed out, the food industry is also highly skilled at getting us to maximize our food intake. Restaurants

**TABLE 9.6**  
**Sugar and Fat in Traditional and Hyperpalatable Foods**

Food	Portion Size	Type	Sugar (g)	Fat (g)
Apple	1 medium	T	19	0
Tomato	1 medium	T	3	0
Orange	1 cup, sections	T	17	0
Chicken breast	3 ounces	T	0	3
Coca-Cola	1 can	H	39	0
McDonald's fries	1 medium	H	0	19
Dairy Queen	1 medium ice cream	H	34	10

Note: T = traditional food; H = hyperpalatable food. Dairy Queen ice cream cone is chocolate flavor.

Source: Gearhardt et al. (2011).

Rats given extended access to high-fat, high-sugar foods quickly gain weight. They also show decreases in brain reward circuits. If food becomes less rewarding, this could potentially drive the development of compulsive eating.

in the United States serve large portions of foods that are engineered to be hyperpalatable (especially tasty and rewarding) because they contain so much sugar or fat. Some examples of commonly eaten foods are shown in Table 9.6. One comparison of the same fast-food chains and eateries in Philadelphia and Paris found that the average portion sizes in Paris were 25 percent smaller (Rozin et al., 2003). In addition, the culture of supersizing tempts us to buy more than we might choose to buy otherwise simply because it costs only a little bit more (Brownell, 2003). In several ballparks you can now buy an “all-you-can-eat” seat. The price includes unlimited hot dogs, nachos, peanuts, popcorn, and soft drinks.

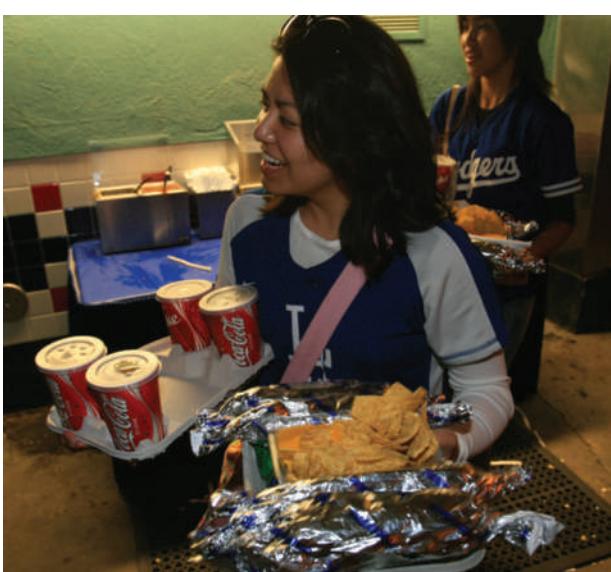

Ultra-processed foods that are high in sugar, fat, and salt may be capable of triggering an addictive process. When rats were given

extended access to a “cafeteria” diet of foods such as chocolate, cheesecake, sausage, and bacon (as well as to standard rat chow), they rapidly gained weight. They also began to consume these foods almost exclusively, eating very little of the rat chow. What was especially noteworthy was that the rats with extended access to the cafeteria diet were also insensitive to cues that signaled the delivery of electric foot shocks. Even under conditions of punishment, these rats did not decrease their intake of the foods they desired (Johnson & Kenny, 2010). There was also evidence that extended access to the high-fat, high-sugar foods resulted in a down-regulation of activity in brain reward circuits, perhaps because the brain reward systems had been overstimulated by the excessive consumption of the palatable foods. If this is true, overconsumption of ultra-processed foods could contribute to the development and maintenance of compulsive eating because eating these foods becomes less and less rewarding over time and more and more food is required to obtain the same amount of “reward.”

Consider also the issue of accessibility. Foods with low nutritional value (high fat, high sugar) are less expensive and also much easier to find than foods with high nutritional value. Next time you go to a gas station or go out to see a movie, look at the food choices that are available. How much healthy food is on offer? Is it easier to find an apple or a candy bar? Notice how easy it is to mindlessly pick up a cheap high-calorie item that provides little nutrition.

If you like to snack in front of the TV you should also be aware of how powerful food advertising can be. Food advertising seems to trigger the kind of automatic and unconscious eating that is not related to being hungry. In one study, children ate 45 percent more after watching a TV cartoon that contained food advertisements than they did if the cartoon contained advertising for other products (Harris et al., 2009).

Continued exposure to a culture that provides easy access to highly palatable foods, offers large portions, and bombards people with endless food advertisements may explain why rates of obesity increase in immigrants after they have lived in the United States for a while. Although recent immigrants are less likely to be overweight and obese than people born in the United States, after they have lived in the country for 10 years or longer they have a significant increase in their body mass index (Goel et al., 2004). This suggests that sociocultural factors are likely to be playing a major role. In addition to the emphasis on food,

An LA Dodgers fan carries four hot dogs, nachos, peanuts, and four sodas from the concessions area. Sitting in the popular all-you-can-eat area costs \$40, in seats that used to cost \$8.

Food advertising leads us to eat more even when we are not hungry. In one study, children ate 45 percent more when they watched a cartoon that contained food advertising.

what other aspects of American culture do you think might be exerting an influence here?

## Family Influences

Family behavior patterns may also play a role in the development of excessive eating and obesity. In some families, a high-fat, high-calorie diet (or an overemphasis on food) may lead to obesity in many or all family members, including the family pet. In other families, eating (or overeating) becomes a habitual means of alleviating emotional distress or showing love (Musante et al., 1998). Children whose mothers smoked during pregnancy or whose mothers gained a lot of weight during the pregnancy are also at a higher risk of being overweight at age 3 (Gillman et al., 2008).

Family attitudes toward food are important because their consequences are likely to remain with us for a long time. Obesity is related to the number and size of fat (adipose) cells in the body (Heymsfield et al., 1995). People who are obese have markedly more adipose cells than people of normal weight (Peeke & Chrouzos, 1995). When obese people lose weight, the size of the cells is reduced but not their number. Some evidence suggests that the total number of adipose cells stays the same from childhood onward (Crisp et al., 1970).

It is possible that overfeeding infants and young children causes them to develop more adipose cells and may thus predispose them to weight problems in adulthood. Consistent with this, DiPietro and colleagues (1994) found that, in a 40-year follow-up study, the majority of a sample of 504 overweight children became overweight adults.

Finally, there is some evidence that obesity might be "socially contagious." Provocative research findings have shown that if someone close to us (e.g., a spouse, sibling, or friend) becomes obese, the chance that we ourselves will later become obese can increase by as much as 57 percent. The effect is most marked within same-sex versus opposite-sex relationships, suggesting that social influences might be playing a key role. In contrast, weight gain in neighbors was not associated with later

Research suggests that obesity can be socially contagious. If someone close to us becomes obese, the chance that we will later become obese can increase by as much as 57 percent.

weight gain in those who lived close by, again suggesting that it is the closeness of the relationship, rather than exposure to common environmental factors, that might be important (Christakis & Fowler, 2007). Although the mechanisms of this social transmission are far from clear, it is possible that obesity in our close friends and family members could lead us to change our attitudes about weight or perhaps influences our eating patterns.

## Stress and "Comfort Food"

Do you eat when you are stressed or unhappy? If you do, what kinds of food do you crave? Foods that are high in fat or carbohydrates are the foods that console most of us when we are feeling troubled (Canetti et al., 2002). Workers who say that they are under a lot of stress report that they eat less healthy foods, and foods that are higher in fat, relative to their less stressed counterparts (Ng & Jeffery, 2003).

Eating for comfort is found in rats too. When rats were placed under chronic stress (being subjected to cold temperatures), they selected diets that were higher in fat and sugar (Dallman et al., 2003). What is also interesting in this study is that the rats that ate the comfort food gained weight in their bellies and became calmer in the face of new acute stress. This prompted the researchers to speculate that the sugary and fatty foods helped to reduce activation in the stress response system.

Might overeating function as a means of reducing feelings of distress or depression? Certainly many people with obesity experience psychological problems such as depression. In a large community sample of more than 40,000 people, lifetime rates of mood disorders were higher in people who were obese than in people whose weight was in the normal range (Petry et al., 2008). Other research has found that a striking percentage of people with an eating disorder binge eat in response to aversive emotional states, such as feeling depressed or anxious (Kenardy et al., 1996).

In light of Dallman's data on the stressed rats, it is easy to grasp how weight gain (or a tendency to maintain excessive weight) may be explained quite simply in terms of learning principles. We are all conditioned to eat in response to a wide range of environmental stimuli (at parties, during movies, while watching TV). Obese individuals have been shown to be conditioned to more cues—both internal and external—than others of normal weight. Anxiety, anger, boredom, and depression may lead to overeating. Eating in response to such cues is then reinforced because the taste of good food is pleasurable and because the individual's emotional tension is reduced.

### Pathways to Obesity

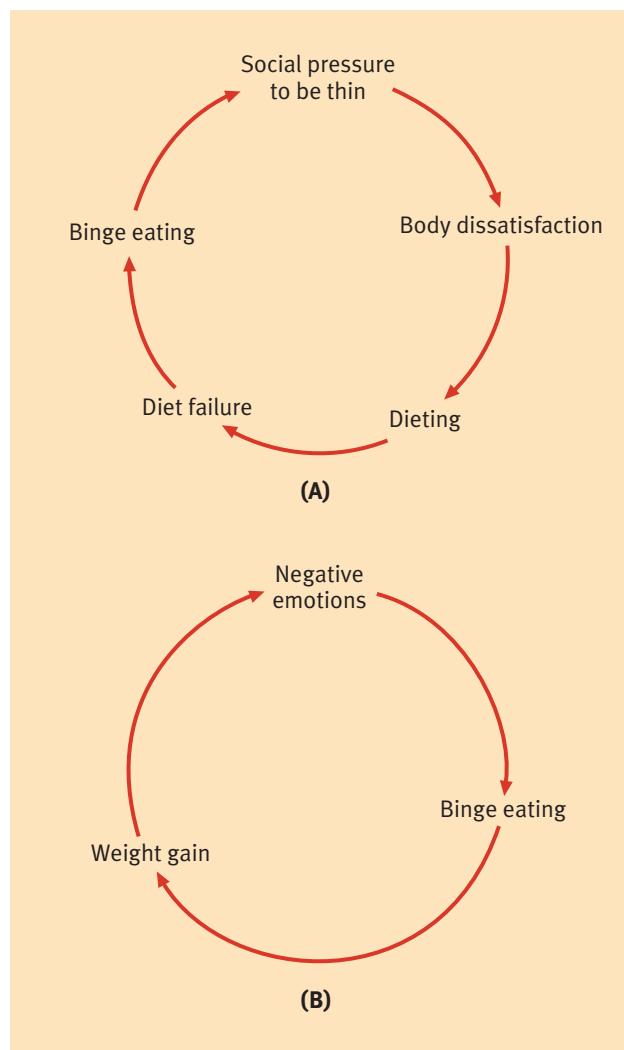

Understanding the causes of obesity is complex. In all probability, obesity results from a combination of genetic, environmental, and sociocultural influences. An important step along the pathway to obesity, however, may be binge eating. In a prospective study of 231 adolescent girls, Stice, Presnell, and Spangler (2002) established that binge eating is a predictor of later obesity. This suggests that we should pay close attention to the causes of binge eating.

Animal studies show that, in rats, any genetic differences that exist in the tendency to binge eat only start to emerge during puberty (Klump et al., 2011). Biological risk factors may thus become more important as we enter adolescence. Unfortunately, this is also the developmental period when sociocultural pressures may be most intense.

Relevant here is research suggesting that one pathway to binge eating may be through social pressure to conform to the thin ideal, as ironic as this may seem (Stice et al., 2002). Being heavy often leads to dieting, which may lead to binge eating when willpower wanes (see Figure 9.6). Another pathway to binge eating may operate through depression and low self-esteem. In Stice and colleagues' (2002) prospective study, low levels of support from peers, as well as depression, made girls more at risk for binging. We further have confirmation that when children are overweight, they are more likely to be rejected by their peers (Latner & Stunkard, 2003; Strauss & Pollack, 2003), consequently increasing their negative affect. As Figure 9.6 shows, a pattern of binge eating in response to negative emotions may make a bad situation much worse—increasing weight, depression, and fostering alienation from peers in a vicious cycle.

### in review

- What role do genetic factors play in obesity?
- How do hormones such as leptin and ghrelin help regulate appetite?
- In what ways might negative emotional states contribute to the development of obesity?
- In what ways is the food industry implicated in the obesity epidemic?
- Why is understanding binge eating important for understanding obesity?

**FIGURE 9.6**

**Pathways to Obesity.** One pathway to obesity is through social pressures to be thin. Another pathway may operate via depression and low self-esteem.

### Treatment of Obesity

There are three main treatment options for people who are overweight or obese. These are (1) lifestyle modifications (diet, exercise, and behavior therapy), (2) medications, and (3) bariatric surgery.

### Lifestyle Modifications

A first step in the treatment of obesity is a clinical approach that, ideally, involves a low-calorie diet, exercise, and some form of behavioral intervention. Several research trials have now demonstrated that lifestyle modification approaches yield positive benefits for patients, although the results are far from dramatic. Sustained weight loss of around 7 pounds (3.2 kilograms) is quite typical (Powell et al., 2007). However, it is important to keep in mind that for people who are overweight, even small amounts of weight loss may yield some health benefits. Using

Sustained weight loss of around 7 pounds is typical for people who exercise and reduce their intake of calories. Even modest weight loss can lead to health benefits.

meal-replacement products (e.g., calorie-controlled shakes), continuing a relationship with a treatment provider, and maintaining a high level of physical activity all help improve efforts at long-term weight control (Fabricatore & Wadden, 2006).

What about popular diets? Gardner and colleagues (2007) compared the Atkins diet, the Zone diet, the Ornish diet, and a more traditional diet approach in a sample of overweight and obese women aged 25 to 50. At the end of a year, those who had followed the Atkins diet had lost the most weight (10.4 pounds or 4.7 kilograms) compared with a weight loss of 3.5 pounds (1.6 kilograms) for the Zone, 5.7 pounds (2.6 kilograms) for the Ornish, and 4.8 pounds (2.2 kilograms) for the traditional approach. Nonetheless, even for the most successful dieters, the amount of weight loss was not especially large.

Weight Watchers is the only commercial weight-loss program with demonstrated efficacy in a randomized controlled trial. Over the course of 6 months, overweight and obese people who attended Weight Watchers lost more weight (10.5 versus 3 pounds) than did people who received self-help materials and two brief sessions with a nutritionist (Heshka et al., 2000). At a later follow-up, those who had attended Weight Watchers were still doing better than the people who had been assigned to the self-help group (Heshka et al., 2003).

“Crash” diets and extreme treatments to bring about dramatic weight loss (including starvation of patients in a hospital setting) are now considered to be outmoded and ineffective approaches. Although they lead to weight loss in the short term, the weight loss is not maintained. Indeed, at follow-up, people who have been subjected to these procedures usually weigh more than they did before the treatment started (Mann et al., 2007).

Although we may be tempted by every new diet or weight loss fad that comes along, in the long run it is the calories that matter. Recent research has shown that focusing on the proportion of fat, protein, or carbohydrates in the diet is far less important than just eating less (Sacks et al., 2009). If you are able to do this, regardless of what kind of diet you chose, you will have some success.

But the harsh reality is that losing weight is difficult for most people. And for those who are obese, losing weight and maintaining the weight loss present a truly formidable challenge. As we mentioned earlier, our bodies try to defend a set-point weight. When we try to go below this, marked metabolic and

hormonal changes occur. The body goes into “starvation mode” and hunger is increased, the metabolic rate slows, and we also feel less full after eating (Goldsmith et al., 2010). It is also the case that energy expenditure decreases significantly following weight loss. This means that if an obese person loses 100 pounds, decreasing in weight from 300 pounds to 200 pounds, the person has to consume far fewer calories to maintain this new weight than a person who already weighed 200 pounds would (Friedman, 2004). It is hardly surprising, therefore, that relapse rates are so high after weight loss and that people who attempt to lose weight often feel so discouraged. Indeed, some researchers now maintain that obesity is resistant to psychological methods of treatment (Cooper et al., 2010). This makes prevention all the more important.

## Medications

Drugs that are used to promote weight loss fall into two main categories. One group of medications reduces eating by suppressing appetite, typically by increasing the availability of neurotransmitters. A second group of medications works by preventing some of the nutrients in food from being absorbed.

Two medications are approved by the FDA for use in conjunction with a reduced-calorie diet. Sibutramine (Meridia) inhibits the reuptake of serotonin and norepinephrine and, to a lesser extent, dopamine. Orlistat (Xenical) works by reducing the amount of fat in the diet that can be absorbed once it enters the gut. Both medications provide modest clinical benefits and lead to more weight loss than placebo (Fabricatore & Wadden, 2006). In some cases, however, the differences are not especially impressive. Patients who take Orlistat for 1 year lose approximately 9 percent of their pretreatment weight. The weight loss for controls who take a placebo medication during this time is just under 6 percent (Heck et al., 2000; Yanovski & Yanovski, 2002).

In addition to specific weight loss drugs, recent research suggests that two medications routinely used in psychiatry and addiction medicine might also be helpful. The 1,742 obese participants with a BMI between 30 and 45 were randomly assigned to receive a higher or lower dose of naltrexone combined with another drug called bupropion. A third group received a placebo. Only about half of the participants completed the treatment. However, the results showed that both drug treatment groups lost more weight over the course of the following year than did people in the placebo group (Greenway et al., 2010). These results are comparable to those associated with weight loss medications like Orlistat. Also, because naltrexone and bupropion act on the midbrain dopamine system, they provide some support for the growing conceptualization of obesity as an addiction.

## Bariatric Surgery

Bariatric or gastric bypass surgery is the most effective long-term treatment for people who are morbidly obese (Bult et al., 2008; Moldovan & David, 2011). Several different

techniques can be used both to reduce the storage capacity of the stomach and, sometimes, to shorten the length of the intestine so that less food can be absorbed. Before the operation, the stomach might be able to hold about a quart of food and liquid. After the procedure, the stomach might be able to hold only the contents of a shot glass. Binge eating becomes virtually impossible. The operation takes only a few hours, but because it is performed on an obese patient, recovery can be difficult.

Surgical treatment of obesity tends to result in substantial weight loss, averaging between 44 and 88 pounds (Bult et al., 2008). Interestingly, levels of the appetite hormone ghrelin are also suppressed after particular types of surgical procedures. Of course, some patients manage to find ways to continue to binge eat after surgery (Kalarchian et al., 1998) and tend to regain their weight over an 18-month period (Hsu et al., 1998). Although bariatric surgery is not without risk (mortality rates hover around 1%), the risk of the surgery should be evaluated against the health risks that accompany untreated obesity. The case study below describes a successful outcome from the procedure.

**→ People Hardly Recognize Him** Stanley's weight problems began when he was 19. He gained weight and then kept on gaining. A big man with a fun-loving personality, he tried dieting from time to time. But nothing really worked for him. Part of the problem was that he hated to exercise. By the time he was 59 years old he weighed close to 400lbs. He had mobility issues. He also had diabetes.

Stanley knew he had to do something. Although he was comfortable with who he was, he was concerned about the impact his obesity was having on his health and long-term longevity. His doctor recommended gastric bypass surgery. Stanley agreed.

There was much to be done before the surgery itself. To ensure that he was physically able to cope with the procedure, Stanley was evaluated by a staff physician. Other members of the team included a dietitian, who explained the many changes Stanley would need to make before and after the surgery. A psychologist also explored Stanley's readiness to commit to what was ahead. Finally, Stanley's surgeon carefully explained the details of the procedure and what would be involved. Stanley was then placed on a diet and told to lose weight before a surgery date could be arranged.

On the day of the surgery, Stanley arrived – already 13lbs lighter as a result of following the prescribed diet. Then, during a procedure that lasted 5 hours, part of Stanley's stomach was permanently closed off with staples. His stomach was reduced from the size of a football to the size of an egg. In addition, a piece of his intestine was re-routed so that food from the newly-created stomach pouch by-passed the early sections of the intestines

(where nutrients and calories are typically absorbed after eating). Following the surgery, Stanley spent 5 days in the hospital recovering.

Almost immediately after the surgery, Stanley's diabetes disappeared. He was put on a liquid diet for the first few weeks and told to drink a lot of water. Then he graduated to eating soft foods like boiled eggs. Eventually, he began to eat more normal foods, although Stanley was surprised by how little he could actually tolerate.

Now, one year after the surgery, Stanley still has to be careful about what he eats. Carbonated beverages and spicy foods no longer agree with him and he has become intolerant of lactose. The amount of food he can eat without discomfort is very small. But Stanley has already lost 140lbs and he is still losing weight. He talks about a fellow patient who had the same procedure. "He was telling me that he had figured out a way to get around the eating restrictions," says Stanley. "I don't get it. Why would anyone go through this procedure and then do that?" In contrast, Stanley feels that the gastric bypass he received has given him a tremendous opportunity. He feels better. He has more energy. And he knows he has improved his chances of living a longer life. He is especially amused when people he knows hardly recognize him. "I like that," he says.

## The Importance of Prevention

Reducing the prevalence of obesity is now a top priority. But if obesity is to be prevented, it must first be recognized. Astonishingly, in a recent study conducted in Finland, 57 percent of

Al Roker, the NBC weatherman on the *Today* show, had gastric bypass surgery, one form of bariatric surgery. He weighed 320 pounds at the time of his surgery. A year later, Roker had shed 100 pounds.

parents who had an overweight or obese 7-year-old child failed to recognize that their child was overweight (Vanhala et al., 2009). In this Finnish study, childhood obesity was predicted by having an obese parent, skipping breakfast, habitual overeating, and not being physically active. Because we know that childhood obesity predicts adult obesity, parental education is clearly very important.

Losing weight is difficult because it is a battle against biological mechanisms designed to keep us at our current weight. This highlights the importance of not gaining weight in the first place. Over an 8-year period, the average adult (in the 20–40 age range) will gain about 14 to 16 pounds (Hill et al., 2003). How may this be avoided? Most of the weight gain that people often regard as inevitable could be prevented through a combination of increased energy expenditure and reduced food intake. And this may be easier to do than we might imagine. Hill and colleagues (2003) have calculated that all that we need to do is cut back on our intake of calories by a mere 100 calories per day or walk an extra mile each day. Here are some simple ways to accomplish this:

- Eat three fewer bites of food when you eat a meal. Three bites of hamburger, for example, equal 100 calories.
- Take the stairs, combine a meeting with a walk, or park a little farther from your destination. A mile of walking is only 2,000 to 2,500 extra steps, and we can add these in small increments throughout the day.
- Sleep more. Research is showing that babies who sleep fewer than 12 hours a day are more likely to be overweight at age 3 (Taveras et al., 2008). And adults who sleep only 5 to 6 hours a night gain more weight over time than those who sleep 7 to 8 hours a night (Chaput et al., 2008).

## UNRESOLVED issues

### The Role of Public Policy in the Prevention of Obesity

The prevalence of childhood obesity has tripled since 1980. Almost 32 percent of children and teens are now overweight or obese (Weir, 2012). Once people become obese, treatment is very difficult. Preventing obesity, both in children and adults, is therefore a major priority.

At the national level the problem of obesity is unlikely to be solved without changes in public policy. We are all aware that rates of lung cancer have decreased as a result of increased taxes on cigarettes. Can we reduce obesity by changing the environmental conditions that encourage unhealthy eating or limit physical activity? And are we, as a society, ready for this?

In 2008, much to the dismay of the restaurant industry, New York City became the first place to require chain restaurants to post calorie information on their menu boards. This was an important move because most people consistently underestimate the calories in the food they eat outside the home. A recent

It has been estimated that increasing the tax on sugar-sweetened beverages by 20 percent could lead to an average weight loss of almost 4 pounds a year for adults.

By making these habits part of your daily routine, you will be able to prevent weight gain as you age, improving your overall health.

#### in review

- Why is losing weight so difficult for most people?
- What is the most effective treatment for people who are morbidly obese?
- What are the elements of a lifestyle modification treatment for obesity?
- What social policy changes might reduce or prevent obesity?

study also suggests that when people order from a menu that includes calorie information, they consume 14 percent fewer calories than people who order from a menu that contains no calorie information (Roberto et al., 2010). Even more recently, the New York Board of Health voted to ban the sale of sugary drinks over 16 ounces in size. Although many medical professionals applauded this ban, others were angry that their choices were being limited. The ban is now a focus of legal action and is not yet in effect.

Children consume 35 to 50 percent of their daily calories while they are at school. Many of these calories come from foods purchased from vending machines, school stores, or a la carte cafeteria offerings (Weir, 2012). However, this may soon change. In 2010 Congress passed the Healthy Hunger-free Kids Act. This puts in place new policies for food in schools via the School Lunch Program. The new law will also require the development

of nutritional standards for all of the foods sold in schools. This could be very beneficial. Evidence suggests that children who live in states where there are stringent laws governing the sale of junk food gain less weight between the fifth and eighth grades than those who live in states with more lax soda and snack food regulations (Taber et al., 2012). In California, some cities have even passed ordinances requiring children's restaurant meals to meet certain nutritional standards if a toy is to be included in the meal. However, McDonald's has simply responded by charging an extra 10 cents for the toy rather than changing the nutritional content of the "Happy Meal."

Other approaches that have been suggested include improving opportunities for physical activity, better regulation of

food advertising aimed at children, subsidizing the sale of healthful foods, and increasing taxes on sugar-sweetened beverages like soda (Gearhardt et al., 2012; Novak & Brownell, 2011). Needless to say, many of these ideas are being strenuously opposed by some citizen's groups and by the food industry.

What do you think? Have you seen calorie information on menus? Did it effect what you decided to order? Is being able to buy a supersized beverage important to you? Do you support increased taxes on unhealthy foods? What do you think needs to be done to stop the nationwide problem of obesity from escalating even further out of control?

## 9 summary

### 9.1 What are the clinical aspects of eating disorders?

- Included in *DSM-5* are three different eating disorders: anorexia nervosa, bulimia nervosa, and binge eating disorder. Binge eating disorder is a new disorder that was officially recognized for the first time in *DSM-5*.
- Both anorexia nervosa and bulimia nervosa are characterized by an intense fear of becoming fat and by a drive for thinness. Patients with anorexia nervosa are severely underweight. This is not true of patients with bulimia nervosa.
- Eating disorders are more common in women than in men (3:1 ratio). They can develop at any age, although they typically emerge in adolescence or early adulthood. Anorexia nervosa usually begins at an earlier age (15–19) than bulimia nervosa (20–24).
- Anorexia nervosa has a lifetime prevalence of approximately 0.9 percent in women and 0.3 percent in men. Bulimia nervosa is more common, with a lifetime prevalence of 1.5 percent in women and 0.5 percent in men. Binge eating disorder is the most common eating disorder with a prevalence of 3.5 percent in women and 2.0 percent in men. Many more people suffer from less severe forms of disturbed eating patterns

### 9.2 What are the risk and causal factors for eating disorders?

- Genetic factors play an important role in eating disorders. Genes may make some people more susceptible to binge eating or to sociocultural influences, or may underlie personality styles (e.g., perfectionism) that increase risk for eating disorders.
- The neurotransmitter serotonin has been implicated in eating disorders. This neurotransmitter is also involved in mood disorders, which are highly comorbid with eating disorders.

- Sociocultural influences are integral in the development of eating disorders. Our society places great value on being thin. Western values concerning thinness may be spreading. This may help explain why eating disorders are now found throughout the world.

- Individual risk factors such as internalizing the thin ideal, body dissatisfaction, dieting, negative affect, and perfectionism have been implicated in the development of eating disorders.

### 9.3 How are eating disorders treated?

- Anorexia nervosa is very difficult to treat. Treatment is long term, and many patients resist getting well. For younger patients, family therapy appears to be very beneficial. Olanzapine is also helpful.
- The treatment of choice for bulimia nervosa is CBT. CBT is also helpful for binge-eating disorder. Interpersonal therapy (IPT) seems to be helpful for binge eating disorder and may be especially acceptable to minorities.

### 9.4 How do we define obesity and why is it a worldwide problem?

- Obesity is defined as having a body mass index of 30 or above. Obesity is associated with many medical problems and increased mortality. Obesity is not currently viewed as an eating disorder or as a psychiatric condition in the *DSM*.

### 9.5 Who is most at risk for obesity?

- A tendency toward being thin or heavy may be inherited. Our genetic makeup may make us more or less likely to gain weight in a cultural environment that promotes overconsumption of food and a sedentary lifestyle.
- Minorities are at especially high risk for obesity. Obesity rates are highest (50 percent) in black women. Low income is associated with obesity for women, but higher income is associated with obesity in black and Mexican American men.

## **9.6 How is obesity treated?**

- Obesity is a chronic problem. Lifestyle modifications and medications help patients to lose small amounts of weight. Drastic weight loss, however, usually requires bariatric surgery.
- Because obesity tends to be a lifelong problem and because treating obesity is so difficult, there is now a focus on trying to prevent people from becoming obese in the first place. Implementing many of the approaches that have been recommended will require changes in social policy.

What are the features of antisocial personality disorder and psychopathy?

A person's broadly characteristic traits, coping styles, and ways of interacting in the social environment emerge during childhood and normally crystallize into established patterns by the end of adolescence or early adulthood. These patterns constitute the individual's *personality*—the set of unique traits and behaviors that characterize the individual. Today there is reasonably broad agreement among personality researchers that about five basic personality trait dimensions can be used to characterize normal personality. This five-factor model of personality traits includes the following five trait dimensions: neuroticism, extraversion/introversion, openness to experience, agreeableness/antagonism, and conscientiousness (e.g., Goldberg, 1990; John & Naumann, 2008; McCrae & Costa, 2008).

## Clinical Features of Personality Disorders

For most of us, our adult personality is attuned to the demands of society. In other words, we readily comply with most societal expectations. In contrast, there are certain people who, although

they do not necessarily display obvious symptoms of most of the disorders discussed in this book, nevertheless have certain traits that are so inflexible and maladaptive that they are unable to perform adequately at least some of the varied roles expected of them by their society, in which case we may say that they have a **personality disorder** (formerly known as a *character disorder*). Two of the general features that characterize most personality disorders are chronic interpersonal difficulties and problems with one's identity or sense of self (Livesley, 2001).

In the case below, many of the varied characteristics of someone with a personality disorder are illustrated.

→ **Narcissistic Personality Disorder** Bob, age 21, comes to the psychiatrist's office accompanied by his parents. He begins the interview by announcing he has no problems. . . . The psychiatrist was able to obtain the following story from Bob and his parents. Bob had apparently spread malicious and false rumors about several of the teachers who had given him poor grades, implying that they were having homosexual affairs with students. This, as well as increasingly erratic attendance at his classes over the past term, following the loss of a girlfriend, prompted the school counselor to suggest to Bob and his parents that help was urgently needed. Bob claimed that his academic problems were exaggerated, his success in theatrical productions was being overlooked, and he was in full control of the situation. He did not deny that he spread the false rumors but showed no remorse or apprehension about possible repercussions for himself.

Bob is a tall, stylishly dressed young man. His manner is distant but charming . . . . However, he assumes a condescending, cynical, and bemused manner toward the psychiatrist and the evaluation process. He conveys a sense of superiority and control over the evaluation. . . . His mother . . . described Bob as having been a beautiful, joyful baby who was gifted and brilliant. The father . . . noted that Bob had become progressively more resentful with the births of his two siblings. The father laughingly commented that Bob "would have liked to have been the only child." . . . In his early school years, Bob seemed to play and interact less with other children than most others do. In fifth grade, after a change in teachers, he became arrogant and withdrawn and refused to participate in class. Nevertheless, he maintained excellent grades. . . . It became clear that Bob had never been "one of the boys." . . . When asked, he professed to take pride in "being different" from his peers. . . . Though he was well known to classmates, the relationships he had with them were generally under circumstances in which he was looked up to for his intellectual or dramatic talents. Bob conceded that others viewed him as cold or insensitive . . . but he dismissed this as unimportant. This represented strength to him. He went on to note that when others complained about these qualities in him, it was largely because of their own weakness. In his view, they envied him and longed to have him care about them. He believed they sought to gain by having an association with him.

Source: Adapted with permission from *DSM-IV-TR Casebook: A Learning Companion to the Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision (pp. 239–41) (Copyright © 2002), Washington, DC: American Psychiatric Association.

According to general *DSM-5* criteria for diagnosing a personality disorder, the person's enduring pattern of behavior must be *pervasive* and *inflexible*, as well as *stable* and of *long duration*. It must also cause either *clinically significant distress* or *impairment in functioning* and be manifested in at least two of the following areas: cognition, affectivity, interpersonal functioning, or impulse control. From a clinical standpoint, people with personality disorders often cause at least as much difficulty in the lives of others as they do in their own lives. Other people tend to find the behavior of individuals with personality disorders confusing, exasperating, unpredictable, and, to varying degrees, unacceptable. Whatever the particular trait patterns affected individuals have developed (obstinacy, covert hostility, suspiciousness, or fear of rejection, for example), these patterns color their reactions to each new situation and lead to a repetition of the same maladaptive behaviors because they do not learn from previous mistakes or troubles. For example, a dependent person may wear out a relationship with someone such as a spouse by incessant and extraordinary demands such as never being left alone. After that partner leaves, the person may go almost immediately into another equally dependent relationship without choosing the new partner carefully.

Personality disorders typically do not stem from debilitating reactions to stress in the recent past, as do posttraumatic stress disorder (PTSD) or many cases of major depression. Rather, these disorders stem largely from the gradual development of inflexible and distorted personality and behavioral patterns that result in persistently maladaptive ways of perceiving, thinking about, and relating to the world. In many cases, major stressful life events early in life help set the stage for the development of these inflexible and distorted personality patterns.

The category of personality disorders is broad, encompassing behavioral problems that differ greatly in form and severity. In the milder cases we find people who generally function adequately but who would be described by their relatives, friends, or associates as troublesome, eccentric, or hard to get to know. Like Bob, they may have difficulties developing close relationships with others or getting along with those with whom they do have close relationships. One severe form of personality disorder (*antisocial personality disorder*) results in extreme and often unethical “acting out” against society. Many such individuals are incarcerated in prisons, although some are able to manipulate others and keep from getting caught.

The *DSM-5* personality disorders are grouped into three clusters. These were derived on the basis of what were originally thought to be important similarities of features among the disorders within a given cluster. Table 10.1 on page 333 provides a summary.

- **Cluster A: Includes paranoid, schizoid, and schizotypal personality disorders.** People with these disorders often seem

odd or eccentric, with unusual behavior ranging from distrust and suspiciousness to social detachment.

- **Cluster B: Includes histrionic, narcissistic, antisocial, and borderline personality disorders.** Individuals with these disorders share a tendency to be dramatic, emotional, and erratic.
- **Cluster C: Includes avoidant, dependent, and obsessive-compulsive personality disorders.** In contrast to the other two clusters, people with these disorders often show anxiety and fearfulness.

Personality disorders first appeared in the *DSM* in 1980 (in *DSM-III*). Although the use of clusters has continued since then, research has raised many questions about their validity. As will be discussed later in this chapter (see “Unresolved Issues”), there are substantial limitations to the category and cluster designations. Indeed, several proposals carefully considered by the *DSM-5* task force were to remove four personality disorders entirely and abandon the cluster organization. One of the primary issues is that there are simply too many overlapping features across both categories and clusters (Krueger & Eaton, 2010; Sheets & Craighead, 2007; Widiger & Mullins-Sweatt, 2005). Nevertheless, because much of the research literature to date has used these clusters as an organizing rubric in one way or another, we still mention them here.

There is not as much evidence for the prevalence of personality disorders as there is for most of the other disorders discussed in this book, in part because there has never been a really large *epidemiological study* comprehensively examining all the personality disorders the way the two National Comorbidity Surveys examined the other disorders we have discussed (Kessler et al., 1994; Kessler, Berglund, Demler et al., 2005b). Nevertheless, a handful of epidemiological studies in recent years have assessed the prevalence of the personality disorders, albeit with differing conclusions (Lenzenweger, 2008; Paris, 2010). However, prevalence estimates for one or more personality disorders have ranged from 4.4 to 14.8 percent (Grant et al., 2005; Lenzenweger, 2008; Paris, 2010). Such discrepancies are likely due to problematic diagnostic criteria, which will be discussed later in this chapter. One review averaging across six relatively small epidemiological studies estimated that about 13 percent of the population meets criteria for at least one personality disorder at some point in their lives (Mattia & Zimmerman,

### research CLOSE-UP

#### Epidemiological Study

Epidemiological studies are designed to establish the prevalence (number of cases) of a particular disorder in a very large sample (usually many thousands) of people living in the community.

2001; see also Weissman, 1993). Several studies from Sweden yielded very similar estimates (Ekselius et al., 2001; Torgersen et al., 2001, 2012). In addition, a very large subset of people in the NCS-Replication received a modified personality disorders interview that allowed assessment of the prevalence of Cluster A, B, and C personality disorders but only two specific personality disorders (Lenzenweger et al., 2007). This study estimated that about 10 percent of the population exhibits at least one personality disorder, with 5.7 percent in Cluster A, 1.5 percent in Cluster B, and 6 percent in Cluster C. Due to the high comorbidity between clusters, some individuals meet criteria for personality disorders in more than one cluster, so the percent of people in each cluster adds up to more than 10 percent.

Since their entry into the *DSM* in 1980, the personality disorders have been coded on a separate axis, Axis II. This was because they were regarded as different enough from the standard psychiatric syndromes (which were coded on Axis I) to warrant separate classification. However, in *DSM-5*, the multiaxial system was abandoned. Personality disorders are now included with the rest of the disorders we discuss in this textbook. Personality disorders are often associated with (or comorbid with) anxiety disorders (Chapters 5 and 6), mood disorders (Chapter 7), substance use problems (Chapter 11), and sexual deviations (Chapter 12). (See, for example, L. A. Clark, 2005, 2007; Grant, Hasin et al., 2005; Grant, Stinson et al., 2005; Links et al., 2012; Mattia & Zimmerman, 2001) One summary of evidence estimated that about three-quarters of people diagnosed with a personality disorder also have another disorder as well (Dolan-Sewell et al., 2001).

- What is the definition of a personality disorder?
- What are the general *DSM* criteria for diagnosing personality disorders?

## Difficulties Doing Research on Personality Disorders

Before we discuss the clinical features and causes of personality disorders, we should note that several important aspects of doing research in this area have hindered progress relative to what is known about many other disorders. Two major categories of difficulties are briefly described.

### Difficulties in Diagnosing Personality Disorders

A special caution is in order regarding the diagnosis of personality disorders because more misdiagnoses probably occur here than in any other category of disorder. There are a number of reasons for this. One problem is that diagnostic criteria for personality disorders are not as sharply defined as they are for most other diagnostic categories, so they are often not very precise or easy to follow in practice. For example, it may be difficult to

diagnose reliably whether someone meets a given criterion for dependent personality disorder such as “goes to excessive lengths to obtain nurturance and support from others” or “has difficulty making everyday decisions without an excessive amount of advice and reassurance from others.” Because the criteria for personality disorders are defined by inferred traits or consistent patterns of behavior rather than by more objective behavioral standards (such as having a panic attack or a prolonged and persistent depressed mood), the clinician must exercise more judgment in making the diagnosis than is the case for many other disorders.

With the development of semistructured interviews and self-report inventories for the diagnosis of personality disorders, certain aspects of diagnostic reliability increased substantially. However, because the agreement between the diagnoses made on the basis of different structured interviews or self-report inventories is often rather low, there are still substantial problems with the reliability and validity of these diagnoses (Clark & Harrison, 2001; Livesley, 2003; Trull & Durrett, 2005). This means, for example, that three different researchers using three different assessment instruments may identify groups of individuals with substantially different characteristics as having a particular diagnosis such as borderline or narcissistic personality disorder. Of course, this virtually ensures that few obtained research results will be replicated by other researchers even though the groups studied by the different researchers have the same diagnostic label (e.g., Clark & Harrison, 2001).

Given problems with the unreliability of diagnoses (e.g., Clark, 2007; Livesley, 2003; Trull & Durrett, 2005), a great deal of work over the past 20 years has been directed toward developing a more reliable and accurate way of assessing personality disorders. Several theorists have attempted to deal with the problems inherent in categorizing personality disorders by developing dimensional systems of assessment for the symptoms and traits involved in personality disorders (e.g., Clark, 2007; Krueger & Eaton, 2010; Trull & Durrett, 2005; Widiger et al., 2009). However, a unified dimensional classification of personality disorders has been slow to emerge, and a number of researchers have been trying to develop an approach that will integrate the many different existing approaches (e.g., Markon et al., 2005; Krueger, Eaton, Clark et al., 2011a; Widiger et al., 2009, 2012).

The model that has perhaps been most influential is the five-factor model. This builds on the five-factor model of normal personality mentioned earlier to help researchers understand the commonalities and distinctions among the different personality disorders by assessing how these individuals score on the five basic personality traits (e.g., Clark, 2007; Widiger & Trull, 2007; Widiger et al., 2009, 2012). To fully account for the myriad ways in which people differ, each of these five basic personality traits also has subcomponents or facets. For example, the trait of neuroticism is comprised of the following six facets: anxiety, angry-hostility, depression, self-consciousness, impulsiveness, and vulnerability. Different individuals who all have high

levels of neuroticism may vary widely in which facets are most prominent—for example, some might show more prominent anxious and depressive thoughts, others might show more self-consciousness and vulnerability, and yet others might show more angry-hostility and impulsivity. And the trait of extraversion is composed of the following six facets: warmth, gregariousness, assertiveness, activity, excitement seeking, and positive emotions. (All the facets of each of the five basic trait dimensions and how they differ across people with different personality disorders are explained in Table 10.2 on p. 335.) By assessing whether a person scores low, high, or somewhere in between on each of these 30 facets, it is easy to see how this system can account for an enormous range of different personality patterns—far more than the 10 personality disorders currently classified in the *DSM*.

Within a dimensional approach, normal personality trait dimensions can be recast into corresponding domains that represent more pathological extremes of these dimensions: negative

affectivity (neuroticism); detachment (extreme introversion); antagonism (extremely low agreeableness); and disinhibition (extremely low conscientiousness). A fifth dimension, psychotism, does not appear to be a pathological extreme of the final dimension of normal personality (openness)—rather, as we will discuss later in the chapter in the section on schizotypal personality disorder, it reflects traits similar to the symptoms of psychotic disorders (e.g., schizophrenia) (Watson et al., 2008).

With these cautions and caveats in mind, we will look at the elusive and often exasperating clinical features of the personality disorders. It is important to bear in mind, however, that what we are describing is merely the prototype for each personality disorder. In reality, as would be expected from the standpoint of the five-factor model of personality disorders, it is rare for any individual to fit these “ideal” descriptions. And, as the Thinking Critically About *DSM-5* box below illustrates, this situation will not change in *DSM-5*.

## THINKING CRITICALLY about *DSM-5*

### Why Were No Changes Made to the Way Personality Disorders Are Diagnosed? *DSM-5*

Many new and innovative proposals were offered for inclusion in the personality disorders section of *DSM-5*. Indeed, the proposed revisions were among the most radical for any of the disorders covered in this book. The details were hotly debated, although the general goal was to incorporate a more dimensional approach to the assessment and diagnosis of personality pathology (Livesley, 2011; Skodol et al., 2011; Widiger et al., 2009).

In the end, the *DSM-5* task force proposed revisions that reflected a *hybrid dimensional–categorical* model. This consisted of both categorical components and dimensional components. This model includes a set of general criteria for all personality disorders, an overall dimensional measure of the severity of personality dysfunction, a limited set of personality disorder types, and a set of pathological personality traits that could be specified in the absence of one of the personality disorder types. The proposed categorical component also retained 6 of the original 10 specific personality disorder types (antisocial, avoidant, borderline, narcissistic, obsessive-compulsive, and schizotypal).

The greatest change to the status quo came from the incorporation of dimensional components. The new personality domain was intended to describe personality characteristics of *all* patients, even those without a specific personality disorder. The proposals would have allowed clinicians to rate the level of impairment in personality functioning, reflecting aspects of both identity (having a stable and coherent sense of self and the ability to pursue meaningful life goals) and interpersonal functioning (the capacity for empathy and intimacy). In addition,

diagnosticians could indicate the degree to which the patient showed substantial abnormality on five trait domains (negative affectivity, detachment, antagonism, disinhibition, and psychotism), which are based primarily on the five-factor trait model discussed in this chapter.

In the end, however, the Board of Trustees of the American Psychiatric Association vetoed all of the proposed changes and decided to retain the old categories of personality disorders. In other words, personality disorders in *DSM-5* are the same as they were in *DSM-IV*. Why were no changes accepted? We cannot be sure. But, as you may have gathered from our description above, the new system was very complicated. Although it may have led to a better classification system, the fact that it was not very intuitive or user-friendly may have been a problem. The primary audience for the *DSM* is clinicians who diagnose and treat people with mental disorders. We suspect that the new proposed system was rejected because it was quite cumbersome and judged too time-consuming for overworked clinicians to learn and use. Moreover clinicians probably would not have found the proposed system to be user-friendly in part because the idea of rating people on dimensions is foreign to the way clinicians have been taught to think. The new proposals were not dismissed entirely, however. They now appear in Section III of *DSM-5*, which describes disorders in need of further study. This may have been a wise course of action. Perhaps with more time and more research, it will become apparent whether or not the new approach provides enough benefits to make people willing to accept the challenges learning to use it will require.

One of the problems with the diagnostic categories of personality disorders is that the exact same observable behaviors may be associated with different personality disorders and yet have different meanings with each disorder. For example, this woman's behavior and expression could suggest the suspiciousness and avoidance of blame seen in paranoid personality disorder. Or they could indicate the social withdrawal and absence of friends that characterize schizoid personality disorder. Or they could indicate the social anxiety about interacting with others because of fear of being rejected or negatively evaluated that is seen in avoidant personality disorder.

### Difficulties in Studying the Causes of Personality Disorders

Relatively little is known about the causal factors involved in the development of most personality disorders. One reason for this is that personality disorders only began to receive consistent attention from researchers after they entered the *DSM* in 1980. Another problem stems from the high level of comorbidity among them. For example, in an early review of four studies, Widiger and colleagues found that 85 percent of patients who qualified for one personality disorder diagnosis also qualified for at least one more, and many qualified for several more (Widiger & Rogers, 1989; Widiger et al., 1991). A study of nearly 900 psychiatric outpatients reported that 45 percent qualified for at least one personality disorder diagnosis and, among those with one, 60 percent had more than one and 25 percent had two or more (Zimmerman et al., 2005). Even in a nonpatient sample, Zimmerman and Coryell (1989) found that of those with one personality disorder, almost 25 percent had at least one more (see also Mattia & Zimmerman, 2001; Trull et al., 2012). This substantial comorbidity adds to the difficulty of untangling which causal factors are associated with which personality disorder.

Another problem in drawing conclusions about causes occurs because researchers have more confidence in prospective studies, in which groups of people are observed before a disorder appears and are followed over a period of time to see which individuals develop problems and what causal factors have been present. Although this has begun to change, to date, relatively little prospective research has been conducted with most of the personality disorders. Instead, the vast majority of research has been conducted on people who already have the disorders; some

of it relies on retrospective recall of prior events, and some of it relies on observing current biological, cognitive, emotional, and interpersonal functioning. Thus, any conclusions about causes that are suggested must be considered very tentative.

Of possible biological factors, it has been suggested that infants' temperament (an inborn disposition to react affectively to environmental stimuli; see Chapter 3) may predispose them to the development of particular personality traits and disorders (e.g., L. A. Clark, 2005; Mervielde et al., 2005; Paris, 2012). Some of the most important dimensions of temperament are negative emotionality, sociability versus social inhibition or shyness, and activity level. One way of thinking about temperament is that it lays the early foundation for the development of the adult personality, but it is not the sole determinant of adult personality. Given that most temperamental and personality traits have been found to be moderately heritable (e.g., Bouchard & Loehlin, 2001; Livesley, 2005), it is not surprising that there is increasing evidence for genetic contributions to certain personality disorders (e.g., Kendler et al., 2008, 2011; Livesley, 2005, 2008; Livesley & Jang, 2008; South et al., 2012; Torgersen et al., 2000). However, for at least most disorders, the genetic contribution appears to be mediated by the genetic contributions to the primary trait dimensions most implicated in each disorder rather than to the disorders themselves (Livesley, 2005; Kendler et al., 2008). In addition, some progress is being made in understanding the psychobiological substrate of at least some of the traits prominently involved in the personality disorders (e.g., Depue, 2009; Depue & Lenzenweger, 2001, 2006; Livesley, 2008; Paris, 2005, 2007; Roussos & Siever, 2012).

Among psychological factors, psychodynamic theorists originally attributed great importance in the development of character disorders to an infant's getting excessive versus insufficient gratification of his or her impulses in the first few years of life (Fonagy & Luyten, 2012). More recently, learning-based habit patterns and maladaptive cognitive styles have received

Genetic propensities and temperament may be important predisposing factors for the development of particular personality traits and disorders. Parental influences, including emotional, physical, and sexual abuse, may also play a big role in the development of personality disorders.

more attention as possible causal factors (e.g., Beck et al., 1990, 2004; Lobbstad & Arntz, 2012). Many of these maladaptive habits and cognitive styles that have been hypothesized to play important roles for certain disorders may originate in disturbed parent–child attachment relationships rather than derive simply from differences in temperament (e.g., Benjamin, 2005; Fraley & Shaver, 2008; Meyer & Pilkonis, 2005; Shiner, 2009). Parental psychopathology and ineffective parenting practices have also been implicated in certain disorders (e.g., Farrington, 2006; Paris, 2001, 2007). Many studies have also suggested that early emotional, physical, and sexual abuse may be important factors in a subset of cases for several different personality disorders (Battle et al., 2004; Grover et al., 2007).

Various kinds of social stressors, societal changes, and cultural values have also been implicated as sociocultural causal factors (Paris, 2001). Ultimately, of course, the goal is to achieve a biopsychosocial perspective on the origins of each personality disorder, but today we are far from reaching that goal.

## in review

- What are three reasons for the high frequency of misdiagnoses of personality disorders?
- What are two reasons why it is difficult to conduct research on personality disorders?

## Cluster A Personality Disorders

People with Cluster A personality disorders display unusual behaviors such as distrust, suspiciousness, and social detachment and often come across as odd or eccentric. In the following section, we will look at paranoid, schizoid, and schizotypal personality disorders.

### Paranoid Personality Disorder

Individuals with **paranoid personality disorder** have a pervasive suspiciousness and distrust of others, leading to numerous interpersonal difficulties. They tend to see themselves as

**TABLE 10.1**  
**Summary of Personality Disorders**

Personality Disorder	Characteristics	Prevalence	Gender Ratio Estimate
<b>Cluster A</b>			
Paranoid	Suspiciousness and mistrust of others; tendency to see self as blameless; on guard for perceived attacks by others	0.5–2.5%	males > females
Schizoid	Impaired social relationships; inability and lack of desire to form attachments to others	<1%	males > females
Schizotypal	Peculiar thought patterns; oddities of perception and speech that interfere with communication and social interaction	3%	males > females
<b>Cluster B</b>			
Histrionic	Self-dramatization; over concern with attractiveness; tendency to irritability and temper outbursts if attention seeking is frustrated	2–3%	males = females
Narcissistic	Grandiosity; preoccupation with receiving attention; self-promoting; lack of empathy	<1%	males > females
Antisocial	Lack of moral or ethical development; inability to follow approved models of behavior; deceitfulness; shameless manipulation of others; history of conduct problems as a child	1% females, 3% males	males > females
Borderline	Impulsiveness; inappropriate anger; drastic mood shifts; chronic feelings of boredom; attempts at self-mutilation or suicide	2%	females = males
<b>Cluster C</b>			
Avoidant	Hypersensitivity to rejection or social derogation; shyness; insecurity in social interaction and initiating relationships	0.5–1%	males = females
Dependent	Difficulty in separating in relationships; discomfort at being alone; subordination of needs in order to keep others involved in a relationship; indecisiveness	2%	males = females
Obsessive-Compulsive	Excessive concern with order, rules, and trivial details; perfectionistic; lack of expressiveness and warmth; difficulty in relaxing and having fun	1%	males > females (by 2:1)

Source: APA (2013); Weissman (1993); Zimmerman & Coryell (1990).

- A. A pervasive distrust and suspiciousness of others such that their motives are interpreted as malevolent, beginning by early adulthood and present in a variety of contexts, as indicated by four (or more) of the following:
  - 1. Suspects, without sufficient basis, that others are exploiting, harming, or deceiving him or her.
  - 2. Is preoccupied with unjustified doubts about the loyalty or trustworthiness of friends or associates.
  - 3. Is reluctant to confide in others because of unwarranted fear that the information will be used maliciously against him or her.
  - 4. Reads hidden demeaning or threatening meanings into benign remarks or events.
  - 5. Persistently bears grudges (i.e., is unforgiving of insults, injuries, or slights).

6. Perceives attacks on his or her character or reputation that are not apparent to others and is quick to react angrily or to counterattack.

7. Has recurrent suspicions, without justification, regarding fidelity of spouse or sexual partner.

- B. Does not occur exclusively during the course of schizophrenia, a bipolar disorder or depressive disorder with psychotic features, or another psychotic disorder and is not attributable to the physiological effects of another medical condition.

**Note:** If criteria are met prior to the onset of schizophrenia, add "premorbid," i.e., "paranoid personality disorder (premorbid)."

Source: Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, (Copyright © 2013). American Psychiatric Association.

blameless, instead blaming others for their own mistakes and failures—even to the point of ascribing evil motives to others. Such people are chronically tense and “on guard,” constantly expecting trickery and looking for clues to validate their expectations while disregarding all evidence to the contrary. They are often preoccupied with doubts about the loyalty of friends and hence are reluctant to confide in others. They commonly bear grudges, refuse to forgive perceived insults and slights, and are quick to react with anger and sometimes violent behavior (Bernstein & Useda, 2007; Oltmanns & Okada, 2006). Recent research has suggested that paranoid personality disorder may consist of elements of both suspiciousness and hostility (Edens et al., 2009; Falkum et al., 2009).

It is important to keep in mind that people with paranoid personalities are not usually psychotic; that is, most of the time they are in clear contact with reality, although they may experience transient psychotic symptoms during periods of stress (M. B. Miller, Useda et al., 2001). People with paranoid schizophrenia share some symptoms found in paranoid personality, but they have many additional problems including more persistent loss of contact with reality, delusions, and hallucinations. Nevertheless, individuals with paranoid personality disorder do appear to be at elevated liability for schizophrenia (Lenzenweger, 2009).

→ **Paranoid Construction Worker** A 40-year-old construction worker believes that his coworkers do not like him and fears that someone might let his scaffolding slip in order to cause him injury on the job. This concern followed a recent disagreement on the lunch line when the patient felt that a coworker was sneaking ahead and complained to him. He began noticing his new “enemy” laughing with the other men and often wondered if he were the butt of their mockery. . . .

The patient offers little spontaneous information, sits tensely in the chair, is wide-eyed, and carefully tracks all movements in the room. He reads between the lines of the interviewer’s questions, feels criticized, and imagines that the interviewer is siding with his coworkers. . . .

He was a loner as a boy and felt that other children would form cliques and be mean to him. He did poorly in school but blamed his teachers—he claimed that they preferred girls or boys who were “sissies.” He dropped out of school and has since been a hard and effective worker, but he feels he never gets the breaks. He believes that he has been discriminated against because of his Catholicism but can offer little convincing evidence. He gets on poorly with bosses and coworkers, is unable to appreciate joking around, and does best in situations where he can work and have lunch alone. He has switched jobs many times because he felt he was being mistreated.

The patient is distant and demanding with his family. His children call him “Sir” and know that it is wise to be “seen but not heard” when he is around. . . . He prefers not to have people visit his house and becomes restless when his wife is away visiting others.

**CAUSAL FACTORS** Little is known about important causal factors for paranoid personality disorder (Falkum et al., 2009). Some have argued for partial genetic transmission that may link the disorder to schizophrenia, but results examining this issue are inconsistent, and if there is a significant relationship it is not a strong one (Kendler et al., 2006; M. B. Miller, Useda

et al., 2001). There is a modest genetic liability to paranoid personality disorder itself that may occur through the heritability of high levels of antagonism (low agreeableness) and neuroticism (angry-hostility), which are among the primary traits in paranoid personality disorder (Widiger, Trull et al., 2002; see also Falkum et al., 2009; Hopwood & Thomas, 2012; Kendler et al., 2006). (See Table 10.2 below.) Psychosocial causal factors that are suspected to play a role include parental neglect or abuse and exposure to violent adults, although any links between early adverse experiences and adult paranoid personality disorder are clearly not specific to this one personality disorder and may play a role in other disorders as well (Battle et al., 2004; Grover et al., 2007; Natsuaki et al., 2009).

## Schizoid Personality Disorder

Individuals with **schizoid personality disorder** are usually unable to form social relationships and usually lack much interest in doing so. Consequently, they tend not to have good friends, with the possible exception of a close relative. Such people are unable to express their feelings and are seen by others as cold and distant. They often lack social skills and can be classified as loners or introverts, with solitary interests and occupations, although not all loners or introverts have schizoid personality disorder (Bernstein et al., 2009; M. B. Miller, Useda et al., 2001). People with this disorder tend not to take pleasure in many activities, including sexual activity, and rarely marry. More generally, they are not very emotionally reactive, rarely

- A. A pervasive pattern of detachment from social relationships and a restricted range of expression of emotions in interpersonal settings, beginning by early adulthood and present in a variety of contexts, as indicated by four (or more) of the following:
  - 1. Neither desires nor enjoys close relationships, including being part of a family.
  - 2. Almost always chooses solitary activities.
  - 3. Has little, if any, interest in having sexual experiences with another person.
  - 4. Takes pleasure in few, if any, activities.
  - 5. Lacks close friends or confidants other than first-degree relatives.

- 6. Appears indifferent to the praise or criticism of others.
  - 7. Shows emotional coldness, detachment, or flattened affectivity.
- B. Does not occur exclusively during the course of schizophrenia, a bipolar disorder or depressive disorder with psychotic features, another psychotic disorder, or autism spectrum disorder and is not attributable to the physiological effects of another medical condition.

**Note:** If criteria are met prior to the onset of schizophrenia, add "premorbid," i.e., "schizoid personality disorder (premorbid)."

experiencing strong positive or negative emotions, but rather show a generally apathetic mood. These deficits contribute to their appearing cold and aloof (M. B. Miller, Useda et al., 2001; Mittal et al., 2007). In terms of the five-factor model, they show extremely high levels of introversion (especially low on warmth, gregariousness, and positive emotions). They are also low on openness to feelings (one facet of openness to experience) (Widiger, Trull et al., 2002) and on achievement striving (e.g., Hopwood & Thomas, 2012).

**CAUSAL FACTORS** Like paranoid personality disorder, schizoid personality disorder has not been the focus of much research attention. This is hardly surprising since people with schizoid personality disorder are not exactly the people we might expect to volunteer for a research study. Early theorists considered a schizoid personality to be a likely precursor to the development of schizophrenia, but this viewpoint has been challenged, and any genetic link that may exist is very modest (Kalus et al., 1995; Kendler et al., 2006; Lenzenweger, 2010; M. B. Miller, Useda et al., 2001). Schizoid personality traits have also been shown to have only a modest heritability (Kendler et al., 2006).

Some theorists have suggested that the severe disruption in sociability seen in schizoid personality disorder may be due to severe impairment in an underlying affiliative system (Depue & Lenzenweger, 2005, 2006). Cognitive theorists propose that individuals with schizoid personality disorder exhibit cool and aloof behavior because of maladaptive underlying schemas that lead them to view themselves as self-sufficient loners and to view others as intrusive. Their core dysfunctional belief might be, "I am basically alone" (Beck et al., 1990, p. 51) or "Relationships are messy [and] undesirable" (Pretzer & Beck, 1996, p. 60; see also Beck et al., 2004). Unfortunately, we do not know why or how some people might develop such dysfunctional beliefs.

## Schizotypal Personality Disorder

Individuals with **schizotypal personality disorder** are also excessively introverted and have pervasive social and interpersonal deficits (like those that occur in schizoid personality disorder), but in addition they have cognitive and perceptual distortions, as well as oddities and eccentricities in their communication and behavior (Kwapil & Barrantes-Vidal, 2012; Raine, 2006). Although contact with reality is usually maintained, highly personalized and superstitious thinking is characteristic of people with schizotypal personality, and under extreme stress they may experience transient psychotic symptoms (APA, 2013; Widiger & Frances, 1994). Indeed, they often believe that they have magical powers and may engage in magical rituals. Other cognitive-perceptual problems include ideas of reference (the belief that conversations or gestures of others have special meaning or personal significance), odd speech, and paranoid beliefs.

→ **The Introverted Computer Analyst** Bill, a highly intelligent but quite introverted and withdrawn 33-year-old computer analyst, was referred for psychological evaluation by his physician, who was concerned that Bill might be depressed and unhappy. Bill had virtually no contact with other people. He lived alone in his apartment, worked in a small office by himself, and usually saw no one at work except his supervisor, who occasionally visited to give him new work and pick up completed projects. He ate lunch by himself, and about once a week, on nice days, went to the zoo for his lunch break.

Bill was a lifelong loner; as a child he had had few friends and had always preferred solitary activities over family outings (he was the oldest of five children). In high school he had never dated and in college had gone out with a woman only once—and that was with a group of students after a game. He had been

active in sports, however, and had played varsity football in both high school and college. In college he had spent a lot of time with one relatively close friend—mostly drinking. However, this friend now lived in another city.

Bill reported rather matter-of-factly that he had a hard time making friends; he never knew what to say in a conversation. On a number of occasions he had thought of becoming friends with other people but simply couldn't think of the right words, so "the conversation just died." He reported that he had given some thought lately to changing his life in an attempt to be more "positive," but it had never seemed worth the trouble. It was easier for him not to make the effort because he became embarrassed when someone tried to talk with him. He was happiest when he was alone.

.....

Oddities in thinking, speech, and other behaviors are the most stable characteristics of schizotypal personality disorder (McGlashan et al., 2005) and are similar to those often seen in patients with schizophrenia. In fact, many researchers conceptualize schizotypal personality disorder as an attenuated form of schizophrenia (Lenzenweger, 2010; Raine, 2006). Interestingly, although some aspects of schizotypy appear related to the five-factor model of normal personality (specifically facets of introversion and neuroticism), the other aspects related to cognitive and perceptual distortions are *not* adequately explained by the five-factor model of normal personality (Watson et al., 2008). Indeed, these core symptoms of schizotypy form the basis of the only proposed trait that does not map neatly unto the five factors of normal personality. This final pathological trait is psychotism, which consists of three facets: unusual beliefs and experiences, eccentricity, and cognitive and perceptual dysregulation (Krueger, Eaton, Derringer et al., 2011b).

**CAUSAL FACTORS** Unlike schizoid and paranoid personality disorders, there has been a significant amount of research on schizotypal personality disorder (Esterberg et al., 2010). In fact, in the original proposal for the *DSM-5*, schizotypal personality was the only categorical disorder retained from Cluster A. Estimates of the prevalence of this disorder in the general population have varied somewhat, but one good review of such studies has estimated that the prevalence is about 2 to 3 percent in the general population (Raine, 2006). The heritability of schizotypal personality disorder is moderate (Kwapil & Barrantes-Vidal, 2012; Raine, 2006; Lin et al., 2006, 2007).

The biological associations of schizotypal personality disorder with schizophrenia are remarkable (Cannon et al., 2008; Jang et al., 2005; Siever & Davis, 2004; Yung et al., 2004). A number of studies on patients, as well as on college students, with schizotypal personality disorder (e.g., Raine, 2006; Siever et al., 1995) have shown the same deficit in the ability to track a moving target visually that is found in schizophrenia (Coccaro, 2001; see also Chapter 13). They also show numerous other mild impairments in cognitive functioning (Voglmaier et al., 2005), including deficits in their ability to sustain attention (Lees-Roitman et al., 1997; Raine, 2006) and deficits in working memory (e.g., being able to remember a span of digits), both of which are common in schizophrenia (Farmer et al., 2000; Squires-Wheeler et al., 1997). In addition, individuals with schizotypal personality disorder, like patients with schizophrenia, show deficits in their ability to inhibit attention to a second stimulus that rapidly follows presentation of a first stimulus. For example, normal individuals presented with a weak auditory stimulus about 0.1 second before a loud sound that elicits a startle response show a smaller startle response than those not presented the weak auditory stimulus first (Cadenhead, Light

## criteria for Schizotypal Personality Disorder

DSM-5

- A. A pervasive pattern of social and interpersonal deficits marked by acute discomfort with, and reduced capacity for, close relationships as well as by cognitive or perceptual distortions and eccentricities of behavior, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:
1. Ideas of reference (excluding delusions of reference).
  2. Odd beliefs or magical thinking that influences behavior and is inconsistent with subcultural norms (e.g., superstition, belief in clairvoyance, telepathy, or "sixth sense"; in children and adolescents, bizarre fantasies or preoccupations).
  3. Unusual perceptual experiences, including bodily illusions.
  4. Odd thinking and speech (e.g., vague, circumstantial, metaphorical, overelaborate, or stereotyped).
  5. Suspiciousness or paranoid ideation.
  6. Inappropriate or constricted affect.
  7. Behavior or appearance that is odd, eccentric, or peculiar.
  8. Lack of close friends or confidants other than first-degree relatives.
  9. Excessive social anxiety that does not diminish with familiarity and tends to be associated with paranoid fears rather than negative judgments about self.
- B. Does not occur exclusively during the course of schizophrenia, a bipolar disorder or depressive disorder with psychotic features, another psychotic disorder, or autism spectrum disorder.
- Note:** If criteria are met prior to the onset of schizophrenia, add "premorbid," e.g., "schizotypal personality disorder (premorbid)."

Source: Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, (Copyright © 2013). American Psychiatric Association.

et al., 2000a; Cadenhead, Swerdlow et al., 2000b). This normal inhibitory effect is reduced in people with schizotypal personality disorder and with schizophrenia, a phenomenon that may be related to their high levels of distractibility and difficulty staying focused (see also Hazlett et al., 2003; Raine, 2006). Finally, they also show language abnormalities that may be related to abnormalities in their auditory processing (Dickey et al., 2008).

A genetic relationship to schizophrenia has also long been suspected. In fact, this disorder appears to be part of a spectrum of liability for schizophrenia that often occurs in some of the first-degree relatives of people with schizophrenia (Kendler & Gardner, 1997; Kwapis & Barrantes-Vidal, 2012; Raine, 2006; Tienari et al., 2003). Moreover, teenagers who have schizotypal personality disorder have been shown to be at increased risk for developing schizophrenia and schizophrenia-spectrum disorders in adulthood (Asarnow, 2005; Cannon et al., 2008; Raine, 2006; Tyrka et al., 1995). Nevertheless, it has also been proposed that there is a second subtype of schizotypal personality disorder that is not genetically linked to schizophrenia. This subtype is characterized by cognitive and perceptual deficits and is instead linked to a history of childhood abuse and early trauma (Berenbaum et al., 2008; Raine, 2006). Schizotypal personality disorder in adolescence has been associated with elevated exposure to stressful life events (Anglin et al., 2008; Tessner et al., 2011) and low family socioeconomic status (Cohen et al., 2008).

## Cluster B Personality Disorders

In the following section, we look closely at histrionic, narcissistic, antisocial, and borderline personality disorders. Remember that people with Cluster B personality disorders share a tendency to be dramatic, emotional, and erratic.

### Histrionic Personality Disorder

Excessive attention-seeking behavior and emotionality are the key characteristics of individuals with **histrionic personality disorder**. As you can see from the table of *DSM-5* criteria, these individuals tend to feel unappreciated if they are not the center of attention; their lively, dramatic, and excessively extraverted styles often ensure that they can charm others into attending to them. But these qualities do not lead to stable and satisfying relationships because others tire of providing this level of attention. In craving stimulation and attention, their appearance and behavior are often quite theatrical and emotional as well as sexually provocative and seductive (Freeman et al., 2005). They may attempt to control their partners through seductive behavior and emotional manipulation, but they also show a good deal of dependence (e.g., Blagov et al., 2007; Bornstein & Malka, 2009; P. R. Rasmussen, 2005). Their speech is often vague and impressionistic, and they are usually considered self-centered, vain, and excessively concerned about the approval of others, who see them as overly reactive, shallow, and insincere.

This woman could be just “clowning around” one night in a bar with friends. But if she frequently seeks opportunities to engage in seductive and attention-seeking behavior, she could have histrionic personality disorder.

The prevalence of histrionic personality disorder in the general population is estimated at 2 to 3 percent, although the prevalence of this disorder may be decreasing (Blashfield et al., 2012). Some (but not all) studies suggest that this disorder occurs more often in women than in men (Lynam & Widiger, 2007; Widiger & Bornstein, 2001). Reasons for the possible sex difference have been very controversial. One review of these controversies suggested that this sex difference is not surprising, given the number of traits that occur more often in females that are involved in the diagnostic criteria. For example, many of the criteria for histrionic personality disorder (as well as for several other personality disorders such as dependent) involve maladaptive variants of female-related traits (e.g., Widiger & Bornstein, 2001) such as overdramatization, vanity, seductiveness, and overconcern with physical appearance. However, other personality traits prominent in histrionic personality disorder are actually more common in men than in women (e.g., high excitement seeking and low self-consciousness). A recent careful analysis of the issue suggests that the higher prevalence of histrionic personality in women actually would not be predicted based on known sex differences in the personality traits prominent in the disorder. This does indeed suggest the influence of some form of sex bias in the diagnosis of this disorder (Lynam & Widiger, 2007).

**CAUSAL FACTORS** Very little systematic research has been conducted on histrionic personality disorder, perhaps as a result of the difficulty researchers have had in differentiating it from other personality disorders (Bornstein & Malka, 2009) and/or because many do not believe it is a valid diagnosis (Blashfield et al., 2012). Indeed one leading theorist and researcher on this topic has referred to the diagnosis as being “dead” (Blashfield et al., 2012). Reflecting this, histrionic personality disorder was one of the four diagnoses that was recommended for removal in *DSM-5*. Histrionic personality disorder is highly comorbid with

borderline, antisocial, narcissistic, and dependent personality disorder diagnoses (Bakkevig & Karterud, 2010; Blagov & Westen, 2008; Bornstein & Malka, 2009).

→ **A Histrionic Housewife** Lulu, a 24-year-old housewife, was seen in an inpatient unit several days after she had been picked up for "vagrancy" after her husband had left her at the bus station to return her to her own family because he was tired of her behavior and of taking care of her. Lulu showed up for the interview all made-up and in a very feminine robe, with her hair done in a very special way. Throughout the interview with a male psychiatrist, she showed flirtatious and somewhat childlike seductive gestures and talked in a rather vague way about her problems and her life. Her chief complaints were that her husband had deserted her and that she couldn't return to her family because two of her brothers had abused her. Moreover, she had no friends to turn to and wasn't sure how she was going to get along. Indeed, she complained that she had never had female friends, whom she felt just didn't like her, although she wasn't quite sure why, assuring the interviewer that she was a very nice and kind person.

Recently she and her husband had been out driving with a couple who were friends of her husband's. The wife had accused Lulu of being overly seductive toward the wife's husband, and Lulu had been hurt, thinking her behavior was perfectly innocent and not at all out of line. This incident led to a big argument with her own husband, one in a long series over the past 6 months in which he complained about her inappropriate behavior around other men and about how vain and needing of attention she was. These arguments and her failure to change her behavior had ultimately led her husband to desert her.

There is some evidence for a genetic link with antisocial personality disorder, the idea being that there may be some common underlying predisposition that is more likely to be manifested in women as histrionic personality disorder and in men

as antisocial personality disorder (e.g., Cale & Lilienfeld, 2002a, 2002b). The suggestion of some genetic propensity to develop this disorder is also supported by findings that histrionic personality disorder may be characterized as involving extreme versions of two common, normal personality traits, extraversion and, to a lesser extent, neuroticism—two normal personality traits known to have a partial genetic basis (Widiger & Bornstein, 2001). In terms of the five-factor model (refer back to Table 10.2 on p. 335), the very high levels of extraversion of patients with histrionic personality disorder include high levels of gregariousness, excitement seeking, and positive emotions. Their high levels of neuroticism particularly involve the depression and self-consciousness facets; they are also high on openness to fantasies (Widiger, Trull et al., 2002).

Cognitive theorists emphasize the importance of maladaptive schemas revolving around the need for attention to validate self-worth. Core dysfunctional beliefs might include, "Unless I captivate people, I am nothing" and "If I can't entertain people, they will abandon me" (Beck et al., 1990, p. 50). No systematic research has yet explored how these dysfunctional beliefs might develop.

## Narcissistic Personality Disorder

Individuals with **narcissistic personality disorder** show an exaggerated sense of self-importance, a preoccupation with being admired, and a lack of empathy for the feelings of others (Pincus & Lukowitsky, 2010; Ronningstam, 2005, 2009, 2012). Numerous studies support the notion of two subtypes of narcissism: grandiose and vulnerable narcissism (Cain et al., 2008; Ronningstam, 2005, 2012). The grandiose presentation of narcissistic patients, highlighted in the *DSM-5* criteria, is manifested by traits related to grandiosity, aggression, and dominance. These are reflected in a strong tendency to overestimate their abilities and accomplishments while underestimating the abilities and accomplishments of others. Their sense of entitlement is frequently a source of astonishment to others, although they themselves seem to regard their lavish expectations as merely what they deserve. They behave in stereotypical ways (e.g., with constant self-references and bragging)

### criteria for Histrionic Personality Disorder

A pervasive pattern of excessive emotionality and attention seeking, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:

1. Is uncomfortable in situations in which he or she is not the center of attention.
2. Interaction with others is often characterized by inappropriate sexually seductive or provocative behavior.
3. Displays rapidly shifting and shallow expression of emotions.
4. Consistently uses physical appearance to draw attention to self.

DSM-5

5. Has a style of speech that is excessively impressionistic and lacking in detail.
6. Shows self-dramatization, theatricality, and exaggerated expression of emotion.
7. Is suggestible (i.e., easily influenced by others or circumstances).
8. Considers relationships to be more intimate than they actually are.

Source: Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, (Copyright © 2013). American Psychiatric Association.

A pervasive pattern of grandiosity (in fantasy or behavior), need for admiration, and lack of empathy, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:

1. Has a grandiose sense of self-importance (e.g., exaggerates achievements and talents, expects to be recognized as superior without commensurate achievements).
2. Is preoccupied with fantasies of unlimited success, power, brilliance, beauty, or ideal love.
3. Believes that he or she is "special" and unique and can only be understood by, or should associate with, other special or high-status people (or institutions).
4. Requires excessive admiration.

5. Has a sense of entitlement (i.e., unreasonable expectations of especially favorable treatment or automatic compliance with his or her expectations).
6. Is interpersonally exploitative (i.e., takes advantage of others to achieve his or her own ends).
7. Lacks empathy: is unwilling to recognize or identify with the feelings and needs of others.
8. Is often envious of others or believes that others are envious of him or her.
9. Shows arrogant, haughty behaviors or attitudes.

Source: Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, (Copyright © 2013). American Psychiatric Association.

to gain the acclaim and recognition they crave. Because they believe they are so special, they often think they can be understood only by other high-status people or that they should associate only with such people, as was the case with Bob at the beginning of the chapter. Finally, their sense of entitlement is also associated with their unwillingness to forgive others for perceived slights, and they easily take offense (Exline et al., 2004).

The vulnerable presentation of narcissism is not as clearly reflected in the *DSM* criteria but nevertheless represents a subtype long observed by researchers and clinicians. Vulnerable narcissists have a very fragile and unstable sense of self-esteem, and for these individuals, arrogance and condescension is merely a façade for intense shame and hypersensitivity to rejection and criticism (Cain et al., 2008; Miller et al., 2010; Pincus & Lukowitsky, 2010; Ronningstam, 2005, 2012). Vulnerable narcissists may become completely absorbed and preoccupied with fantasies of outstanding achievement but at the same time experience profound shame about their ambitions. They may avoid interpersonal relationships due to fear of rejection or criticism.

There is increasing evidence that the grandiose and vulnerable presentations of narcissism are related but distinct in important ways. In terms of the five-factor model, both subtypes are associated with high levels of interpersonal antagonism/low agreeableness (which includes traits of low modesty, arrogance, grandiosity, and superiority), low altruism (expecting favorable treatment and exploiting others), and tough-mindedness (lack of empathy). (Refer back to Table 10.2 on p. 335.) However, the primarily grandiose narcissist is exceptionally low in certain facets of neuroticism and high in extraversion. For the grandiose narcissist, close friends and relatives may be more distressed about his or her behavior than the narcissist him- or herself. One study concluded, "The strongest impairment associated with narcissistic personality disorder is the distress of 'pain and suffering' experienced not by the narcissist but by his or her significant

others" (J. D. Miller, 2007, p. 176). However, the case is quite different for the vulnerable narcissist, who has very *high* levels of negative affectivity/neuroticism (Cain et al., 2008; Miller et al., 2010). Thus, spouses describe patients with either grandiosity or vulnerability as being "bossy, intolerant, cruel, argumentative, dishonest, opportunistic, conceited, arrogant, and demanding," but only those high on grandiosity were additionally described as being "aggressive, hardheaded, outspoken, assertive, and determined," while those high on vulnerability were described as "worrying, emotional, defensive, anxious, bitter, tense, and complaining" (Wink, 1991, p. 595). Importantly, some narcissistic individuals may fluctuate between grandiosity and vulnerability (Pincus & Lukowitsky, 2010; Ronningstam, 2009).

Narcissistic personalities also share another central trait—they are unwilling or unable to take the perspective of others, to see things other than "through their own eyes." Moreover, if they do not receive the validation or assistance they desire, they are inclined to be hypercritical and retaliatory (P. S. Rasmussen, 2005). Indeed, one study of male students with high levels of narcissistic traits showed that they had greater tendencies toward sexual coercion when they were rejected by the target of their sexual desires than did men with lower levels of narcissistic traits. They also rated filmed depictions of rape less unfavorably and as more enjoyable and sexually arousing than did the men with low levels of narcissistic traits (Bushman et al., 2003).

Narcissistic personality disorder may be more frequently observed in men than in women (Golomb et al., 1995). A recent quantitative review supports this finding and has also shown that this gender difference is to be expected, based on known sex differences in the personality traits most prominent in narcissistic personality disorder (Lynam & Widiger, 2007). Compared with some of the other personality disorders, narcissistic personality disorder is thought to be relatively rare. It is estimated to occur in about 1 percent of the population.

**CAUSAL FACTORS** Until the past decade, there was a wealth of theories (Kohut & Wolff, 1978; Millon & Davis, 1995; Widiger & Bornstein, 2001) but precious little empirical data on the environmental and genetic factors involved in the etiology of narcissistic personality disorder. Fortunately, a number of researchers are now actively trying to understand the causes of this fascinating disorder. A key finding has been that the grandiose and vulnerable forms of narcissism are associated with different causal factors. Grandiose narcissism has not generally been associated with childhood abuse, neglect, or poor parenting. Indeed, there is some evidence that grandiose narcissism is associated with parental overvaluation. By contrast, vulnerable narcissism has been associated with emotional, physical, and sexual abuse, as well as parenting styles characterized as intrusive, controlling, and cold (Horton et al., 2006; Miller, 2011; Miller & Campbell, 2008; Otway & Vignoles, 2006).

→ **A Narcissistic Student** A 25-year-old, single graduate student complains to his psychoanalyst of difficulty completing his Ph.D. in English literature and expresses concerns about his relationships with women. He believes that his thesis topic may profoundly increase the level of understanding in his discipline and make him famous, but so far he has not been able to get past the third chapter. His mentor does not seem sufficiently impressed with his ideas, and the patient is furious at him but also self-doubting and ashamed. He blames his mentor for his lack of progress and thinks that he deserves more help with his grand idea, and that his mentor should help with some of the research. The patient brags about his creativity and complains that other people are "jealous" of his insight. He is very envious of students who are moving along faster than he and regards them as "dull drones and ass-kissers." He prides himself on the brilliance of his class participation and imagines someday becoming a great professor.

He becomes rapidly infatuated with women and has powerful and persistent fantasies about each new woman he meets, but after several sexual experiences feels disappointed and finds them dumb, clinging, and physically repugnant. He has many "friends," but they turn over quickly, and no one relationship lasts very long. People get tired of his continual self-promotion and lack of consideration of them. For example, he was lonely at Christmas and insisted that his best friend stay in town rather than visit his family. The friend refused, criticizing the patient's self-centeredness; and the patient, enraged, decided never to see this friend again.

## Antisocial Personality Disorder

Individuals with antisocial personality disorder (ASPD) continually violate and show disregard for the rights of others through deceitful, aggressive, or antisocial behavior, typically without

Otto Kernberg (b. 1928) is an influential contemporary psychoanalytic theorist who has written a great deal about borderline and narcissistic personality disorders.

Heinz Kohut (1913–1981), another contemporary psychoanalytic thinker, theorized that poor parenting can cause narcissistic personality disorder by failing to build a child's normal self-confidence.

remorse or loyalty to anyone. They tend to be impulsive, irritable, and aggressive and to show a pattern of generally irresponsible behavior. This pattern of behavior must have been occurring since the age of 15, and before age 15 the person must have had symptoms of conduct disorder, a similar disorder occurring in children and young adolescents who show persistent patterns of aggression toward people or animals, destruction of property, deceitfulness or theft, and serious violation of rules at home or in school. Because this personality disorder and its causes have been studied far more extensively than the others, and because of its enormous costs to society, it will be examined in some detail later (refer back to Table 10.2 on p. 335).

## → A Thief With Antisocial Personality Disorder

Mark, a 22-year-old, was awaiting trial for car theft and armed robbery. His case records included a long history of arrests beginning at age 9, when he had been picked up for vandalism. He had been expelled from high school for truancy and disruptive behavior. On a number of occasions he had run away from home for days or weeks at a time—always returning in a

disheveled and “rundown” condition. To date he had not held a job for more than a few days at a time even though his generally charming manner enabled him to obtain work readily. He was described as a loner with few friends. Although initially charming, Mark usually soon antagonized those he met with his aggressive, self-oriented behavior. Shortly after his first therapy session, he skipped bail and presumably left town to avoid his trial.

## Borderline Personality Disorder

People with **borderline personality disorder (BPD)** show a pattern of behavior characterized by impulsivity and instability in interpersonal relationships, self-image, and moods. However, the term *borderline personality* has a long and rather confusing history (Hooley et al., 2012). Originally it was most often used to refer to a condition that was thought to occupy the “border” between neurotic and psychotic disorders (as in the term *borderline schizophrenia*). Later, however, this sense of the term *borderline* became identified with schizotypal personality disorder, which (as we noted earlier) is biologically related to schizophrenia. The current diagnosis of BPD is no longer considered to be biologically related to schizophrenia.

 Watch the Video *Liz: Borderline Personality Disorder* on MyPsychLab

The central characteristic of BPD is *affective instability*, manifested by unusually intense emotional responses to environmental triggers, with delayed recovery to a baseline emotional state. Affective instability is also characterized by drastic and rapid shifts from one emotion to another (Livesley, 2008; Paris, 2007). In addition, people with BPD have a *highly unstable self-image* or sense of self, which is sometimes described as “impooverished

and/or fragmented” (Livesley, 2008, p. 44). Given their affective instability combined with unstable self-image, it is not surprising that these people have highly unstable interpersonal relationships. These relationships tend to be intense but stormy, typically involving overidealizations of friends or lovers that later end in bitter disillusionment, disappointment, and anger (Gunderson et al., 1995; Lieb et al., 2004). Nevertheless, they may make desperate efforts to avoid real or imagined abandonment, perhaps because their fears of abandonment are so intense (Lieb et al., 2004; Livesley, 2008). Recent experimental research supports a causal link between the perception of rejection and intense, uncontrollable rage in BPD (Berenson et al., 2011).

Another very important feature of BPD is *impulsivity* characterized by rapid responding to environmental triggers without thinking (or caring) about long-term consequences (Paris, 2007). These individuals’ high levels of impulsivity combined with their extreme affective instability often lead to erratic, self-destructive behaviors such as gambling sprees or reckless driving. Suicide attempts, sometimes flagrantly manipulative, can be part of the clinical picture (Paris, 1999, 2007). However, such attempts are not always simply manipulative; prospective studies suggest that approximately 8 to 10 percent may ultimately complete suicide (Oldham, 2006; Skodol, Gunderson et al., 2002). *Self-mutilation* (such as repetitive cutting behavior) is another characteristic feature of borderline personality. However, as illustrated in the Thinking Critically About *DSM-5* box on page 343, many people who engage in self-injury do not have BPD. In some cases the self-injurious behavior is associated with relief from anxiety or dysphoria, and it also serves to communicate the person’s level of distress to others (Paris, 2007). Research has also documented that borderline personality is associated with analgesia in as many as 70 to 80 percent of women with BPD (analgesia is the

### criteria for Borderline Personality Disorder

DSM-5

A pervasive pattern of instability of interpersonal relationships, self-image, and affects, and marked impulsivity, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:

1. Frantic efforts to avoid real or imagined abandonment. (**Note:** Do not include suicidal or self-mutilating behavior covered in Criterion 5.)
2. A pattern of unstable and intense interpersonal relationships characterized by alternating between extremes of idealization and devaluation.
3. Identity disturbance: markedly and persistently unstable self-image or sense of self.
4. Impulsivity in at least two areas that are potentially self-damaging (e.g., spending, sex, substance abuse, reckless

driving, binge eating). (**Note:** Do not include suicidal or self-mutilating behavior covered in Criterion 5.)

5. Recurrent suicidal behavior, gestures, or threats, or self-mutilating behavior.
6. Affective instability due to a marked reactivity of mood (e.g., intense episodic dysphoria, irritability, or anxiety usually lasting a few hours and only rarely more than a few days).
7. Chronic feelings of emptiness.
8. Inappropriate, intense anger or difficulty controlling anger (e.g., frequent displays of temper, constant anger, recurrent physical fights).
9. Transient, stress-related paranoid ideation or severe dissociative symptoms.

Source: Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, (Copyright © 2013). American Psychiatric Association.

People with borderline personality disorder often engage in self-destructive behaviors including repetitive cutting and other forms of self-injury. But not everyone who engages in self-injury has borderline personality disorder. In *DSM-5* a new disorder called nonsuicidal self-injury disorder has been added provisionally as a disorder in need of further research.

absence of the experience of pain in the presence of a theoretically painful stimulus; Figueroa & Silk, 1997; Schmahl et al., 2004). The following prototypic case illustrates the frequent risk of suicide and self-mutilation among borderline personalities.

### → Self-Mutilation in Borderline Personality

**Disorder** A 26-year-old unemployed woman was referred for

admission to a hospital by her therapist because of intense suicidal preoccupation and urges to mutilate herself with a razor. The patient was apparently well until her junior year in high school, when she became preoccupied with religion and philosophy, avoided friends, and was filled with doubt about who she was. Academically she did well, but later, during college, her performance declined. In college she began to use a variety of drugs, abandoned the religion of her family, and seemed to be searching for a charismatic religious figure with whom to identify. At times, massive anxiety swept over her, and she found it would suddenly vanish if she cut her forearm with a razor blade.

Three years ago she began psychotherapy and initially rapidly idealized her therapist as being incredibly intuitive and empathic. Later she became hostile and demanding of him, requiring more and more sessions, sometimes twice in 1 day. Her life centered on her therapist, by this time to the exclusion of everyone else. Although her hostility toward her therapist was obvious, she could neither see it nor control it. Her difficulties with her therapist culminated in many episodes of her forearm cutting and suicidal threats, which led to the referral for admission.

## THINKING CRITICALLY about *DSM-5*

### Nonsuicidal Self-Injury: Distinct Disorder or Symptom of Borderline Personality Disorder?

DSM-5

**N**onsuicidal self-injury (NSSI) involves deliberate damage to body tissue such as might occur with skin cutting or burning (Nock, 2009). This behavior (which is sometimes called self-mutilation) occurs in the absence of an intent to die (hence the term nonsuicidal). Self-mutilating behavior has long been listed in the *DSM* as a symptom of BPD. However, many people who engage in self-injury do not have BPD, although they do report high levels of depressive symptoms, anxiety, suicidality, and generally low levels of functioning (Selby et al., 2012). People who engage in NSSI are also at elevated risk for later suicide (Wilkinson et al., 2011). For these reasons, the *DSM-5* task force was charged with determining whether people who display a significant amount of nonsuicidal self-injurious behavior should be diagnosed with a new disorder that would be called “nonsuicidal self-injury disorder”.

NSSI is found in males and females, as well as in people of all ethnicities and economic backgrounds. However, the risk for NSSI seems to be greatest in the adolescent years. One Finnish study reported a 11.5 percent prevalence rate in young people aged 13–18. And an Internet-based study of college students at

two U.S. universities found a lifetime prevalence of 17 percent. Perhaps most shocking were the results from a U.S. study of 10- to 14-year-old girls that found a lifetime prevalence of NSSI of 56 percent (Hilt et al., 2008).

Why do people hurt themselves by cutting or burning? Tension relief is one reason that many people give. NSSI is often used to regulate intense or extreme emotions. Hooley et al. (2010) have also found that people who engage in NSSI tend to have higher pain endurances than the rest of us. In addition, they have a highly self-critical cognitive style and “may regard suffering and pain as something they deserve” (Hooley et al., 2010, p. 170). This may help explain why such people choose to regulate their emotions by engaging in behaviors that are self-damaging and painful.

NSSI is a growing problem. Recognizing this, it has now been added to *DSM-5*. NSSI disorder is listed in Section III, which is used to describe conditions in need of further study. This move is likely to stimulate research. As we learn more we may be in a better position to understand, treat, and perhaps even prevent this increasingly prevalent condition.

In addition to affective and impulsive behavioral symptoms, as many as 75 percent of people with BPD have cognitive symptoms. These include relatively short or transient episodes in which they appear to be out of contact with reality and experience delusions or other psychotic-like symptoms such as hallucinations, paranoid ideas, or severe dissociative symptoms (Lieb et al., 2004; Paris, 2007; Skodol, Gunderson et al., 2002).

Estimates are that only about 1 to 2 percent of the population may qualify for the diagnosis of BPD (Lenzenweger et al., 2007), but they represent about 10 percent of patients in outpatient and 20 percent of patients in inpatient clinical settings (Lieb et al., 2004; Torgersen et al., 2001). Although early research found that approximately 75 percent of individuals receiving this diagnosis in clinical settings are women, such findings likely arise from a gender imbalance in treatment seeking rather than prevalence of the disorder. In support of this, more recent epidemiological studies of community residents suggest an equal gender ratio (Coid et al., 2009; Grant et al., 2008; Hooley et al., 2012).

**COMORBIDITY WITH OTHER DISORDERS** Given the many and varied symptoms of BPD, it is not surprising that this personality disorder produces significant impairment in social, academic, and occupational functioning (Bagge et al., 2004; Grant et al., 2008). BPD commonly co-occurs with a variety of other disorders ranging from unipolar and bipolar mood and anxiety disorders (especially panic and PTSD) to substance-use and eating disorders (Hooley et al., 2012; Pagura et al., 2010). In the past, many clinical researchers hypothesized that BPD had a special relationship with bipolar and recurrent unipolar mood disorders because about 50 percent of those with BPD also qualified for a mood disorder diagnosis at some point (Adams et al., 2001; Paris, 2007). However, other personality disorders (such as dependent, avoidant, and obsessive-compulsive personality disorder) are actually more commonly associated with depression than is BPD. Moreover, recent neuroimaging data indicate that BPD individuals show different neural responses to emotional stimuli than do individuals with chronic depression (Hooley et al., 2010).

There is also substantial co-occurrence of BPD with other personality disorders—especially histrionic, dependent, antisocial, and schizotypal personality disorders. Nevertheless, Widiger and Trull (1993) noted the following differences in prototypic cases of these personality disorders: “The prototypic borderline’s exploitative use of others is usually an angry and impulsive response to disappointment, whereas the antisocial’s is a guiltless and calculated effort for personal gain. Sexuality may play a more central role in the relationships of histrionics than in [those of] borderlines, evident in the histrionic’s tendency to eroticize situations . . . and to be inappropriately seductive. The prototypic schizotypal lacks the emotionality of the borderline, and tends to be more isolated, odd and peculiar” (Widiger & Trull, 1993, p. 371). These differences can also be seen using the five-factor model of personality disorders (refer back to Table 10.2 on p. 335).

**CAUSAL FACTORS** Research suggests that genetic factors play a significant role in the development of BPD (Distel et al., 2009; Livesley, 2008; Skodol, Siever et al., 2002). This heritability may be partly a function of the fact that personality traits of affective instability and impulsivity, which are both very prominent in BPD, are themselves partially heritable (Hooley et al., 2012; Paris, 2007). There is also some preliminary evidence that certain parts of the 5-HTT gene implicated in depression (Chapter 7) may also be associated with BPD (e.g., Lis et al., 2007; Ni et al., 2006). Recent research also suggests a link with other genes involved in regulating dopamine transmission (Hooley et al., 2012).

There has also been an intense search for the biological substrate of BPD. For example, people with BPD often appear to be characterized by lowered functioning of the neurotransmitter serotonin, which is involved in inhibiting behavioral responses. This may be why they show impulsive-aggressive behavior, as in acts of self-mutilation; that is, their serotonergic activity is too low to “put the brakes on” impulsive behavior (e.g., Figueroa & Silk, 1997; Schmahl & Bremner, 2006; Skodol, Siever et al., 2002). Patients with BPD may also show disturbances in the regulation of noradrenergic neurotransmitters that are similar to those seen in chronic stress conditions such as PTSD (see Chapter 5; Hooley, 2008). In particular, their hyperresponsive noradrenergic system may be related to their hypersensitivity to environmental changes (Figueroa & Silk, 1997; Skodol, Siever et al., 2002). Moreover, certain brain areas that ordinarily serve to inhibit aggressive behavior when activated by serotonin (such as the orbital prefrontal and medial prefrontal cortex) seem to show decreased activation in BPD (Skodol, Siever et al., 2002; see also Lieb et al., 2004). In addition, research suggests certain structural brain abnormalities in BPD, including reductions in both hippocampal and amygdalar volume, features associated with aggression and impulsivity (Hooley et al., 2012).

Much theoretical and research attention has also been directed to the role of psychosocial causal factors in BPD. Although the vast majority of this research is retrospective in nature, relying on people’s memories of their past to discover the antecedents of the disorder, two prospective community-based studies have shown that childhood adversity and maltreatment is linked to adult BPD (Johnson et al., 1999; Widom et al., 2009). These studies are consistent with a wealth of retrospective research showing that people with this disorder usually report a large number of negative—even traumatic—events in childhood. These experiences include abuse and neglect, and separation and loss. For example, in one large study on abuse and neglect, Zanarini and colleagues (1997) reported on the results of detailed interviews of over 350 patients with BPD and over 100 patients with other personality disorders. Patients with BPD reported significantly higher rates of abuse than did patients with other personality disorders (which were also quite high): emotional abuse (73 versus 51 percent), physical abuse (59 versus 34 percent), and sexual abuse (61 versus 32 percent). Overall, about 90 percent of patients with BPD reported some type of

childhood abuse or neglect (emotional, physical, or sexual). (See also Bandelow et al., 2005; Battle et al., 2004.) Although these rates of abuse and neglect seem alarming, remember that the majority of children who experience early abuse and neglect do not end up with any serious personality disorders or other psychopathology (see Paris, 1999, 2007; Rutter & Maughan, 1997; see also Chapter 12).

Although this and many other related studies (see Dolan-Sewell et al., 2001; Paris, 2007) suggest that BPD (and perhaps other personality disorders as well) is often associated with early childhood trauma, most such studies have many shortcomings and unfortunately cannot tell us that such early childhood trauma plays a causal role. First, although prospective research to date supports this idea (Johnson et al., 1999; Widom et al., 2009), the majority of evidence comes from retrospective self-reports of individuals who are known for their exaggerated and distorted views of other people (Paris, 1999, 2007; Rutter &

Maughan, 1997). Second, childhood abuse is certainly not a specific risk factor for borderline pathology because it is also reported at relatively high rates with some other personality disorders as well as with other disorders such as dissociative identity disorder (see also Chapter 8; Moran et al., 2010). Third, childhood abuse nearly always occurs in families with various other pathological dynamics, such as marital discord and family violence. These factors may be more important than the abuse in the development of BPD (Paris, 1999, 2007).

Paris (1999, 2007) offered an interesting multidimensional diathesis-stress theory of BPD. He proposes that people who have high levels of two normal personality traits—impulsivity and affective instability—may have a diathesis to develop BPD, but only in the presence of certain psychological risk factors such as trauma, loss, and parental failure (see Figure 10.1, p. 346). When such nonspecific psychological risk factors occur in someone who is affectively unstable, he or she may become dysphoric and labile and, if he or she is also impulsive, may engage in impulsive acting out to cope with this negative mood. Thus the dysphoria and impulsive acts fuel each other. In addition, Paris proposes that children who are impulsive and unstable tend to be “difficult” or troublesome children. They may therefore be at increased risk for being rejected or abused. Moreover, if the parents themselves have personality pathology, they may be especially insensitive to their difficult child, leading to a vicious cycle in which the child’s problems are exacerbated by inadequate parenting, which in turn leads to increased dysphoria, and so on. Paris further suggests that BPD may be more prevalent in our society than in many other cultures, and more prevalent today than in the past, because of the weakening of the family structure in our society.

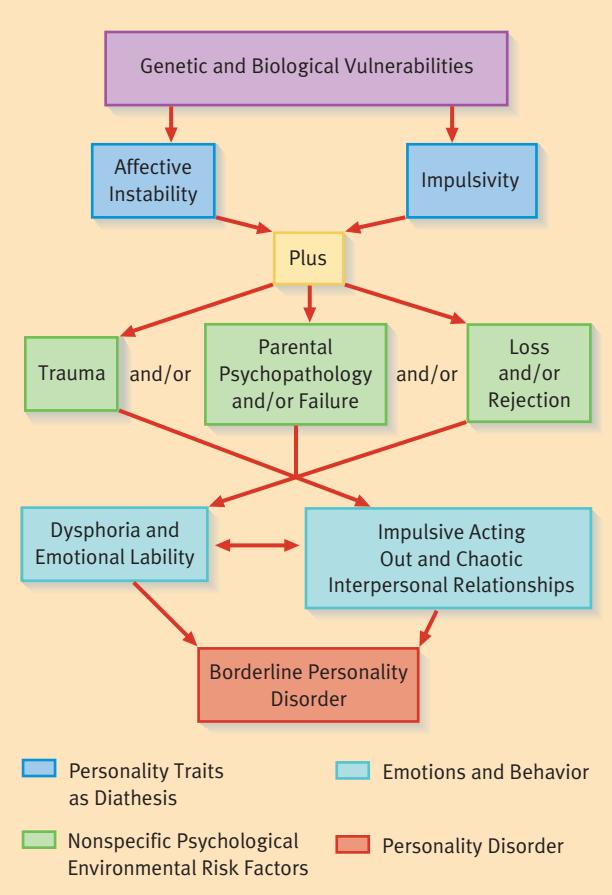

Many studies have shown that people with borderline personality disorder report a large number of negative, even traumatic, events in childhood. These include abuse and neglect, and separation and loss.

## Cluster C Personality Disorders

People with Cluster C personality disorders often show anxiety and fearfulness. These are characteristics that we do not see in the other two clusters. In the following section, we examine avoidant, dependent, and obsessive-compulsive personality disorders.

### Avoidant Personality Disorder

Individuals with **avoidant personality disorder** show extreme social inhibition and introversion, leading to lifelong patterns of limited social relationships and reluctance to enter into social interactions. Because of their hypersensitivity to, and fear of, criticism and rebuff, they do not seek out other people, yet they desire affection and are often lonely and bored. Unlike schizoid personalities, people with avoidant personality disorder do not enjoy their aloneness; their inability to relate comfortably to other people causes acute anxiety and is accompanied by low self-esteem and excessive self-consciousness, which in turn are often associated with depression (Grant, Hasin et al., 2005; Sanislow et al., 2012). Feeling inept and socially inadequate are the two most prevalent and stable features of avoidant personality disorder (McGlashan et al., 2005).

**FIGURE 10.1**

*Multidimensional Diathesis-Stress Theory of Borderline Personality Disorder.*  
Source: Paris (1999).

In addition, researchers have documented that individuals with this disorder also show more generalized timidity and avoidance of many novel situations and emotions (including positive emotions), and show deficits in their ability to experience pleasure as well (Taylor et al., 2004).

→ **The Avoidant Librarian** Sally, a 35-year-old librarian, lived a relatively isolated life and had few acquaintances and no close personal friends. From childhood on, she had been very shy and had withdrawn from close ties with others to keep from being hurt or criticized. Two years before she entered therapy, she had had a date to go to a party with an acquaintance she had met at the library. The moment they had arrived at the party, Sally had felt extremely uncomfortable because she had not been "dressed properly." She left in a hurry and refused to see her acquaintance again.

In the early treatment sessions, she sat silently much of the time, finding it too difficult to talk about herself. After several sessions, she grew to trust the therapist, and she related numerous incidents in her early years in which she had been "devastated" by her alcoholic father's obnoxious behavior in public. Although she had tried to keep her school friends from knowing about her family problems, when this had become impossible, she instead had limited her friendships, thus protecting herself from possible embarrassment or criticism.

When Sally first began therapy, she avoided meeting people unless she could be assured that they would "like her." With therapy that focused on enhancing her assertiveness and social skills, she made some progress in her ability to approach people and talk with them.

The key difference between the loner with schizoid personality disorder and the loner who is avoidant is that the latter is shy, insecure, and hypersensitive to criticism, whereas someone with a schizoid personality is more aloof, cold, and relatively indifferent to criticism (Millon & Martinez, 1995). The person with avoidant personality also desires interpersonal contact but avoids it for fear of rejection, whereas in schizoid personality disorder there is a lack of desire or ability to form social relationships. A less clear distinction is that between avoidant personality disorder and generalized social phobia (Chapter 6). Numerous studies have

### criteria for Avoidant Personality Disorder

DSM-5

A pervasive pattern of social inhibition, feelings of inadequacy, and hypersensitivity to negative evaluation, beginning by early adulthood and present in a variety of contexts, as indicated by four (or more) of the following:

1. Avoids occupational activities that involve significant interpersonal contact because of fears of criticism, disapproval, or rejection.
2. Is unwilling to get involved with people unless certain of being liked.
3. Shows restraint within intimate relationships because of the fear of being shamed or ridiculed.

4. Is preoccupied with being criticized or rejected in social situations.
5. Is inhibited in new interpersonal situations because of feelings of inadequacy.
6. Views self as socially inept, personally unappealing, or inferior to others.
7. Is unusually reluctant to take personal risks or to engage in any new activities because they may prove embarrassing.

Source: Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, (Copyright © 2013). American Psychiatric Association.

The person with avoidant personality desires social contact but avoids it because of a fear of rejection.

found substantial overlap between these two disorders, leading some investigators to conclude that avoidant personality disorder may simply be a somewhat more severe manifestation of generalized social phobia (Alpert et al., 1997; Carter & Wu, 2010; Tillfors et al., 2004) that does not warrant a separate diagnosis (Chambless et al., 2008). This is consistent with the finding that there are cases of generalized social phobia without avoidant personality disorder but very few cases of avoidant personality disorder without generalized social phobia. Somewhat higher levels of dysfunction and distress are also found in the individuals with avoidant personality disorder, including more consistent feelings of low self-esteem (Millon & Martinez, 1995; Hummelen et al., 2007; Tillfors et al., 2004).

**CAUSAL FACTORS** Some research suggests that avoidant personality may have its origins in an innate “inhibited” temperament that leaves the infant and child shy and inhibited in novel and ambiguous situations. A large twin study in Norway has shown that traits prominent in avoidant personality disorder show a modest genetic influence (Reichborn-Kjennerud et al., 2006), and that the genetic vulnerability for avoidant personality disorder is at least partially shared with that for social phobia (Reichborn-Kjennerud et al., 2007). Moreover, there is also evidence that the fear of being negatively evaluated, which is prominent in avoidant personality disorder, is moderately heritable (Stein et al., 2002); introversion and neuroticism are also both elevated (refer back to Table 10.2 on p. 335), and they too are moderately heritable. This genetically and biologically based inhibited temperament may often serve as the diathesis that leads to avoidant personality disorder in some children who experience emotional abuse, rejection, or humiliation from parents who are not particularly affectionate (Alden et al., 2002; Bernstein & Travaglini, 1999; Kagan, 1997). Such abuse and rejection would be especially likely to lead to anxious and fearful attachment patterns in temperamentally inhibited children (Bartholomew et al., 2001).

## Dependent Personality Disorder

Individuals with **dependent personality disorder** show an extreme need to be taken care of, which leads to clinging and submissive behavior. They also show acute fear at the possibility of separation or sometimes of simply having to be alone because they see themselves as inept (Bornstein, 2007, 2012; Widiger & Bornstein, 2001). These individuals usually build their lives around other people and subordinate their own needs and views to keep these people involved with them. Accordingly, they may be indiscriminate in their selection of mates. They often fail to get appropriately angry with others because of a fear of losing their support, which means that people with dependent personalities may remain in psychologically or physically abusive relationships. They have great difficulty making even simple, everyday decisions without a great deal of advice and reassurance because they lack self-confidence and feel helpless even when they have actually developed good work skills or other competencies. They may function well as long as they are not required to be on their own.

→ **The Dependent Wife** Sarah, a 32-year-old mother of two and a part-time tax accountant, came to a crisis center late one evening after Michael, her husband of a year and a half, had abused her physically and then left home. Although he never physically harmed the children, he frequently threatened to do so when he was drunk. Sarah appeared acutely anxious and worried about the future and “needed to be told what to do.” She wanted her husband to come back and seemed rather unconcerned about his regular pattern of physical abuse. At the time, Michael was an unemployed resident in a day treatment program at a halfway house for paroled drug abusers. He was almost always in a surly mood and “ready to explode.”

Although Sarah had a well-paying job, she voiced great concern about being able to make it on her own. She realized that it was foolish to be “dependent” on her husband, whom she referred to as a “real loser.” (She had had a similar relationship with her first husband, who had left her and her oldest child when she was 18.) Several times in the past few months, Sarah had made up her mind to get out of the marriage but couldn’t bring herself to break away. She would threaten to leave, but when the time came to do so, she would “freeze in the door” with a numbness in her body and a sinking feeling in her stomach at the thought of “not being with Michael.”

Estimates are that dependent personality disorder occurs in 1 to 2 percent of the population and is more common in women than in men (Bornstein, 2012). This gender difference is not due to a sex bias in making the diagnosis but rather to the higher prevalence in women of certain personality traits such as neuroticism and agreeableness, which are prominent in dependent personality disorder (Lynam & Widiger, 2007). It is quite common

for people with dependent personality disorder to have a comorbid diagnosis of mood and anxiety disorders (Bornstein, 1999; Grant, Hasin et al., 2005), as well as eating disorders (Bornstein, 2012).

Some features of dependent personality disorder overlap with those of borderline, histrionic, and avoidant personality disorders, but there are differences as well (refer back to Table 10.2 on p. 335). For example, both borderline personalities and dependent personalities fear abandonment. However, the borderline personality, who usually has intense and stormy relationships, reacts with feelings of emptiness or rage if abandonment occurs, whereas the dependent personality reacts initially with submissiveness and appeasement and then finally with an urgent seeking of a new relationship. Histrionic and dependent personalities both have strong needs for reassurance and approval, but the histrionic personality is much more gregarious, flamboyant, and actively demanding of attention, whereas the dependent personality is more docile and self-effacing. It can also be hard to distinguish between dependent and avoidant personalities. As noted, dependent personalities have great difficulty separating in relationships because they feel incompetent on their own and have a need to be taken care of, whereas avoidant personalities have trouble initiating relationships because they fear criticism or rejection, which will be humiliating (Millon & Martinez, 1995). Even so, we should remember that avoidant personality occurs with dependent personality disorder rather frequently (Alden et al., 2002; Arntz et al., 2009; Bernstein & Travaglini, 1999; Bornstein, 2011). This fits with the observation that people with avoidant personality disorder do not avoid absolutely everyone and that their dependent personality disorder characteristics are focused on the one or few individuals whom they do not avoid (Alden et al., 2002). In terms of the five-factor model,

dependent personality disorder is associated with high levels of neuroticism and agreeableness (Lowe et al., 2009).

**CAUSAL FACTORS** Some evidence indicates that there is a modest genetic influence on dependent personality traits (Bornstein, 2011, 2012; Reichborn-Kjennerud et al., 2006). Moreover, several other personality traits such as neuroticism and agreeableness that are also prominent in dependent personality disorder also have a genetic component (Widiger & Bornstein, 2001). It is possible that people with these partially genetically based predispositions to dependence and anxiousness may be especially prone to the adverse effects of parents who are authoritarian and overprotective (not promoting autonomy and individuation in their child but instead reinforcing dependent behavior). This might lead children to believe that they are reliant on others for their own well-being and are incompetent on their own (Widiger & Bornstein, 2001). Cognitive theorists describe the underlying maladaptive schemas for these individuals as involving core beliefs about weakness and competence and needing others to survive (P. S. Rasmussen, 2005), such as, “I am completely helpless” and “I can function only if I have access to somebody competent” (Beck et al., 1990, p. 60; Beck et al., 2003). Recent experimental evidence supports the hypothesis that these beliefs characterize those with dependent personality disorder (Arntz et al., 2011).

### **Obsessive-Compulsive Personality Disorder**

Perfectionism and an excessive concern with maintaining order and control characterize individuals with **obsessive-compulsive personality disorder (OCPD)**. Their preoccupation with maintaining mental and interpersonal control occurs in part through careful attention to rules, order, and schedules. They are very

#### **criteria for Dependent Personality Disorder**

A pervasive and excessive need to be taken care of that leads to submissive and clinging behavior and fears of separation, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:

1. Has difficulty making everyday decisions without an excessive amount of advice and reassurance from others.
2. Needs others to assume responsibility for most major areas of his or her life.
3. Has difficulty expressing disagreement with others because of fear of loss of support or approval. (**Note:** Do not include realistic fears of retribution.)
4. Has difficulty initiating projects or doing things on his or her own (because of a lack of self-confidence in judgment or abilities rather than a lack of motivation or energy).

**DSM-5**

5. Goes to excessive lengths to obtain nurturance and support from others, to the point of volunteering to do things that are unpleasant.
6. Feels uncomfortable or helpless when alone because of exaggerated fears of being unable to care for himself or herself.
7. Urgently seeks another relationship as a source of care and support when a close relationship ends.
8. Is unrealistically preoccupied with fears of being left to take care of himself or herself.

Source: Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, (Copyright © 2013). American Psychiatric Association.

Individuals with obsessive-compulsive personality disorder are highly perfectionistic, leading to serious problems finishing various projects. They are also excessively devoted to work, inflexible about moral and ethical issues, and have difficulty delegating tasks to others. They are also inclined to be ungenerous with themselves and others.

careful in what they do so as not to make mistakes, but because the details they are preoccupied with are often trivial they use their time poorly and have a difficult time seeing the larger picture (Aycicegi-Dinn et al., 2009; Yovel et al., 2005). This perfectionism is also often quite dysfunctional in that it can result in their never finishing projects. They also tend to be devoted to work to the exclusion of leisure activities and may have difficulty relaxing or doing anything just for fun (Widiger & Frances,

1994). At an interpersonal level, they have difficulty delegating tasks to others and are quite rigid, stubborn, and cold, which is how others tend to view them. Research indicates that rigidity, stubbornness, and perfectionism, as well as reluctance to delegate, are the most prevalent and stable features of OCPD (Ansell et al., 2008; Grilo et al., 2004; McGlashan et al., 2005; Samuel & Widiger, 2011).

It is important to note that people with OCPD do not have true obsessions or compulsive rituals that are the source of extreme anxiety or distress in people with obsessive-compulsive disorder (OCD; see Chapter 6). Instead, people with OCPD have lifestyles characterized by overconscientiousness, high neuroticism, inflexibility, and perfectionism but without the presence of true obsessions or compulsive rituals (Samuels & Costa, 2012). Indeed, only about 20 percent of patients with OCD have a comorbid diagnosis of OCPD. This is not significantly different from the rate of OCPD in patients with panic disorder (Albert et al., 2004). People with OCD are more likely to be diagnosed with avoidant or dependent personality disorder than with OCPD (Wu et al., 2006), and there are only three symptoms of OCPD that seem to occur at elevated rates in people with OCD relative to controls: perfectionism, preoccupation with details, and hoarding (Eisen et al., 2006).

→ **The Perfectionist Train Dispatcher** Alan appeared to be well suited to his work as a train dispatcher. He was conscientious, perfectionistic, and attended to minute details. However, he was not close to his coworkers, and they reportedly thought him "off." He would get quite upset if even minor variations to his daily routine occurred. For example, he would become tense and irritable if coworkers did not follow exactly his elaborately constructed schedules and plans.

### criteria for Obsessive-Compulsive Personality Disorder

A pervasive pattern of preoccupation with orderliness, perfectionism, and mental and interpersonal control, at the expense of flexibility, openness, and efficiency, beginning by early adulthood and present in a variety of contexts, as indicated by four (or more) of the following:

1. Is preoccupied with details, rules, lists, order, organization, or schedules to the extent that the major point of the activity is lost.
2. Shows perfectionism that interferes with task completion (e.g., is unable to complete a project because his or her own overly strict standards are not met).
3. Is excessively devoted to work and productivity to the exclusion of leisure activities and friendships (not accounted for by obvious economic necessity).

4. Is overconscientious, scrupulous, and inflexible about matters of morality, ethics, or values (not accounted for by cultural or religious identification).
5. Is unable to discard worn-out or worthless objects even when they have no sentimental value.
6. Is reluctant to delegate tasks or to work with others unless they submit to exactly his or her way of doing things.
7. Adopts a miserly spending style toward both self and others; money is viewed as something to be hoarded for future catastrophes.
8. Shows rigidity and stubbornness.

Source: Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, (Copyright © 2013). American Psychiatric Association.

DSM-5

In short, Alan got little pleasure out of life and worried constantly about minor problems. His rigid routines were impossible to maintain, and he often developed tension headaches or stomachaches when he couldn't keep his complicated plans in order. His physician, noting the frequency of his physical complaints and his generally perfectionistic approach to life, referred him for a psychological evaluation. Psychotherapy was recommended, but he did not follow up on the treatment recommendations because he felt that he could not afford the time away from work.

Some features of OCPD overlap with some features of narcissistic, antisocial, and schizoid personality disorders, although there are also distinguishing features. For example, individuals with narcissistic and ASPDs may share the lack of generosity toward others that characterizes OCPD, but the former tend to indulge themselves, whereas those with OCPD are equally unwilling to be generous with themselves. In addition, both the schizoid and the obsessive-compulsive personalities may have a certain amount of formality and social detachment, but only the schizoid personality lacks the capacity for close relationships. The person with OCPD has difficulty in interpersonal relationships because of excessive devotion to work and great difficulty expressing emotions.

**CAUSAL FACTORS** Theorists who take a five-factor dimensional approach to understanding OCPD note that these individuals have excessively high levels of conscientiousness (Samuel & Widiger, 2011). This leads to extreme devotion to work, perfectionism, and excessive controlling behavior (McCann, 1999). They are also high on assertiveness (a facet of extraversion) and low on compliance (a facet of agreeableness). (Refer back to Table 10.2 on p. 335.) Another influential biological dimensional approach—that of Cloninger (1987)—posits three primary dimensions of personality: novelty seeking, reward dependence, and harm avoidance. Individuals with obsessive-compulsive personalities have low levels of novelty seeking (i.e., they avoid change) and reward dependence (i.e., they work excessively at the expense of pleasurable pursuits) but high levels of harm avoidance (i.e., they respond strongly to aversive stimuli and try to avoid them). Recent research has also demonstrated that the OCPD traits show a modest genetic influence (Calvo et al., 2009; Reichborn-Kjennerud et al., 2006).

## General Sociocultural Causal Factors for Personality Disorders

The sociocultural factors that contribute to personality disorders are not well understood. As with other forms of psychopathology, the incidence and particular features of personality disorders vary somewhat with time and place, although not as much as one might guess (Allik, 2005; Rigozzi et al., 2009). Indeed, there is less variance across cultures than within cultures. This may be related to findings that all cultures (both Western and

non-Western, including Africa and Asia) share the same five basic personality traits discussed earlier, and their patterns of covariation also seem universal (see Allik, 2005, for a review).

Some researchers believe that certain personality disorders have increased in American society in recent years (e.g., Paris, 2001). If this claim is true, we can expect to find the increase related to changes in our culture's general priorities and activities. Is our emphasis on impulse gratification, instant solutions, and pain-free benefits leading more people to develop the self-centered lifestyles that we see in more extreme forms of the personality disorders? For example, there is some evidence that narcissistic personality disorder is more common in Western cultures, where personal ambition and success are encouraged and reinforced (e.g., Widiger & Bornstein, 2001). There is also some evidence that histrionic personality might be expected to be (and is) less common in Asian cultures, where sexual seductiveness and drawing attention to oneself are frowned on; by contrast, it may be higher in Hispanic cultures, where such tendencies are common and well tolerated (e.g., Bornstein, 1999). Within the United States, rates of BPD are higher in Hispanic Americans than in African Americans and Caucasians, but rates of schizotypal personality disorder are higher in African Americans than in Caucasians (Chavira et al., 2003).

It has also been suggested that known increases over the 60 years since World War II in emotional dysregulation (e.g., depression, self-injurious behavior, and suicide) and impulsive behaviors (substance abuse and criminal behavior) may be related to increases in the prevalence of borderline and ASPDs over the same time period. This could stem from increased breakdown of the family and other traditional social structures (Paris, 2001, 2007) and may vary across cultures depending on whether similar breakdowns have occurred.

### in review

- What are the general characteristics of the three clusters of personality disorders?
- Describe and differentiate among the following Cluster A personality disorders: paranoid, schizoid, and schizotypal.
- Describe and differentiate among the following Cluster B personality disorders: histrionic, narcissistic, antisocial, and borderline.
- Describe and differentiate among the following Cluster C personality disorders: avoidant, dependent, and obsessive-compulsive.

## Treatments and Outcomes for Personality Disorders

Personality disorders are generally very difficult to treat, in part because they are, by definition, relatively enduring, pervasive, and inflexible patterns of behavior and inner experience. Moreover, many different goals of treatment can be formulated, and some are more difficult to achieve than others. Goals might

include reducing subjective distress, changing specific dysfunctional behaviors, and changing whole patterns of behavior or the entire structure of the personality.

In many cases, people with personality disorders enter treatment only at someone else's insistence, and they often do not believe that they need to change. Moreover, those from the odd/eccentric Cluster A and the erratic/dramatic Cluster B have general difficulties in forming and maintaining good relationships, including with a therapist. For those from the erratic/dramatic Cluster B, the pattern of acting out typical in their other relationships is carried into the therapy situation, and instead of dealing with their problems at the verbal level they may become angry at their therapist and loudly disrupt the sessions. Non-completion of treatment is a particular problem in the treatment of personality disorders; a recent review of the research reported that an average of 37 percent of personality disorder patients drop out of therapy prematurely (McMurran et al., 2010).

In addition, people who have a personality disorder in addition to another disorder (such as depression or an eating disorder) do not, on average, do as well in treatment for their other disorder as do patients without comorbid personality disorders (Crits-Christoph & Barber, 2002, 2007; Pilkonis, 2001). This is partly because people with personality disorders have rigid, ingrained personality traits that often lead to poor therapeutic relationships and additionally make them resist doing the things that would help improve their other conditions.

### Adapting Therapeutic Techniques to Specific Personality Disorders

Therapeutic techniques must often be modified. For example, recognizing that traditional individual psychotherapy tends to encourage dependence in people who are already too dependent (as in dependent, histrionic, and BPDs), it is often useful to develop treatment strategies specifically aimed at altering these traits. Patients from the anxious/fearful Cluster C, such as those with dependent and avoidant personalities, may also be hypersensitive to any criticism they may perceive from the therapist, so therapists need to be extremely careful to make sure that they do not come across in this way.

For people with severe personality disorders, therapy may be more effective in situations where acting-out behavior can be constrained. For example, many patients with BPD are hospitalized at times, for safety reasons, because of their frequent suicidal behavior. However, partial-hospitalization programs are increasingly being used as an intermediate and less expensive alternative to inpatient treatment (Azim, 2001). In these programs, patients live at home and receive extensive group treatment and rehabilitation only during weekdays. Several studies conducted in the Netherlands suggest that short-term inpatient treatment is more effective than outpatient treatment in both Cluster B and Cluster C personality disorders (Bartak et al., 2010, 2011).

Specific therapeutic techniques are a central part of the relatively new cognitive approach to personality disorders that

assumes that the dysfunctional feelings and behavior associated with the personality disorders are largely the result of schemas that tend to produce consistently biased judgments, as well as tendencies to make cognitive errors (e.g., Beck et al., 2003; Cottraux & Blackburn, 2001; Leahy & McGinn, 2012; Pretzer & Beck, 2005). Changing these underlying dysfunctional schemas is difficult but is at the heart of cognitive therapy for personality disorders. Such an approach uses standard cognitive techniques of monitoring automatic thoughts, challenging faulty logic, and assigning behavioral tasks in an effort to challenge the patient's dysfunctional beliefs.

### Treating Borderline Personality Disorder

Of all personality disorders, most clinical and research attention has been paid to the treatment of BPD. This is due to the severity of this disorder and the high risk of suicide that is associated with it. Treatment often involves both psychological and biological treatment approaches, with medications being used as an adjunct to psychological treatment, which is considered essential.

**BIOLOGICAL TREATMENTS** The use of medications is controversial with this disorder because it is so frequently associated with suicidal behavior. Today, antidepressant medications (most often from the SSRI category) are considered most safe and useful for treating rapid mood shifts, anger, and anxiety (Lieb et al., 2004), as well as for impulsivity symptoms including impulsive aggression such as self-mutilation (Koenigsberg et al., 2002, 2007; Markowitz, 2004; Silk & Fuerino, 2012). In addition, low doses of antipsychotic medication (see Chapters 13 and 16) have modest effects that are broad based; that is, patients show some improvement in depression, anxiety, suicidality, impulsive aggression, rejection sensitivity, and especially transient psychotic symptoms and cognitive and perceptual distortions (Koenigsberg et al., 2007; Markowitz, 2001, 2004; Silk & Fuerino, 2012). Finally, mood-stabilizing medications such as carbamazepine may be useful in reducing irritability, suicidality, affective instability and impulsive aggressive behavior (Koenigsberg et al., 2007; Lieb et al., 2004). However, the consensus to date is that drugs are only mildly beneficial for BPD (Paris, 2009).

**PSYCHOSOCIAL TREATMENTS** Clinical trials suggest that several types of psychotherapy may be effective for BPD. As discussed below, however, these treatments share two common weaknesses. These are their relative complexity and long duration, both of which makes them difficult to disseminate to the broader population (Paris, 2009).

**Dialectical behavior therapy**, developed by Marsha Linehan, is a unique kind of cognitive and behavioral therapy specifically adapted for BPD (Linehan, 1993; Linehan & Dexter-Mazza, 2008; Lynch & Cuper, 2012; Robins et al., 2001). Linehan believes that patients' inability to tolerate strong states of negative affect is central to this disorder. One of the primary goals of treatment is to encourage patients to accept

this negative affect without engaging in self-destructive or other maladaptive behaviors. Accordingly, Linehan has developed a problem-focused treatment based on a clear hierarchy of goals, which prioritizes decreasing suicidal and self-harming behavior and increasing coping skills. The therapy combines individual and group components as well as phone coaching. In the group setting, patients learn interpersonal effectiveness, emotion regulation, and distress tolerance skills. The individual therapist, in turn, uses therapy sessions and phone coaching to help the patient identify and change problematic behavior patterns and apply newly learned skills effectively.

Dialectical behavior therapy (DBT) appears to be an efficacious treatment for BPD (Binks et al., 2006; Paris, 2009). However, there are still not enough randomized controlled trials to say whether it works as well in men as in women, and whether it works well with minority patients (Lynch & Cuper, 2012). Patients receiving DBT show reductions in self-destructive and suicidal behaviors as well as in levels of anger (Linehan et al., 2006; Lynch et al., 2007). Evidence also suggests that these gains are sustainable (Zanarini et al., 2005). Such results are considered extraordinary by most therapists who work with this population, and many psychodynamic therapists are now incorporating important components of this treatment into their own treatment. However, DBT is still not in widespread use, likely because the treatment is complex and lasts several years (Paris, 2009). Accordingly, some researchers are currently working on developing briefer versions of the treatment (Stanley et al., 2007).

Other psychosocial treatments for BPD involve variants of psychodynamic psychotherapy adapted for the particular problems of people with this disorder. For example, Kernberg (1985, 1996) and colleagues (Koenigsberg et al., 2000; see also Clarkin et al., 2004) have developed a form of psychodynamic psychotherapy that is much more directive than is typical of psychodynamic treatment. The primary goal is seen as strengthening the weak egos of these individuals, with a particular focus on their primary primitive defense mechanism of splitting. This leads them to black-and-white, all-or-none thinking, as well as to rapid shifts in their reactions to themselves and to other people (including the therapist) as "all good" or "all bad." One major goal is to help patients see the shades of gray between these extremes and integrate positive and negative views of themselves and others into more nuanced views. Although this treatment is often expensive and time-consuming (often lasting a number of years), it has been shown in at least one study to be as effective as DBT, which is now regarded as the most established, effective treatment (Clarkin et al., 2007). Such results will, however, need to be replicated in other treatment centers before we can place a great deal of confidence in its usefulness (Clarkin et al., 2004; Crits-Christoph & Barber, 2002, 2007).

Finally, we note that there is one other promising treatment approach that deserves mention. Bateman and Fonagy have developed a new therapeutic approach called mentalization (see Bateman & Fonagy, 2010). This uses the therapeutic relationship to

help patients develop the skills they need to accurately understand their own feelings and emotions, as well as the feelings and emotions of others. Randomized controlled trials of mentalization-based therapy have revealed it to be an efficacious treatment for BPD. Moreover, many clinical improvements seem to be maintained even after an 8-year follow-up (Bateman & Fonagy, 2008). Although DBT is still a very popular treatment, it is encouraging that people with BPD now have other treatment options available to them.

## Treating Other Personality Disorders

Treatment of Cluster A and other Cluster B personality disorders is not, so far, as promising as some of the recent advances that have been made in the treatment of BPD. In schizotypal personality disorder, low doses of antipsychotic drugs (including the newer, atypical antipsychotics; e.g., Keshavan et al., 2004; Koenigsberg et al., 2007; Raine, 2006) may result in modest improvements. Antidepressants from the SSRI category may also be useful. However, no treatment has yet produced anything approaching a cure for most people with this disorder (Koenigsberg et al., 2002, 2007; Markovitz, 2001, 2004; Silk & Ferino, 2012). Other than uncontrolled studies or single cases, no systematic, controlled studies of treating people with either medication or psychotherapy yet exist for paranoid, schizoid, narcissistic, or histrionic disorder (Beck et al., 2003; Crits-Christoph & Barber, 2007). One reason for this is that these people (because of the nature of their personality pathology) rarely seek treatment.

Although not extensively studied, treatment of some Cluster C disorders, such as dependent and avoidant personality disorder, appears somewhat more promising. Winston and colleagues (1994) found significant improvement in patients with Cluster C disorders using a form of short-term psychotherapy that is active and confrontational (see also Pretzer & Beck, 1996). Several studies using cognitive-behavioral treatment with avoidant personality disorder have also reported significant gains (see Crits-Christoph & Barber, 2007), and a recent meta-analysis concluded both cognitive-behavioral and psychodynamic therapies resulted in significant and lasting treatment gains (Simon, 2009). Another study in the Netherlands concluded that short-term inpatient treatment for Cluster C personality disorders is even more effective than long-term inpatient or outpatient therapy (Bartak et al., 2011). Antidepressants from the MAOI and SSRI categories may also sometimes help in the treatment of avoidant personality disorder, just as they do in closely related social phobia (Koenigsberg et al., 2007; Markovitz, 2001).

### in review

- Why are personality disorders especially resistant to therapy?
- Under what circumstances do individuals with personality disorders generally get involved in psychotherapy?
- What is known about the effectiveness of treatments for borderline personality disorder?

- A. A pervasive pattern of disregard for and violation of the rights of others, occurring since age 15 years, as indicated by three (or more) of the following:
1. Failure to conform to social norms with respect to lawful behaviors, as indicated by repeatedly performing acts that are grounds for arrest.
  2. Deceitfulness, as indicated by repeated lying, use of aliases, or conning others for personal profit or pleasure.
  3. Impulsivity or failure to plan ahead.
  4. Irritability and aggressiveness, as indicated by repeated physical fights or assaults.
  5. Reckless disregard for safety of self or others.

6. Consistent irresponsibility, as indicated by repeated failure to sustain consistent work behavior or honor financial obligations.
  7. Lack of remorse, as indicated by being indifferent to or rationalizing having hurt, mistreated, or stolen from another.
- B. The individual is at least age 18 years.
- C. There is evidence of conduct disorder with onset before age 15 years.
- D. The occurrence of antisocial behavior is not exclusively during the course of schizophrenia or bipolar disorder.

## Antisocial Personality Disorder and Psychopathy

The outstanding characteristic of people with **antisocial personality disorder (ASPD)** is their tendency to persistently disregard and violate the rights of others. They do this through a combination of deceitful, aggressive, and antisocial behaviors. These people have a lifelong pattern of unsocialized and irresponsible behavior with little regard for safety—either their own or that of others. These characteristics bring them into repeated conflict with society, and a high proportion become incarcerated. Only individuals 18 or over are diagnosed with ASPD. According to the *DSM*, this diagnosis is made if, after age 15, the person repeatedly performs acts that are grounds for arrest; shows repeated deceitfulness, impulsivity, irritability, and aggressiveness; shows disregard for safety; and shows consistent irresponsibility in work or financial matters. Moreover, the person must also have shown symptoms of conduct disorder before age 15 (see Chapter 15).

## Psychopathy and Antisocial Personality Disorder

The use of the term antisocial personality disorder dates back only to 1980 when personality disorders first entered *DSM-III*. However, many of the central features of this disorder have long been labeled **psychopathy** or sociopathy. Although several investigators identified the syndrome in the nineteenth century using such terms as “moral insanity” (Prichard, 1835), the most comprehensive early description of psychopathy was made by Cleckley (1941, 1982) in the 1940s. In addition to the defining features noted in the *DSM* criteria, psychopathy also includes such affective and interpersonal traits as lack of empathy, inflated and arrogant self-appraisal, and glib and superficial charm (see Patrick, 2006, for an analysis of Cleckley’s work in

light of contemporary research). With their strong emphasis on behavioral criteria that can be measured reasonably objectively, the features included in the *DSM* do not fully map onto the construct of psychopathy as originally described. This was done deliberately in an attempt to increase the reliability of the diagnosis (i.e., the level of agreement of clinicians on the diagnosis). However, much less attention has been paid to the validity of the ASPD diagnosis—that is, whether it measures a meaningful construct and whether that construct is the same as psychopathy.

According to some estimates, the prevalence of ASPD in the general population is about 3 percent for males and about 1 percent for females but other studies have reported that the preponderance of men is even greater such as 5 to 1 (Hare et al., 2012). However, a recent, very large epidemiological study has shown that the real prevalence may be as low as 1 percent (Lenzenweger et al., 2007). There are no epidemiological studies estimating the prevalence of psychopathy, but Hare et al., (1999) estimated it is likely to be about 1 percent in North America.

**TWO DIMENSIONS OF PSYCHOPATHY** Research suggests that ASPD and psychopathy are related but differ in significant ways. Robert Hare (1980, 1991, 2003) developed a 20-item Psychopathy Checklist-Revised (PCL-R) as a way for clinicians and researchers to diagnose psychopathy on the basis of the Cleckley criteria following an extensive interview and careful checking of past school, police, and prison records. Extensive research with this checklist has shown that there are two related but separable dimensions of psychopathy, each predicting different types of behavior:

1. The first dimension involves the affective and interpersonal core of the disorder and reflects traits such as lack of remorse or guilt, callousness/lack of empathy, glibness/superficial charm, grandiose sense of self-worth, and pathological lying.

- The first dimension reflects behavior—the aspects of psychopathy that involve antisocial or impulsive acts, social deviance, as well as a need for stimulation, poor behavior controls, irresponsibility, and a parasitic lifestyle.

The second dimension is much more closely related than the first to the *DSM* diagnosis of ASPD (Hare et al., 1999; Widiger, 2006). Not surprisingly, therefore, when comparisons have been made in prison settings to determine what percentage of prison inmates qualify for a diagnosis of psychopathy versus ASPD, it is typically found that about 70 to 80 percent qualify for a diagnosis of ASPD but that only about 25 to 30 percent meet the criteria for psychopathy (Patrick, 2005). Put somewhat differently, only about half of imprisoned individuals diagnosed with ASPD also meet the criteria for psychopathy, but most imprisoned individuals with a diagnosis of psychopathy also meet the criteria for ASPD (Widiger, 2006). That is, a significant number of inmates show the antisocial and aggressive behaviors necessary for a diagnosis of ASPD but do not show enough selfish, callous, and exploitative behaviors to qualify for a diagnosis of psychopathy (Hare et al., 1999).

The issues surrounding these diagnoses remain highly controversial. There was considerable discussion by the *DSM-5* task force about expanding the *DSM-IV* criteria for ASPD to include more of the traditional affective and interpersonal features of psychopathy. However, in the end no official changes were made. An alternative approach to the diagnosis of ASPD appears in Section III of the *DSM-5* manual and is considered to be in need of further study. Many researchers continue to use the Cleckley/Hare psychopathy diagnosis rather than the *DSM* ASPD diagnosis, not only because of the long and rich research tradition on psychopathy but also because the psychopathy diagnosis has been shown to be a better predictor of a variety of important facets of criminal behavior than the ASPD diagnosis (Hare et al., 2012). Overall, a diagnosis of psychopathy appears to be the single best predictor of violence and recidivism (offending again after imprisonment; Douglas et al., 2006; Gretton et al., 2004; Hart, 1998). For example, one review estimated that people with psychopathy are three times more likely to reoffend and four times more likely to reoffend violently following prison terms than are people without a psychopathy diagnosis (Hemphill et al., 1998). Moreover, as illustrated in Figure 10.2, adolescents with higher psychopathy scores are not only more likely to show violent reoffending but are also more likely to reoffend more quickly (Gretton et al., 2004).

An additional concern about the current conceptualization of ASPD is that it fails to include people who show many of the features of the first, affective and interpersonal dimension of psychopathy but not as many features of the second, antisocial dimension, or at least few enough that these individuals do not generally get into trouble with the law. Cleckley did not believe that aggressive behavior was central to the concept of psychopathy (Patrick, 2006). This group might include, for example, unprincipled and predatory business or financial professionals, manipulative lawyers, high-pressure evangelists, and crooked

politicians (Hall & Benning, 2006; Hare et al., 1999). Unfortunately, because they are difficult to find to study, little research has been conducted on psychopathic people who manage to stay out of correctional institutions. To locate these people, one researcher (Widom, 1977) who wanted to study them ran an ingenious ad in local newspapers:

*Are you adventurous? Psychologist studying adventurous, care-free people who've led exciting, impulsive lives. If you're the kind of person who'd do almost anything for a dare and want to participate in a paid experiment, send name, address, phone, and short biography proving how interesting you are to . . . (p. 675)*

When those who responded were given a battery of tests, they turned out to be similar in personality makeup to that of institutionalized psychopaths. Several further studies on people with noncriminal psychopathy confirmed this finding (Hall & Benning, 2006; Hare et al., 1999). However, some experimental research that we will discuss later suggests that these two groups may also differ biologically in some significant ways (Ishikawa et al., 2001).

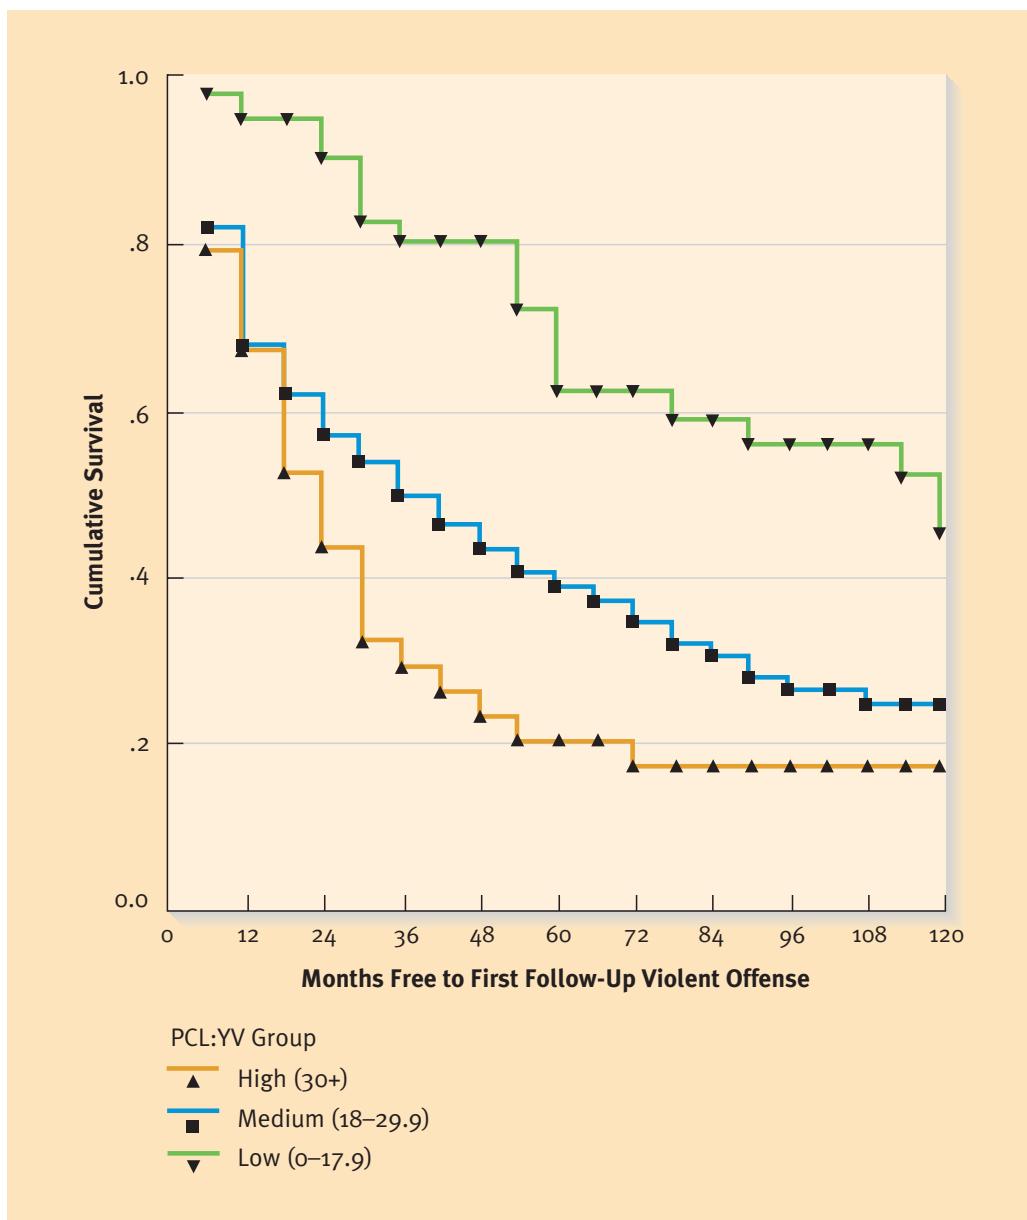

These controversies over the use of a diagnosis of psychopathy versus ASPD are not likely to be resolved soon. Different researchers in this area make different choices, so interpreting the research on causal factors can be difficult. Because the causal factors are almost certainly not identical, we make every effort to make it clear which diagnostic category was used in different studies.

## The Clinical Picture in Psychopathy and Antisocial Personality Disorder

Often charming, spontaneous, and likable on first acquaintance, psychopaths are deceitful and manipulative, callously using others to achieve their own ends. Many of them seem to live in a series of present moments without consideration for the past or future. But also included in this general category are hostile people who are prone to acting out impulses in remorseless and often senselessly violent ways.

We will summarize the major characteristics of psychopaths and antisocial personalities and then describe a case that illustrates the wide range of behavioral patterns that may be involved. Although all the characteristics examined in the following sections are not usually found in any one particular case, they are typical of psychopaths as first described by Cleckley (1941, 1982). A subset of these characteristics occurs in ASPD as well.

**INADEQUATE CONSCIENCE DEVELOPMENT** Psychopaths appear unable to understand and accept ethical values except on a verbal level. They may glibly claim to adhere to high moral standards that have no apparent connection with their behavior. In short, their conscience development is severely retarded or nonexistent, and they behave as though social regulations and laws do not apply to them (Frick & Marsee, 2006; Salekin, 2006). These characteristics of psychopathy are most strongly

**FIGURE 10.2**

Survival curve of months free in the community until first violent reoffense plotted by score on the Hare Psychopathy Checklist: Youth Version (PCL:YV) group. The survival curve illustrates the percentage of individuals in each group who have not shown a violent reoffense at 12-month intervals. Those in the High-PCL-YV group are more likely to have violent reoffenses than those in the other two groups (lower probability of survival) and are more likely to have them sooner after release (indicated by the steeper slope).

Source: From Gretton et al. (2004). Psychopathy and offending from adolescence to adulthood: A 10-year follow-up. *Journal of Consulting and Clinical Psychology*, 72, 636–45. Copyright © 2004 by the American Psychological Association. Reproduced with permission.

related to the interpersonal and affective core of psychopathy (Fowles & Dindo, 2006). In spite of their stunted conscience development, their intellectual development is typically normal. Nevertheless, intelligence is one trait that has different relationships with the two dimensions of psychopathy. The first, affective and interpersonal dimension is positively related to verbal intelligence (Salekin et al., 2004); the second, antisocial dimension is negatively related to intelligence (Frick, 1998; Hare et al., 1999).

**IRRESPONSIBLE AND IMPULSIVE BEHAVIOR** Psychopaths learn to take rather than earn what they want. Prone to thrill seeking and deviant and unconventional behavior, they often break the law impulsively and without regard for the consequences. They seldom forgo immediate pleasure for future gains and long-range goals. These aspects of psychopathy are most

closely related to the second, antisocial dimension of psychopathy (Patrick, 2005).

Many studies have shown that antisocial personalities and some psychopaths have high rates of alcohol abuse and dependence and other substance-abuse/dependence disorders (e.g., Taylor & Lang, 2006; Waldman & Slutske, 2000). Alcohol abuse is related only to the antisocial or deviant dimension of the PCL-R (Patrick, 2005; Reardon et al., 2002). Antisocial personalities also have elevated rates of suicide attempts and completed suicides, which are also associated only with the second, antisocial dimension of psychopathy and not with the first, affective dimension (Verona et al., 2001).

**ABILITY TO IMPRESS AND EXPLOIT OTHERS** Some psychopaths are superficially charming and likable, with a disarming manner that easily wins new friends (Cleckley, 1941, 1982;

Serial killer Ted Bundy exhibited antisocial behavior at its most extreme and dangerous. Bundy used his clean-cut image to get close to his victims—mainly young university women—whom he sexually assaulted and then savagely murdered. From all outward appearances, Bundy was a fine, upstanding citizen.

Patrick, 2006). They seem to have good insight into other people's needs and weaknesses and are adept at exploiting them. These frequent liars usually seem sincerely sorry if caught in a lie and promise to make amends they—but they do not do so. Not surprisingly, then, psychopaths are seldom able to keep close friends. They seemingly cannot understand love in others or give it in return. Manipulative, exploitative, and sometimes coercive in sexual relationships, psychopaths are irresponsible and unfaithful mates.

Hare, a highly influential researcher in this area, summarized the prototypic psychopath in the following manner:

*Conceptualizing psychopaths as remorseless predators helped me to make sense of what often appears to be senseless behavior. These are individuals who, lacking in conscience and feelings for others, find it easy to use charm, manipulation, intimidation, and violence to control others and to satisfy their own social needs . . . without the slightest sense of guilt or regret . . . they form a significant proportion of persistent criminals, drug dealers, spouse and child abusers, swindlers and con men . . . They are well represented in the business and corporate world, particularly during chaotic restructuring, where the rules and their enforcement are lax. . . . Many psychopaths emerge as "patriots" and "saviors" in societies experiencing social, economic, and political upheaval (e.g., Rwanda, the former Yugoslavia, and the former Soviet Union) . . . by callously exploiting ethnic, cultural, or racial tensions and grievances. (1998, pp. 128–29)*

Psychopathy is well illustrated in the following classic case study published by Hare (1970).

→ **A Psychopath in Action** Donald, 30 years old, has just completed a 3-year prison term for fraud, bigamy, false pretenses, and escaping lawful custody. The circumstances leading up to these offenses are interesting and consistent with his past

behavior. With less than a month left to serve on an earlier 18-month term for fraud, he faked illness and escaped from the prison hospital. During the 10 months of freedom that followed, he engaged in a variety of illegal enterprises; the activity that resulted in his recapture was typical of his method of operation. By passing himself off as the "field executive" of an international philanthropic foundation, he was able to enlist the aid of several religious organizations in a fund-raising campaign. The campaign moved slowly at first, and in an attempt to speed things up, he arranged an interview with the local TV station. His performance during the interview was so impressive that funds started to pour in. However, unfortunately for Donald, the interview was also carried on a national news network. He was recognized and quickly arrested. During the ensuing trial it became evident that he experienced no sense of wrongdoing for his activities. . . . At the same time, he stated that most donations to charity are made by those who feel guilty about something and who therefore deserve to be bilked.

While in prison he was used as a subject in some of the author's research. On his release he applied for admission to a university and, by way of reference, told the registrar that he had been one of the author's research colleagues! Several months later the author received a letter from him requesting a letter of recommendation on behalf of Donald's application for a job.

**Background.** Donald was the youngest of three boys born to middle-class parents. Both of his brothers led normal, productive lives. His father spent a great deal of time with his business; when he was home he tended to be moody and to drink heavily when things were not going right. Donald's mother was a gentle, timid woman who tried to please her husband and to maintain a semblance of family harmony. . . . However, . . . on some occasions [the father] would fly into a rage and beat the children, and on others he would administer a verbal reprimand, sometimes mild and sometimes severe.

By all accounts Donald was considered a willful and difficult child. When his desire for candy or toys was frustrated he would begin with a show of affection, and if this failed he would throw a temper tantrum; the latter was seldom necessary because his angelic appearance and artful ways usually got him what he wanted. . . . Although he was obviously very intelligent, his school years were academically undistinguished. He was restless, easily bored, and frequently truant . . . when he was on his own he generally got himself or others into trouble. Although he was often suspected of being the culprit, he was adept at talking his way out of difficulty.

Donald's misbehavior as a child took many forms including lying, cheating, petty theft, and the bullying of smaller children. As he grew older he became more and more interested in sex, gambling, and alcohol. When he was 14 he made crude sexual advances toward a younger girl, and when she threatened to tell her parents he locked her in a shed. It was about 16 hours before she was found. Donald at first denied knowledge of the incident, later stating that she had seduced him and that the door must

have locked itself. . . . His parents were able to prevent charges being brought against him. . . .

When he was 17, Donald . . . forged his father's name to a large check and spent about a year traveling around the world. He apparently lived well, using a combination of charm, physical attractiveness, and false pretenses to finance his way. During subsequent years he held a succession of jobs, never . . . for more than a few months. Throughout this period he was charged with a variety of crimes, including theft, drunkenness in a public place, assault, and many traffic violations. In most cases he was either fined or given a light sentence.

**A Ladies' Man.** His sexual experiences were frequent, casual, and callous. When he was 22, he married a 41-year-old woman whom he had met in a bar. Several other marriages followed, all bigamous. . . . The pattern was the same: He would marry someone on impulse, let her support him for several months, and then leave. One marriage was particularly interesting. After being charged with fraud Donald was sent to a psychiatric institution for a period of observation. While there he came to the attention of a female member of the professional staff. His charm, physical attractiveness, and convincing promises to reform led her to intervene on his behalf. He was given a suspended sentence, and they were married a week later. At first things went reasonably well, but when she refused to pay some of his gambling debts he forged her name to a check and left. He was soon caught and given an 18-month prison term. . . . He escaped with less than a month left to serve.

It is interesting to note that Donald sees nothing particularly wrong with his behavior, nor does he express remorse or guilt for using others and causing them grief. Although his behavior is self-defeating in the long run, he considers it to be practical and possessed of good sense. Periodic punishments do nothing to decrease his egotism and confidence in his own abilities. . . . His behavior is entirely egocentric, and his needs are satisfied without any concern for the feelings and welfare of others. (Reprinted with permission of Robert P. Hare, University of British Columbia, rhare@interchange.ubc.ca)

The repetitive behavior pattern exhibited by Donald is common among people diagnosed as psychopathic. Some of the multitude of etiological factors that are involved in the development of this very serious personality disorder are considered next.

## Causal Factors in Psychopathy and Antisocial Personality

Contemporary research has variously stressed the causal roles of genetic factors, temperamental characteristics, deficiencies in fear and anxiety, more general emotional deficits, the early learning of antisocial behavior as a coping style, and the influence of particular family and environmental patterns. Because an antisocial person's impulsiveness, acting out, and intolerance of discipline and a psychopathic person's callous interpersonal traits tend to

appear early in life, many investigators have focused on the role of early biological and environmental factors as causative agents in antisocial and psychopathic behaviors.

**GENETIC INFLUENCES** Until fairly recently, most behavior genetic research focused on genetic and environmental influences on antisocial behavior or criminality rather than on psychopathy itself. At least 100 studies have compared concordance rates between monozygotic and dizygotic twins, and a number of studies used the adoption method, wherein rates of criminal behavior in the adopted-away children of criminals were compared with the rates of criminal behavior in the adopted-away children of ordinary (non-criminal) parents. The results of both kinds of studies show a moderate heritability for antisocial or criminal behavior (Carey & Goldman, 1997; Hare et al., 2012; Sutker & Allain, 2001) and for ASPD (Waldman & Rhee, 2006), although non-shared environmental influences play an equally important role. More recently, several strong studies have also demonstrated that psychopathy and some of its important features also show a moderate heritability (e.g., Blonigen et al., 2003, 2006; see Hare et al., 2012; Waldman & Rhee, 2006, for reviews). For example, a twin study of 3,687 twin pairs at age 7 found that the early signs of callous/unemotional traits in these children were highly heritable (Viding et al., 2005).

However, researchers also note that strong environmental influences (to be discussed later) interact with genetic predispositions (a genotype–environment interaction) to determine which individuals become criminals or antisocial personalities (Carey & Goldman, 1997; Hare et al., 2012; Moffitt, 2005). Indeed, this must be the case, given the dramatic increases in crime that have occurred in the United States and the United Kingdom since 1960, as well as the tenfold-higher murder rate in the United States than in the United Kingdom (Rutter, 1996); such findings cannot be accounted for by genetic factors alone but must involve psychosocial or sociocultural causal factors.

One excellent study by Cadoret and colleagues (1995; see also Riggins-Caspers et al., 2003) found that adopted-away children of biological parents with ASPD were more likely to develop antisocial personalities if their adoptive parents exposed them to an adverse environment than if their adoptive parents exposed them to a more normal environment. Adverse environments were characterized by some of the following: marital conflict or divorce, legal problems, and parental psychopathology. Similar findings of a gene–environment interaction were also found in twins who were at high or low risk for conduct disorder (typically a childhood precursor of ASPD); in this study, the environmental risk factor was physical maltreatment (Jaffee et al., 2005).

The most exciting study on gene–environment interactions and ASPD identified a candidate gene that seems to be very involved (Caspi et al., 2002). This gene, known as the monoamine oxidase-A gene (MAO-A gene), is involved in the breakdown of neurotransmitters like norepinephrine, dopamine, and serotonin—all neurotransmitters affected by the stress of maltreatment that

can lead to aggressive behavior (see Figure 10.3). In this study, over a thousand children from New Zealand were followed from birth to age 26. Researchers found that individuals with low MAO-A activity were far more likely to develop ASPD if they had experienced early maltreatment than were individuals with high MAO-A activity and early maltreatment and than individuals with low levels of MAO-A activity without early maltreatment. Similar findings have been reported for conduct disorder (Foley et al., 2004) and ADHD (Kim-Cohen et al., 2006)—both common precursors of adult ASPD and psychopathy.

The relationship between antisocial behavior and substance abuse is sufficiently strong that some have questioned whether there may be a common factor leading to both alcoholism and antisocial personality. Early studies of genetic factors involved in the predisposition to antisocial personality and to alcoholism were inconsistent (Carey & Goldman, 1997), but more recent research suggests that there is significant genetic involvement in their high level of comorbidity (e.g., Krueger et al., 2002; Slutske et al., 1998; Taylor & Lang, 2006). Moreover, one study found that ASPD and other externalizing disorders (like alcohol and drug dependence and conduct disorder) all share a strong common genetic vulnerability; environmental factors were more important in determining which disorder a particular person developed (Hicks et al., 2004; Krueger et al., 2007).

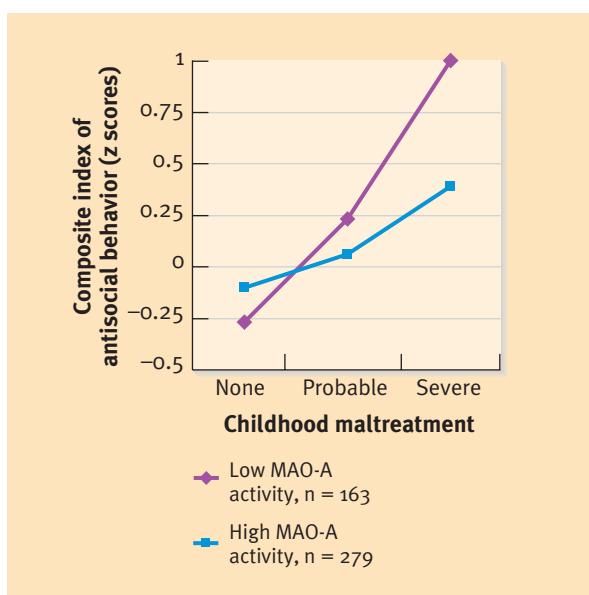

### THE LOW-FEAR HYPOTHESIS AND CONDITIONING

Research evidence indicates that psychopaths who are high on the egocentric, callous, and exploitative dimension have low trait anxiety and show poor conditioning of fear (Fowles &

Dindo, 2006; Lykken, 1995; Patrick, 2005). In an early classic study, Lykken (1957) found that psychopaths showed deficient conditioning of skin conductance responses (reflecting activation of the sympathetic nervous system) when anticipating an unpleasant or painful event and that they were slow at learning to stop responding in order to avoid punishment. As a result, psychopaths presumably fail to acquire many of the conditioned reactions essential to normal passive avoidance of punishment, to conscience development, and to socialization (Trasler, 1978; see also Fowles & Dindo, 2006; Fowles & Kochanska, 2000). Hare aptly summarized work on this issue: “It is the emotionally charged thought, images, and internal dialogue that give the ‘bite’ to conscience, account for its powerful control over behavior, and generate guilt and remorse for transgressions. This is something that psychopaths cannot understand. For them conscience is little more than an intellectual awareness of rules others make up—empty words” (1998, p. 112).

An impressive array of studies since the early work of Lykken has confirmed that psychopaths are deficient in the conditioning of at least subjective and certain physiological components of fear (e.g., Birbaumer et al., 2005; Flor et al., 2002; Fowles, 2001; Lykken, 1995), although they do learn at a purely cognitive level that the CS predicts the US (Birbaumer et al., 2005). Because such conditioning may underlie successful avoidance of punishment, this may also explain why their impulsive behavior goes unchecked. According to Fowles, the deficient conditioning of fear seems to stem from psychopaths’ having a deficient behavioral inhibition system (Fowles, 1993, 2001; Fowles & Dindo, 2006; Hare et al., 1999). The behavioral inhibition system has been proposed by Gray (1987; Gray & McNaughton, 1996) to be the neural system underlying anxiety. It is also the neural system responsible for learning to inhibit responses to cues that signal punishment. In this passive avoidance learning, one learns to avoid punishment by not making a response (e.g., by not committing robbery, one avoids punishment). Thus deficiencies in this neural system (currently identified as involving the septo-hippocampal system and the amygdala) are associated both with deficits in conditioning of anticipatory anxiety and, in turn, with deficits in learning to avoid punishment. Recent research suggests that “successful” psychopaths do not show these same deficits. This may be why they are successful at not getting caught, as discussed in The World Around Us box on the following page.

Other support for the low-fear hypothesis comes from work by Patrick and colleagues on the human startle response. Both humans and animals show a larger startle response if a startle probe stimulus (such as a loud noise) is presented when the subject is already in an anxious state (e.g., Patrick et al., 1993); this is known as fear-potentiated startle. Comparing psychopathic and nonpsychopathic prisoners, Patrick and colleagues found that the psychopaths did not show this effect, but the nonpsychopathic prisoners did. Indeed, the psychopaths showed smaller rather than larger startle responses when viewing unpleasant and

## "Successful" Psychopaths

**M**ost research on antisocial and psychopathic personalities has been conducted on institutionalized individuals, leaving us quite ignorant about the large numbers who stop short of criminal activity or who never get caught. Several early studies found the personality makeup of such individuals (as solicited from ads such as Widom's) to be very similar to that of institutionalized individuals. However, Widom (1978) also speculates that the "everyday" noncriminal psychopaths (sometimes known as "successful" psychopaths because they somehow manage to avoid being incarcerated for long periods of time) she had studied might well not show the same autonomic nervous system deficits that are typically seen in criminal psychopaths. Specifically, as noted earlier, criminal psychopaths typically show smaller skin conductance (sweaty palm) responses in anticipation of punishment than criminal nonpsychopaths, and several other studies showed that criminal psychopaths also demonstrate lower cardiovascular (heart rate) reactivity during fear imagery or anticipation of punishment (e.g., Arnett et al., 1993; Patrick et al., 1994; see Hall & Benning, 2006, for a review).

Several later studies provide tentative support for Widom's hypothesis that successful psychopaths would not show these deficits. One study, for example, showed that 15-year-old antisocial boys who later managed to avoid criminal convictions through age 29 exhibited increased autonomic arousal (heart rate and skin conductance) relative to 15-year-old antisocial boys who were later convicted of crimes (Raine et al., 1995; see also Brennan et al., 1997). More direct support for Widom's hypothesis is provided by a study examining autonomic stress

reactivity in successful and unsuccessful criminal psychopaths and control subjects, all living in the community and trying to find temporary employment (Ishikawa et al., 2001). Each subject was told to give a short speech about his personal faults and weaknesses, during which time he was observed and videotaped. While subjects were preparing for and giving the speech, their heart rate was monitored. The results indicated that successful psychopaths (who had committed approximately the same number and type of crimes as the unsuccessful psychopaths, although they had never been convicted) showed greater heart rate reactivity to this stressful task than did the controls or the unsuccessful psychopaths. Thus, just as Widom had predicted, the successful psychopaths did not show the reduced cardiovascular responsivity that the unsuccessful psychopaths exhibited when anticipating and experiencing a stressor. This is consistent with the idea that the increased cardiac reactivity of the successful psychopaths may serve them well in processing what is going on in risky situations and in making decisions that may prevent their being caught. Additional neuropsychological tests revealed that the successful psychopaths also showed superior "executive functioning" (higher-order cognitive processes such as planning, abstraction, cognitive flexibility, and decision making), which also probably enhanced their ability to elude punishment. Moreover, they also tend to come from less disadvantaged socioeconomic backgrounds than criminal psychopaths (Hall & Benning, 2006). Clearly, more research is needed on this important group of successful, non-incarcerated psychopaths, who commit a great deal of crime but somehow manage to avoid being caught.

pleasant slides than when watching neutral slides (see also Patrick, 1994; Sutton et al., 2002, for related results). These deficits in fear-potentiated startle responding are related only to the first, affective dimension of psychopathy (not to the second, antisocial dimension; Patrick, 2005).

The second important neural system in Gray's model is the behavioral activation system. This system activates behavior in response to cues for reward (positive reinforcement) as well as to cues for active avoidance of threatened punishment (such as in lying or running away to avoid punishment that one has been threatened with). According to Fowles's theory, the behavioral activation system is thought to be normal or possibly overactive in psychopaths, which may explain why they are quite focused on obtaining reward. Moreover, if they are caught in a misdeed, they are very focused on actively avoiding threatened punishment (e.g., through deceit and lies, or running away). This hypothesis of Fowles that psychopaths have a deficient behavioral inhibition system and a normal or possibly overactive behavioral activation system seems to account for three

important features of psychopathy: (1) psychopaths' deficient conditioning of anxiety to signals for punishment, (2) their difficulty learning to inhibit responses that may result in punishment (such as illegal and antisocial acts), and (3) their normal or hypernormal active avoidance of punishment (by deceit, lies, and escape behavior) when actively threatened with punishment (Fowles, 1993, p. 9; see also Hare, 1998).

Newman and colleagues (e.g., Newman, 2008; Newman & Lorenz, 2003) have also conducted research suggesting that people with psychopathy have a dominant response set for reward. Their excessive focus on reward is thought to interfere with their ability to use punishment or other contextual cues or information to modulate (or modify) their responding when rewards are no longer forthcoming at the same rate that they once were. Moreover, Newman and colleagues believe that this response modulation deficit is more central to psychopathy than is a fear deficit (or even a general emotional deficit). A number of interesting studies they have conducted are consistent with their theory. However, there is still significant controversy over

whether this response modulation deficit hypothesis can account for the wide array of findings in support of the low-fear (and other emotional deficits) hypothesis.

**MORE GENERAL EMOTIONAL DEFICITS** Researchers have also been interested in whether there are more general emotional deficits in psychopaths than simply deficits in the conditioning of anxiety (Fowles & Dindo, 2006; Hare et al., 1999; Patrick, 2005). Psychopaths showed less significant physiological reactivity to distress cues (slides of people crying who are obviously quite distressed) than nonpsychopaths. This is consistent with the idea that psychopaths are low on empathy (Blair, 2006; Blair et al., 1997), in addition to being low on fear. However, they were not underresponsive to unconditioned threat cues such as slides of sharks, pointed guns, or angry faces. Patrick and colleagues have demonstrated that this effect of smaller (rather than larger) startle responses when viewing unpleasant slides is especially pronounced with slides depicting scenes of victims who have been mutilated or assaulted but not with slides representing threats to the self (aimed weapons or looming attackers; Levenson et al., 2000). This specific failure to show larger startle responses with victim scenes might be related to the lack of empathy common in psychopathy (e.g., Blair et al., 1997). Blair (2006) summarizes evidence showing that such emotional deficits seem to be due, at least in part, to the dysfunction in the amygdala that is commonly seen in psychopathy. For example, individuals with psychopathy show less activity in the amygdala (relative to controls) not only during fear conditioning but also when viewing sad or frightened faces (see Marsh & Blair, 2008, for a quantitative review).

Hare has hypothesized that the kinds of emotional deficits discussed so far are only a subset of more general difficulties that psychopaths have with processing and understanding the meaning of affective stimuli, including positive and negative words and sounds (e.g., Blair et al., 2006; Lorenz & Newman, 2002; Verona et al., 2004). Hare summarized work in this area as follows: "Psychopaths . . . seem to have difficulty in fully understanding and using words that for normal people refer to ordinary emotional events and feelings. . . . It is as if emotion is a second language for psychopaths, a language that requires a considerable amount of . . . cognitive effort on their part" (1998, p. 115). It has been suggested that such deficits in turn are closely linked to the deficits in moral reasoning and behavior seen in people with psychopathy because to reason about moral issues requires that an individual has concern about the rights and welfare of other people (Blair, 2007b).

**EARLY PARENTAL LOSS, PARENTAL REJECTION, AND INCONSISTENCY** In addition to genetic factors and emotional deficits, slow conscience development and high levels of both reactive and instrumental aggression are influenced by the damaging effects of parental rejection, abuse, and neglect accompanied by inconsistent discipline (e.g., Farrington, 2006;

Luntz & Widom, 1994). However, studies of gene-environment interactions reviewed earlier clearly indicate that these kinds of disturbances are not sufficient explanations for the origins of psychopathy or antisocial personality because some people are clearly more susceptible to these effects than others. Moreover, these same conditions have been implicated in a wide range of later maladaptive behaviors. In the following section, we present an integrated developmental perspective using a biopsychosocial approach with multiple interacting causal pathways.

## A Developmental Perspective on Psychopathy and Antisocial Personality

It has long been known that (1) these disorders generally begin early in childhood, especially for boys, (2) that the number of antisocial behaviors exhibited in childhood is the single best predictor of who will develop an adult diagnosis of ASPD, and (3) the younger they start, the higher the risk (Robins, 1978, 1991). Today, early antisocial symptoms are associated with a diagnosis of conduct disorder (see Chapter 15) and include theft, truancy, running away from home, and associating with delinquent peers. Long-term prospective studies have now shown that the family factors that are most important in predicting which children will show the most antisocial behaviors are poor parental supervision, harsh or erratic parental discipline, physical abuse or neglect, disrupted family life, and a convicted mother (Farrington, 2006). But what causes some children to be more susceptible than others to the adverse effects of such environmental influences?

Prospective studies have shown that it is children with an early history of oppositional defiant disorder—characterized by a pattern of hostile and defiant behavior toward authority figures that usually begins by the age of 6 years, followed by early-onset conduct disorder around age 9—who are most likely to develop ASPD as adults (e.g., Lahey et al., 2005). For these children, the types of antisocial behaviors exhibited across the first 25 years of life change a great deal with development but are persistent in nature (Hinshaw, 1994). By contrast, children without the pathological background who develop conduct disorder in adolescence do not usually become lifelong antisocial personalities but instead have problems largely limited to the adolescent years (Frick & Marsee, 2006; Moffitt & Caspi, 2001; Patterson & Yoerger, 2002).

The second early diagnosis that is often a precursor to adult psychopathy or ASPD is attention-deficit/hyperactivity disorder (ADHD). ADHD is characterized by restless, inattentive, and impulsive behavior, a short attention span, and high distractibility (see Chapter 15). When ADHD co-occurs with conduct disorder (which happens in at least 30 to 50 percent of cases), this leads to a high likelihood that the person will develop a severely aggressive form of ASPD and possibly psychopathy (Abramowitz et al., 2004; Lahey et al., 2005; Patterson et al., 2000). Indeed, Lynam (2002) has referred to children with ADHD and conduct disorder as "fledgling psychopaths," and several ways of assessing psychopathy in youth have been developed, with the

Psychopathy Checklist—Youth Version (Forth et al., 2003) being perhaps the best validated (Salekin, 2006; Salekin et al., 2004).

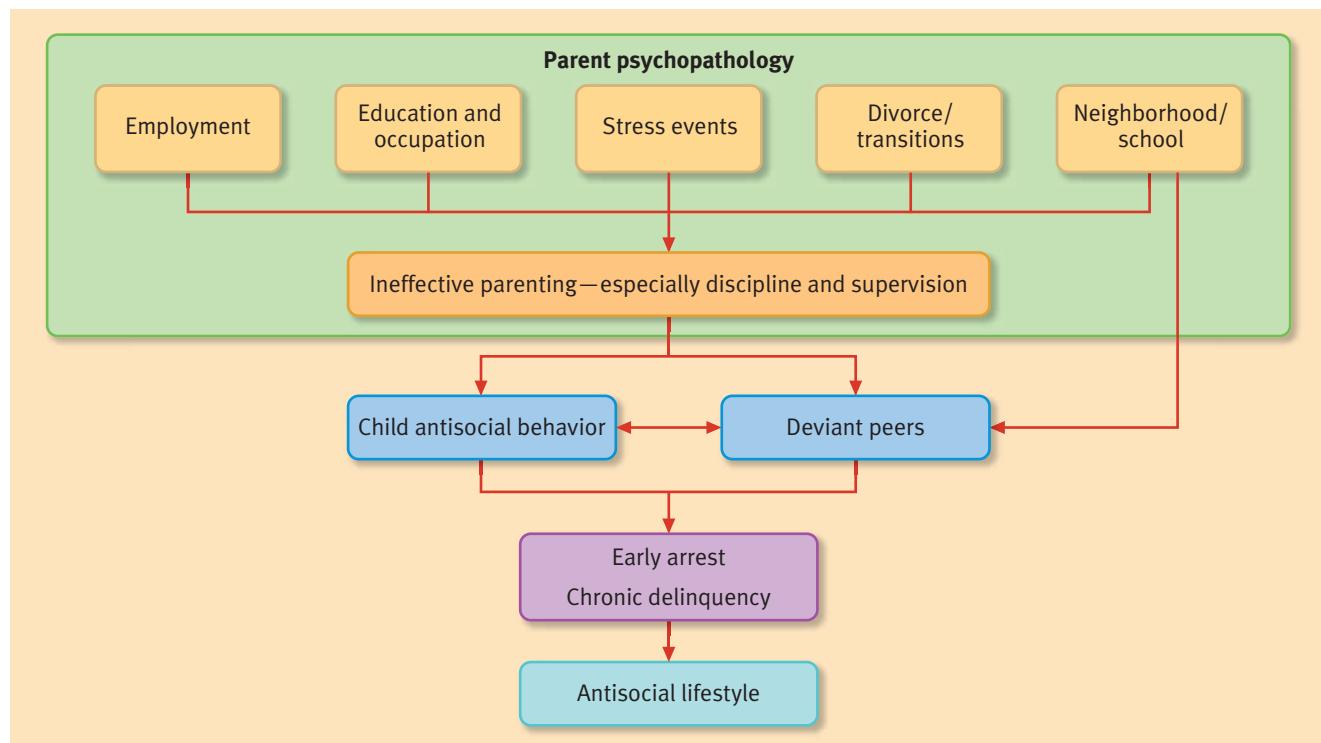

There is increasing evidence that genetic propensities to mild neuropsychological problems such as those leading to hyperactivity or attentional difficulties, along with a difficult temperament, may be important predisposing factors for early-onset conduct disorder, which often leads to life-course-persistent adult ASPD. The behavioral problems that these predisposing factors create have a cascade of pervasive effects over time. For example, on the basis of extensive longitudinal prospective research, Moffitt, Caspi, and colleagues (2002; Moffitt, 2006) have suggested that

*"Life-course-persistent" antisocial behavior originates early in life, when the difficult behavior of a high-risk young child is exacerbated by a high-risk social environment. According to the theory, the child's risk emerges from inherited or acquired neuropsychological variation, initially manifested as subtle cognitive deficits, difficult temperament, or hyperactivity. The environment's risk comprises factors such as inadequate parenting, disrupted family bonds, and poverty. The environmental risk domain expands beyond the family as the child ages, to include poor relations with people such as peers and teachers, then later with partners and employers.*

*Over the first 2 decades of development, transactions between individual and environment gradually construct a disordered personality with hallmark features of physical aggression, and antisocial behavior persisting to midlife. (Moffitt et al., 2002, p. 180)*

Many other psychosocial and sociocultural contextual variables contribute to the probability that a child with the genetic or constitutional liabilities discussed above will develop conduct disorder and, later, ASPD. As discussed previously, these include the parents' own antisocial behaviors, divorce and other parental transitions, poverty and crowded inner-city neighborhoods, and parental stress (e.g., Dishion & Patterson, 1997; Dodge & Pettit, 2003; Farrington, 2006; Reid et al., 2002). All of these contribute to poor and ineffective parenting skills—especially ineffective disciplining, monitoring, and supervising—which are highly predictive of antisocial behavior (e.g., Farrington, 2006; Granic & Patterson, 2006). Moreover, antisocial behavior involving coercive interchanges trains children in these behaviors. This in turn all too often leads to association with deviant and aggressive peers and to the opportunity for further learning of antisocial behavior (Dodge & Pettit, 2003; Farrington, 2006). A general mediational model for how all this occurs is shown in Figure 10.4.

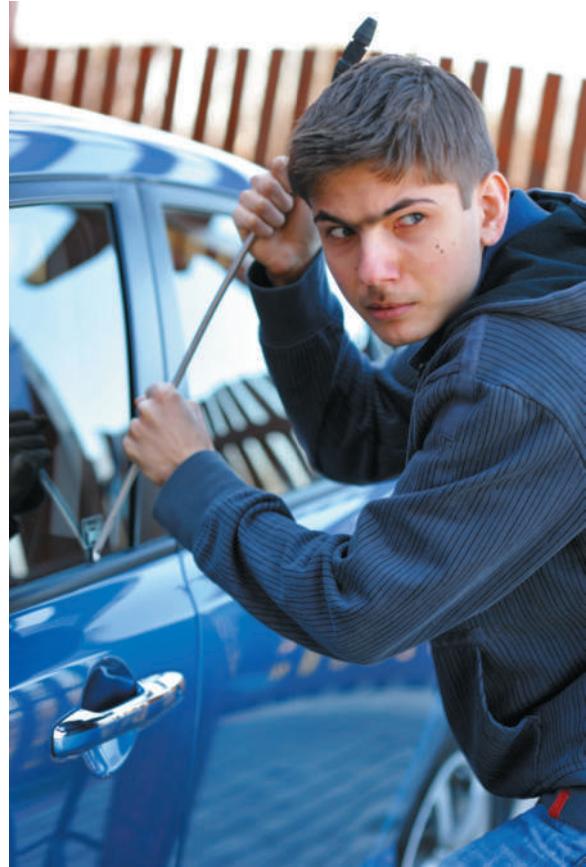

Until fairly recently it was not apparent how this integrated model applied to the development of the traits and behaviors

**FIGURE 10.4**

A model for the association of family context and antisocial behavior. Each of the contextual variables in this model has been shown to be related to antisocial behavior in boys, which in turn is related to antisocial behavior in adults. Antisocial behavior in girls is far less common and has also been found to be less stable over time, making it more difficult to predict. (Capaldi & Patterson, 1994. Interrelated influences of contextual factors on antisocial behavior. In D. C. Fowles et al. (Eds.), *Progress in Experimental Personality and Psychopathology Research*. Springer Publishing Company.)

representing the affective–interpersonal core of psychopathy. In the past decade, Frick and colleagues have developed a way of assessing children’s callous and unemotional traits, which seem to represent early manifestations of this first dimension of psychopathy (e.g., Frick & Marsee, 2006; Frick & Morris, 2004; Frick et al., 2003). They have noted that there are at least two different dimensions of children’s difficult temperament that seem to lead to different developmental outcomes. Some children have great difficulty learning to regulate their emotions and show high levels of emotional reactivity, including aggressive and antisocial behaviors when responding to stressful demands and negative emotions like frustration and anger. Such children are at increased risk for developing ASPD and high scores on the anti-social dimension of psychopathy. But other children may have few problems regulating negative emotions, instead showing fearlessness and low anxiety as well as callous/unemotional traits and reduced amygdala activation while responding to fearful facial expressions (e.g., Marsh et al., 2008). These are the children most likely to show poor development of conscience, and their aggressive behaviors are more instrumental and premeditated rather than reactive as seen with those children who have emotional regulation difficulties. These latter children are likely

Children and adolescents who show persistent patterns of aggression toward people or animals, destruction of property, deceitfulness or theft, and serious violation of rules at home or in school may be at risk for developing conduct disorder and antisocial personality disorder.

to develop high scores on the first, interpersonal affective core of psychopathy, leading to the cold, remorseless psychopaths who show low fear and lack of empathy.

### SOCIOCULTURAL CAUSAL FACTORS AND PSYCHOPATHY

Cross-cultural research by Murphy (1976) on psychopathy reveals that it occurs in a wide range of cultures including nonindustrialized ones as diverse as the Inuit of northwest Alaska and the Yoruba of Nigeria. The Yoruba people’s concept of a psychopath is “a person who always goes his own way regardless of others, who is uncooperative, full of malice, and bullheaded,” and the Inuit’s concept is of someone whose “mind knows what to do but he does not do it. . . . This is an abstract term for the breaking of the many rules when awareness of the rules is not in question” (Murphy, 1976, p. 1026). Nevertheless, the exact manifestations of the disorder are influenced by cultural factors, and the prevalence of the disorder also seems to vary with sociocultural influences that encourage or discourage its development (Cooke et al., 2005; Hare et al., 1999; Sullivan & Kosson, 2006).

Regarding different cross-cultural manifestations of the disorder, one of the primary symptoms where cultural variations occur is the frequency of aggressive and violent behavior. Socialization forces have an enormous impact on the expression of aggressive impulses. Thus it is not surprising that in some cultures, such as China, psychopaths may be much less likely to engage in aggressive, especially violent, behavior than they are in most Western cultures (Cooke, 1996). By contrast, cross-cultural studies have indicated that the affective-interpersonal dimension of psychopathy is the most consistent across cultures (Cooke et al., 2005).

Moreover, cultures can be classified along a dimension distinguishing between individualistic and collectivist societies. Competitiveness, self-confidence, and independence from others are emphasized in relatively individualistic societies, whereas contributions and subservience to the social group, acceptance of authority, and stability of relationships are encouraged in relatively collectivist societies (Cooke, 1996; Cooke & Michie, 1999). Thus we would expect individualistic societies (such as in the United States) to be more likely to promote some of the behavioral characteristics that, carried to the extreme, result in psychopathy. These characteristics include “grandiosity, glibness and superficiality, promiscuity . . . as well as a lack of responsibility for others. . . . The competitiveness . . . not only produces higher rates of criminal behavior but also leads to an increased use of . . . deceptive, manipulative, and parasitic behavior” (Cooke & Michie, 1999, p. 65). Although the evidence bearing on this is minimal, it is interesting to note that estimates of the prevalence of ASPD are much lower in Taiwan, a relatively collectivist society, than they are in the United States (approximately 0.1 to 0.2 percent versus 1.5 to 4 percent).

## Treatments and Outcomes in Psychopathic and Antisocial Personality

Most people with psychopathic and antisocial personalities do not experience much personal distress and do not believe they need treatment. Those who run afoul of the law may participate in rehabilitation programs in penal institutions, but they are rarely changed by them. Even when more and better therapeutic facilities are available, effective treatment will still be a challenging task, and many clinical researchers working with these populations have concluded that these disorders are extraordinarily difficult (if not impossible) to treat, with psychopathy being even more difficult to treat than ASPD (e.g., Hare et al., 1999; Harris & Rice, 2006; Vitale & Newman, 2008). Such conclusions are not made lightly. Dozens of treatment studies have been conducted. Alarmingly, a few studies have found that treatments that work for other criminal offenders can actually be harmful for psychopaths in that rates of reoffending increase rather than decrease (Harris & Rice, 2006). This may be especially likely to occur if the treatment program emphasizes training in social skills or empathy because such skills may simply make them better at charming or conning future victims (Vitale & Newman, 2008).

Biological treatment approaches for antisocial and psychopathic personalities—including electroconvulsive therapy and drugs—have not been systematically studied, partly because the few results that have been reported suggest modest changes at best. Drugs such as lithium and anticonvulsants used to treat bipolar disorder have had some success in treating the aggressive/impulsive behavior of violent aggressive criminals, but evidence on this is scant (Markovitz, 2001; Minzenberg & Siever, 2006). There have also been some tentative but promising results using antidepressants from the SSRI category, which can sometimes reduce aggressive/impulsive behavior and increase interpersonal skills (Lösel, 1998; Minzenberg & Siever, 2006). However, none of these biological treatments has any substantial impact on the disorder as a whole. Moreover, even if effective pharmacological treatments were found, the problem of these individuals generally having little motivation to take their medications would remain (Markovitz, 2001).

**COGNITIVE-BEHAVIORAL TREATMENTS** For reasons discussed earlier, punishment by itself is generally ineffective for changing antisocial behavior. Cognitive-behavioral treatments have thus often been thought to offer the greatest promise of more effective treatment (Hare et al., 2012; Harris & Rice, 2006; Lösel, 1998; Piper & Joyce, 2001). Common targets of cognitive-behavioral interventions include the following: (1) increasing self-control, self-critical thinking, and social perspective taking; (2) increasing victim awareness; (3) teaching anger management; (4) changing antisocial attitudes; and (5) curing drug addiction. Such interventions require a controlled situation in which the therapist can administer or withhold reinforcement and the individual cannot leave treatment (such as

an inpatient or prison setting) because when treating antisocial behavior, we are dealing with a total lifestyle rather than a few specific, maladaptive behaviors (e.g., Hare et al., 2012; Piper & Joyce, 2001). Even the best of these multifaceted, cognitive-behaviorally oriented treatment programs generally produce only modest changes, although they are somewhat more effective in treating young offenders (teenagers) than older offenders, who are often hard-core, lifelong psychopaths. Moreover, although such treatments may be useful in reducing inmates' antisocial behavior while in a prison or other forensic setting, the results do not usually generalize to the real world if the person is released (Harris & Rice, 2006). Thus some experts in the area have concluded that at the present time it may be best to think about management rather than treatment of psychopathic offenders. Or as three prominent researchers recently put it “the programs should be less concerned with developing empathy and conscience or effecting changes in personality than with convincing participants that they alone are responsible for their behavior, and that there are more prosocial ways of using their strengths and abilities to satisfy their needs and wants” (Hare et al., 2012, p. 493).

Fortunately, the criminal activities of many psychopathic and antisocial personalities seem to decline after the age of 40 even without treatment, possibly because of weaker biological drives, better insight into self-defeating behaviors, and the cumulative effects of social conditioning. Such individuals are often referred to as “burned-out psychopaths.” Although there is not a great deal of evidence on this issue (Douglas et al., 2006), one important study that followed a group of male psychopaths over many years found a clear and dramatic reduction in levels of criminal behavior after age 40. However, over 50 percent of these people continued to be arrested after age 40 (Hare et al., 1988). Moreover, it is only the antisocial behavioral dimension of psychopathy that seems to diminish with age; the egocentric, callous, and exploitative affective and interpersonal dimension persists (Cloninger et al., 1997; Hare et al., 1999).

In view of the distress and unhappiness that psychopaths inflict on others and the social damage they cause, it seems desirable—and more economical in the long run—to put increased effort into the development of effective prevention programs. Longitudinal prevention research on children at risk for conduct disorder is discussed in the *Developments in Practice* box.

### in review

- List the three *DSM* criteria that must be met before an individual is diagnosed with ASPD, and cite the additional personality traits that define psychopathy.
- What are several reasons why many researchers believe psychopathy is a more valid construct than ASPD?
- What biological factors contribute to these disorders?
- What are the primary features of a developmental perspective on these disorders?

## Prevention of Psychopathy and Antisocial Personality Disorder

**G**iven the difficulties in treating conduct disorder, ASPD, and psychopathy, there is an increasing focus on prevention programs oriented toward both minimizing some of the developmental and environmental risk factors described earlier and breaking some of the vicious cycles that at-risk children seem to get into. Intelligence is one naturally occurring protective factor for some adolescents who are at risk for developing psychopathy or antisocial personality in adulthood (Hawkins et al., 1997). For example, several studies found that many adolescents with conduct disorder never get involved in criminal behavior because they are positively influenced by schooling and focus their energies on more socially accepted behaviors (e.g., White et al., 1989). Of course, not all at-risk adolescents have high intelligence, and those who do not may benefit from more structured prevention programs.

Given the life-course developmental model for the etiology of ASPD, devising prevention strategies becomes very complex because many different stages present targets for preventive interventions (e.g., Conduct Problems Prevention Research Group, 2007; Dodge & Pettit, 2003). Some interventions that have been shown to help are aimed at mothers estimated to be at high risk (poor, first-time, and single) for producing children who could be at risk and include prenatal care aimed at improving maternal nutrition, decreasing smoking and other substance use, and improving parenting skills (Olds et al., 1986, 1994; Reid & Eddy, 1997).

For young children, Patterson, Dishion, Reid, and colleagues have developed programs that target the family environment and teach effective parental discipline and supervision (e.g., Dishion & Kavanaugh, 2002; Gardner, Shaw et al., 2007; Reid et al., 2002). At-risk children whose families receive such interventions do better academically, are less likely to associate with delinquent peers, and are less likely to get involved in drug use. Such family or parent training can even be effective at reducing or preventing further antisocial behavior in children and adolescents already engaged in antisocial behavior, although conducting the intervention with pre-elementary school children was more effective and less labor intensive (see Reid & Eddy, 1997, for a review). In general, the earlier the prevention and intervention efforts are started, the greater the likelihood that they may succeed. However, it is also important to realize that any single intervention by itself is unlikely to be successful because there are so many different kinds of forces that influence at-risk

children throughout their development (Conduct Problems Prevention Research Group, 2007; Dodge & Pettit, 2003).

Some significant advances have also been made in prevention programs targeting the school environment or the school and family environments concurrently. One especially promising multisite, 10-year intervention study of this sort is called the FAST Track (Families and Schools Together) intervention. In the early 1990s over 400 kindergarten students who attended schools associated with high risk (generally those that serve inner-city and poor neighborhoods) and who already showed poor peer relations and high levels of disruptive behavior were recruited for this intensive program, which included parent training and school interventions. Another group of over 400 high-risk children were assigned to a control group who received treatment as usual (i.e., no new special programs). There was a focus on improving social-cognitive and cognitive skills, friendships with peers, emotional awareness, and self-control. Teachers and parents were taught how to manage disruptive behavior, and parents were informed of what their children were being taught. Early results through the third grade were quite promising in terms of reducing later conduct problems (Conduct Problems Prevention Research Group, 2010). Parenting behavior and children's social-cognitive skills also showed significant improvement. Children in FAST Track were also less likely to be nominated by peers as aggressive, and they tended to be better liked and to show better reading skills (Coie, 1996; Reid & Eddy, 1997). Later results by grade 9 were remarkable for the children in the highest risk category (top 3 percent on risk). Among these children, the intervention group had lower rates of conduct disorder (reduced by 75 percent) and ADHD (reduced by 53 percent) relative to the control group. Importantly, children assigned to the Fast Track intervention also had experienced fewer arrests relative to control children by the time they reached the age of 19. Although such interventions are expensive (the estimated cost per child was \$58,000 over 10 years), if they can prevent (or at least dramatically reduce) the extremely costly effects on society of these children if they develop full-blown adult ASPD or psychopathy, the long-term benefits will outweigh the initial costs. And indeed, estimates are that each very high-risk youth costs society \$1.2 to \$2 million in rehabilitation, incarceration, and costs to victims. Thus a \$58,000 intervention may be enormously cost-effective in the long run (Conduct Problems Prevention Research Group, 2007).

## UNRESOLVED issues

### DSM-5: How Can We Improve the Classification of Personality Disorders?

Reading this chapter will have given you an understanding of some of the difficulties associated with the use of an exclusively categorical diagnostic system for personality disorders. For instance, you may have had some difficulty in developing a clear, distinctive picture of each of the personality disorders. You may also have recognized that the characteristics and attributes of some disorders, such as schizoid personality disorder, seemed to blend with other conditions, such as the schizotypal or the avoidant personality disorders. It is also the case that people frequently do not fit neatly into any one specific diagnostic category. They may also qualify for a diagnosis of more than one personality disorder (e.g., Clark, 2007; Grant, Stinson et al., 2005; Widiger et al., 1991). Indeed, a common diagnosis is “personality disorder not otherwise specified” (e.g., Livesley, 2007; Krueger & Eaton, 2010; Verheul & Widiger, 2004; Verheul et al., 2007), a category reserved for people who exhibit features from several different categories but do not cleanly fit within any of them.

In the past, many studies of personality disorder categories were conducted in an effort to find discrete breaks in such personality dimensions—that is, points at which normal behavior becomes clearly distinct from pathological behavior. None were found (Livesley, 2001; Widiger & Sanderson, 1995). Moreover, changes in the cut-points, or thresholds for diagnosis of a personality disorder, can have drastic and unacceptable effects on the apparent prevalence rates of a particular personality disorder diagnosis (Widiger & Trull, 2007). For instance, when the *DSM-III* was revised to the *DSM-III-R*, it was noted that the rate of schizoid personality disorder increased by 800 percent and narcissistic personality disorder by 350 percent (Morey, 1988).

Such issues are much less problematic when a dimensional (or continuous rating) system is used because it is expected that across individuals there will be many different patterns of elevation of scores on different facets of different traits. As noted earlier, the personality traits classified for the personality disorders are dimensional in nature. For example, everyone is suspicious at times, but the degree to which this trait exists in someone with paranoid personality disorder is extreme. A dimensional system would allow people to be rated on the degree to which they exhibit each facet and trait dimension—not on whether they do or do not have a given personality disorder. Each individual would also be rated on numerous dimensions, and highly personalized patterns of scores would thus be expected rather than problematic.

There has been lively debate among psychologists and psychiatrists over the best way to design a more dimensional system (Clark, 2007; Livesley, 2011; Skodol et al., 2011). Although it has long been clear that a more dimensional system is needed, actually implementing this has proven very difficult. A major challenge has been creating a scientifically valid diagnostic system that is not overly complicated and does not render the substantial research on existing categories useless. As we noted earlier, the proposal that was offered for inclusion in *DSM-5* was not accepted. Although moving to a dimensional system makes a lot of sense for many reasons, the complexity of the model that was proposed was no doubt a major issue. All of this speaks to the difficulty of creating a valid yet utilitarian diagnostic system that satisfies the different needs of both clinicians and researchers.

## 10 summary

### 10.1 What are some of the general features of personality disorders?

- Personality disorders appear to be rather inflexible and distorted behavioral patterns and traits that result in maladaptive ways of perceiving, thinking about, and relating to other people and the environment.
- Three general clusters of personality disorders have been described in *DSM*, although researchers have increasingly questioned the validity of these clusters.

### 10.2 What are some of the difficulties of doing research on personality disorders?

- Even with structured interviews, the reliability of diagnosing personality disorders typically is less than ideal. Most researchers today agree that a dimensional approach for assessing personality disorders would be preferable.
- It is difficult to determine the causes of personality disorders as categories because most people with one personality disorder also have at least one more and because most studies to date are retrospective.

### 10.3 What characteristics do the Cluster A personality disorders have in common?

- Cluster A includes paranoid, schizoid, and schizotypal personality disorders; individuals with these disorders seem odd or eccentric. Little is known about the causes of paranoid and schizoid

disorders, but genetic and other biological factors are implicated in schizotypal personality disorder.

#### 10.4 What characteristics do the Cluster B personality disorders have in common?

- Cluster B includes histrionic, narcissistic, antisocial, and borderline personality disorders; individuals with these disorders share a tendency to be dramatic, emotional, and erratic. Little is known about the causes of histrionic and narcissistic disorders. Certain biological and psychosocial causal factors have been identified as increasing the likelihood of developing borderline personality disorder in those at risk because of high levels of impulsivity and affective instability.

#### 10.5 What characteristics do the Cluster C personality disorders have in common?

- Cluster C includes avoidant, dependent, and obsessive-compulsive personality disorders; individuals with these disorders show fearfulness or tension, as in anxiety-based disorders. Children with an inhibited temperament may be at heightened risk for avoidant personality disorder, and individuals high on neuroticism and agreeableness, with authoritarian and overprotective parents, may be at heightened risk for dependent personality disorder.

#### 10.6 What are the clinical features of borderline personality disorder and how is this disorder treated?

- Borderline personality disorder is characterized by emotional instability, fears of abandonment, impulsivity, self-mutilating

behavior, and an unstable sense of self. People with BPD have intense and stormy personal relationships.

- There is relatively little research on treatments for most personality disorders. However, a form of behavior therapy called dialectical behavior therapy (DBT) is beneficial for people with BPD. DBT helps patients learn to manage their emotions and develop new coping skills. Other recently developed forms of therapy for BPD include transference-focused psychotherapy and mentalization-based treatment. A wide range of medications (antidepressants, antipsychotic medications, and mood stabilizing medications) are also used sometimes.

#### 10.7 What are the features of antisocial personality disorder and psychopathy?

- A person with psychopathy shows elevated levels of two different dimensions of traits: (1) an affective-interpersonal set of traits reflecting lack of remorse or guilt, callousness/lack of empathy, glibness/superficial charm, grandiose sense of self-worth, and pathological lying, and (2) antisocial, impulsive, and socially deviant behavior; irresponsibility; and parasitic lifestyle. A person diagnosed with ASPD is primarily characterized by traits from the second dimension of psychopathy.
- Genetic and temperamental, learning, and adverse environmental factors seem to be important in causing psychopathy and ASPD.
- Psychopaths also show deficiencies in fear and anxiety as well as more general emotional deficits.
- Treatment of individuals with ASPD psychopathy is difficult, partly because they rarely see any need to change and tend to blame other people for their problems.

What is alcohol abuse and dependence?

### 11.2

What is drug abuse and dependence?

### 11.3

Are there addictive disorders other than alcohol and drugs?

### → Remarkable Recoveries from Life-Threatening Substance Abuse

Lyle Prouse was born in Wichita, Kansas, in 1938 of American Indian heritage. As a child he was very interested in aviation and won his first airplane ride by writing an essay for Beechcraft Aircraft Company. Prouse, who grew up in the Indian community in Wichita, had a serious, long-term substance abuse problem, as did his parents, both of whom died from alcohol abuse. Many of his friends and associates were heavy alcohol abusers. After he finished high school he joined the U.S. Marines, became a pilot, and served in the Vietnam War. He was awarded several medals for his service in Vietnam. He left the military and obtained a flying position at Northwest Airlines, where he attained the rank of captain and worked for 22 years, flying Boeing 727 passenger aircraft.

In 1990, Captain Prouse and his flight crew enjoyed a night of heavy drinking while on a layover in Fargo, North Dakota. Prouse consumed a number of rum-and-Diet-Cokes, and his crew drank several pitchers of beer and apparently were very loud and belligerent. Although his crew left the bar earlier, Prouse remained longer and continued drinking. During their drinking binge the flight crew angered a customer in the pub, who later called the FAA, warning them against the problem drinking of the crew. The next morning the Northwest crew continued their flight to Minneapolis and were arrested and given substance use tests. They showed high levels of alcohol in their bloodstreams and were charged with violating a federal law, which included prison time as a result of operating a public transportation carrier under the influence of drugs or alcohol. Captain Prouse and his crewmembers served 12 months of the 16-month sentence they received. All three pilots lost their jobs and their pilot's licenses as a result of the substance use violations.

Captain Prouse felt a great deal of depression and shame at the problems that he created for himself and others following the loss of the aviation career that he loved. He also experienced a

great deal of financial problems from his employment termination. On several occasions he contemplated committing suicide. Captain Prouse entered inpatient substance abuse treatment not long after the incident.

After completing his recovery in an inpatient substance abuse treatment center, Prouse began a long and difficult process of rehabilitation and effort to restore his life without using alcohol. He made many public speeches describing his substance abuse and later wrote a book detailing what he had gone through (Prouse, 2001). Throughout his recovery he was determined to regain his flying status. It was necessary for him to retrain and retake all of the FAA licensing examinations in order to have his qualifications restored because he was required to requalify for every one of his licenses and ratings.

Captain Prouse was assisted in his recovery by a number of people who were impressed by his public disclosure of wrongdoing and his high motivation to recover from his substance abuse. After he appealed to the court to allow him the opportunity to obtain recertification, the court waived the legal restrictions that had been placed upon him at the trial. A friend of his who owned a trainer aircraft allowed him to earn the necessary flying time needed to be relicensed as a pilot. The CEO of Northwest Airlines, John Dasburg, who himself had grown up in a family with alcoholic abuse problems, took personal interest in Prouse's struggle and encouraged his return to duty. He returned to flying with Northwest Airlines. Captain Prouse's efforts and success at rehabilitation were indeed impressive. In 2001 he was granted a presidential pardon by President Clinton.

Interestingly, another one of the pilots on the Northwest "drunk pilots" flight, flight engineer Joe Balzer, who also spent 12 months in federal prison, also rehabilitated himself. He became involved with Alcoholics Anonymous and, over time, requalified for the aviation certification, eventually returning to the cockpit as a pilot for American Airlines (see his autobiographical account in Balzer, 2009).

.....

The extensive problem of substance abuse and substance dependence in our society has drawn both public and scientific attention. Although our present knowledge is far from complete, investigating these problems as maladaptive patterns of adjustment to life's demands, with no social stigma involved, has led to clear progress in understanding and treatment. Such an approach, of course, does not mean that an individual bears no personal responsibility in the development of a problem. On the contrary, individual lifestyles and personality features are thought by many to play important roles in the development of substance-related disorders and are central themes in some types of treatment.

**Substance-related disorders** can be seen all around us: in extremely high rates of alcohol abuse and dependence, and in tragic exposés of cocaine abuse among star athletes and entertainers. **Addictive behavior**—behavior based on the pathological need for a substance—may involve the abuse of substances such

as nicotine, alcohol, Ecstasy, or cocaine. Addictive behavior is one of the most prevalent and difficult-to-treat mental health problems facing our society today.

The most commonly used problem substances are those that affect mental functioning in the central nervous system (CNS)—**psychoactive substances**: alcohol, nicotine, barbiturates, tranquilizers, amphetamines, heroin, Ecstasy, and marijuana. Some of these substances, such as alcohol and nicotine, can be purchased legally by adults; others, such as barbiturates or pain medications like OxyContin (or marijuana in some states), can be used legally under medical supervision; still others, such as heroin, Ecstasy, and methamphetamine, are illegal.

The material described in this chapter was designed to provide both a historic and contemporary view of important research and theoretical strategies in understanding addictive disorders thus we will, in places, refer to the substance abuse versus substance dependence distinction. The following distinctions are important to understanding and diagnosing substance-related disorders:

- **Substance abuse** generally involves an excessive use of a substance resulting in (1) potentially hazardous behavior such as driving while intoxicated or (2) continued use despite a persistent social, psychological, occupational, or health problem.
- **Substance dependence** includes more severe forms of substance-use disorders and usually involves a marked physiological need for increasing amounts of a substance to achieve the desired effects. Dependence in these disorders means that an individual will show a tolerance for a drug and/or experience withdrawal symptoms when the drug is unavailable.
- **Tolerance**—the need for increased amounts of a substance to achieve the desired effects—results from biochemical changes in the body that affect the rate of metabolism and elimination of the substance from the body.
- **Withdrawal** refers to physical symptoms such as sweating, tremors, and tension that accompany abstinence from the drug.

## Alcohol Related Disorders

The terms **alcoholic** and **alcoholism** have been subject to some controversy and have been used differently by various groups in the past. The World Health Organization no longer recommends the term *alcoholism* but prefers the term *alcohol dependence syndrome*—“a state, psychic and usually also physical, resulting from taking alcohol, characterized by behavioral and other responses that always include a compulsion to take alcohol on a continuous or periodic basis in order to experience its psychic effects, and sometimes to avoid the discomfort of its absence; tolerance may or may not be present” (1992, p. 4). However, because the terms *alcoholic* and *alcoholism* are still widely used in practice, in scientific journals, and in government agencies and publications, we will sometimes use them in this book.

People of many ancient cultures, including the Egyptians, Greeks, Romans, and Israelites, made extensive and often excessive use of alcohol. Beer was first made in Egypt around 3000 B.C. The oldest surviving wine-making formulas were recorded by Marcus Cato in Italy almost a century and a half before the birth of Christ. About A.D. 800, the process of distillation was developed by an Arabian alchemist, thus making possible an increase in both the range and the potency of alcoholic beverages. Problems with excessive use of alcohol were observed almost as early as its use began. Cambyses, King of Persia in the sixth century B.C., has the dubious distinction of being one of the early alcohol abusers on record.

### The Prevalence, Comorbidity, and Demographics of Alcohol Abuse and Dependence

Alcohol abuse and alcohol dependence are major problems in the United States and are among the most destructive of the psychiatric disorders because of the impact excessive alcohol use can have upon users' lives and those of their families and friends. It is

The picture shows an 1891 Stale Beer Dive on Mulberry Street Bend, New York, with several drunk people from the neighborhood and includes beers being served by a young girl (Campbell et al., 1892).

- A. A problematic pattern of alcohol use leading to clinically significant impairment or distress, as manifested by at least two of the following, occurring within a 12-month period:
1. Alcohol is often taken in larger amounts or over a longer period than was intended.
  2. There is a persistent desire or unsuccessful efforts to cut down or control alcohol use.
  3. A great deal of time is spent in activities necessary to obtain alcohol, use alcohol, or recover from its effects.
  4. Craving, or a strong desire or urge to use alcohol.
  5. Recurrent alcohol use resulting in a failure to fulfill major role obligations at work, school, or home.
  6. Continued alcohol use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of alcohol.
  7. Important social, occupational, or recreational activities are given up or reduced because of alcohol use.
  8. Recurrent alcohol use in situations in which it is physically hazardous.

9. Alcohol use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by alcohol.
10. Tolerance, as defined by either of the following:
  - a. A need for markedly increased amounts of alcohol to achieve intoxication or desired effect.
  - b. A markedly diminished effect with continued use of the same amount of alcohol.
11. Withdrawal, as manifested by either of the following:
  - a. The characteristic withdrawal syndrome for alcohol (refer to Criteria A and B of the criteria set for alcohol withdrawal, pp. 499–500).
  - b. Alcohol (or a closely related substance, such as a benzodiazepine) is taken to relieve or avoid withdrawal symptoms.

estimated that 50 percent of adults who are 18 or older are current regular drinkers and only 21 percent are lifetime abstainers (Pleis et al., 2009). In 2008, 23.3 percent of Americans aged 12 or older reported binge drinking, and 6.7 percent were found to be heavy drinkers (Substance Abuse and Mental Health Services Administration, 2010). An estimated 12.4 percent of persons 12 or older drove under the influence of alcohol at least once over the past year. An estimated 22.2 million persons (8.9 percent of the population aged 12 or older) were classified with substance dependence or abuse in the past year based on *DSM* diagnostic criteria. In this sample, 3.1 million people were classified with dependence on or abuse of both alcohol and illicit drugs, 3.9 million were dependent on or abused illicit drugs but not alcohol, and 15.2 million were dependent on or abused alcohol but not illicit drugs (Substance Abuse and Mental Health Services Administration, 2009).

The potentially detrimental effects of excessive alcohol use—for an individual, his or her loved ones, and society—are legion. Heavy drinking is associated with vulnerability to injury (Cherpitel 1997), marital discord (Hornish & Leonard, 2007), and becoming involved in intimate partner violence (Eckhardt, 2007). The life span of the average person with alcohol dependence is about 12 years shorter than that of the average person without this disorder. Alcohol significantly lowers performance on cognitive tasks such as problem solving—and the more complex the task, the more the impairment (Pickworth et al., 1997). Organic impairment, including brain shrinkage, occurs in a high proportion of people with alcohol dependence (Gazdzinski et al., 2005), especially among binge drinkers—people who abuse alcohol following periods of sobriety (Hunt, 1993).

One study reported that of the 1.3 million emergency room visits associated with drug misuse or abuse in 2007, 7 percent involved alcohol abuse in patients under age 21 (USDHHS, 2010). Cherpitel and colleagues (2006) explored the association of alcohol use and emergency room (ER) services among injured patients in several countries. Of 9,743 injured patients surveyed in 37 ERs in 14 countries, drinking within 6 hours before injury was associated with prior visits to the ER during the last 12 months. People who were heavy drinkers or were alcohol dependent were significantly more likely to report multiple prior emergency room visits.

Alcohol abuse is associated with over 40 percent of the deaths suffered in automobile accidents each year (Chou et al., 2006) and with about 40 to 50 percent of all murders (Bennett & Lehman, 1996), 40 percent of all assaults, and over 50 percent of all rapes (Abbey et al., 2001). About one of every three arrests in the United States is related to alcohol abuse, and over 43 percent of violent encounters with the police involve alcohol (McClelland & Teplin, 2001). In research on substance abuse and violent crime, Dawkins (1997) found that alcohol is more frequently associated with both violent and nonviolent crime than drugs such as marijuana and that people with violence-related injuries are more likely to have a positive Breathalyzer test (Cherpitel, 1997). Of the 1 million violent crimes that were suspected to be alcohol related in 2002, 30 percent of them were determined to involve alcohol use on the part of the offender. Two-thirds of cases in which victims suffered violence from an intimate (a current or former spouse) were alcohol related (U.S. Department of Justice, 2006).

Alcohol is associated with over 40 percent of deaths and serious injuries suffered in automobile accidents in the United States each year (see Chou et al., 2006).

Alcohol abuse and alcohol dependence in the United States cut across all age, educational, occupational, and socioeconomic boundaries. Alcohol abuse is found in priests, politicians, surgeons, law enforcement officers, and teenagers; the image of the alcohol-abusing person as an unkempt resident of skid row is clearly inaccurate. Alcohol abuse is considered a serious problem in industry, in the professions, and in the military as well. Recent research has shown that alcohol abuse has a strong presence in the workplace, with 15 percent of employees showing problem behaviors; many (1.68 percent, or 2.1 million people) actually drinking on the job; and 1.83 percent, or 2.3 million workers, drinking before they go to work (Frone, 2006). Some myths about alcoholism are noted in Table 11.1 on p. 372.

In the past, most problem drinkers—people experiencing life problems as a result of alcohol abuse—were men; for example, men become problem drinkers at about five times the frequency of women (Helzer et al., 1990). Recent epidemiological research has suggested that the traditional gap between men and women has narrowed when it comes to the development of substance abuse disorders (Greenfield et al., 2010). There do not seem to be important differences in rates of alcohol abuse between black and white Americans, although Native Americans tend to have higher rates of alcohol abuse, and Asian Americans tend to have lower usage. It appears that problem drinking may develop during any life period from early childhood through old age. About 10 percent of men over age 65 are found to be heavy drinkers (Breslow et al., 2003). Surveys of alcoholism rates across different cultural groups around the world have found varying rates of the disorder across diverse cultural samples (Caetano et al., 1998; Hibell et al., 2000).

Over 37 percent of alcohol abusers suffer from at least one coexisting mental disorder (Lapham et al., 2001). Not surprisingly, given that alcohol is a depressant, depression ranks high among the mental disorders often comorbid with alcoholism. There is a high comorbidity of substance abuse disorders and eating disorders (Harrop & Marlatt, 2009). It is also no surprise

that many alcoholics commit suicide (McCloud et al., 2004). In addition to the serious problems that excessive drinkers create for themselves, they also pose serious difficulties for others (Gortner et al., 1997). Alcohol abuse also co-occurs with high frequency with personality disorder. Grant and colleagues (2004) report that among individuals with a current alcohol-use disorder, 28.6 percent have at least one personality disorder.

The diagnosis of substance use disorder in *DSM-5* is based upon a pathological pattern of behaviors that are related to the use of a particular substance, for example, alcohol. The DSM Criteria for Alcohol Use Disorder are reproduced on page 370 as an illustration. Two additional diagnostic criteria for Alcohol Related Disorders can be found in the *DSM-5* manual: Alcohol Intoxication (p. 497) and Alcohol Withdrawal (p. 499).

### The Clinical Picture of Alcohol Related Disorders

A great deal of progress has been made in understanding the physiological effects of alcohol on the brain. The first is a tendency toward decreased sexual inhibition but, simultaneously, lowered sexual performance. An appreciable number of alcohol abusers also experience blackouts—lapses of memory. At first these occur at high blood alcohol levels, and a drinker may carry on a rational conversation or engage in other relatively complex activities but have no trace of recall the next day. For heavy drinkers, even moderate drinking can elicit memory lapses. Another phenomenon associated with alcoholic intoxication (intoxication is defined as a state of being affected by one or more psychoactive drugs) is the hangover, which many drinkers experience at one time or another. As yet, no one has come up with a satisfactory explanation of or remedy for the symptoms of headache, nausea, and fatigue that are characteristic of the hangover.

**ALCOHOL'S EFFECTS ON THE BRAIN** Alcohol has complex and seemingly contradictory effects on the brain. At lower levels, alcohol stimulates certain brain cells and activates the brain's

**TABLE 11.1**  
**Some Common Misconceptions About Alcohol and Alcohol Abuse**

Fiction	Fact
Alcohol is a stimulant.	Alcohol is actually both a nervous system stimulant and a depressant.
You can always detect alcohol on the breath of a person who has been drinking.	It is not always possible to detect the presence of alcohol. Some individuals successfully cover up their alcohol use for years.
One ounce of 86-proof liquor contains more alcohol than two 12-ounce cans of beer.	Two 12-ounce cans of beer contain more than an ounce of alcohol.
Alcohol can help a person sleep more soundly.	Alcohol may interfere with sound sleep.
Impaired judgment does not occur before there are obvious signs of intoxication.	Impaired judgment can occur long before motor signs of intoxication are apparent.
An individual will get more intoxicated by mixing liquors than by taking comparable amounts of one kind—e.g., bourbon, Scotch, or vodka.	It is the actual amount of alcohol in the bloodstream rather than the mix that determines intoxication.
Drinking several cups of coffee can counteract the effects of alcohol and enable a drinker to “sober up.”	Drinking coffee does not affect the level of intoxication.
Exercise or a cold shower helps speed up the metabolism of alcohol.	Exercise and cold showers are futile attempts to increase alcohol metabolism.
People with “strong wills” need not be concerned about becoming substance abusers.	Alcohol is seductive and can lower the resistance of even the “strongest will.”
Alcohol cannot produce a true addiction in the same sense that heroin can.	Alcohol has strong addictive properties.
One cannot become a substance abuser by drinking just beer.	One can consume a considerable amount of alcohol by drinking beer. It is, of course, the amount of alcohol that determines whether one becomes a substance abuser.
Alcohol is far less dangerous than marijuana.	There are considerably more individuals in treatment programs for alcohol problems than for marijuana abuse.
In a heavy drinker, damage to the liver shows up long before brain damage appears.	Heavy alcohol use can be manifested in organic brain damage before liver damage is detected.
The physiological withdrawal reaction from heroin is considered more dangerous than is withdrawal from alcohol.	The physiological symptoms accompanying withdrawal from heroin are no more frightening or traumatic to an individual than alcohol withdrawal. Actually, alcohol withdrawal is potentially more lethal than opiate withdrawal.
Everybody drinks.	Actually, 28 percent of men and 50 percent of women in the United States are abstainers.

“pleasure areas,” which release opium-like endogenous opioids that are stored in the body (Braun, 1996). At higher levels, alcohol depresses brain functioning, inhibiting one of the brain’s excitatory neurotransmitters, glutamate, which in turn slows down activity in parts of the brain (Koob et al., 2002). Inhibition of glutamate in the brain impairs the organism’s ability to learn and affects the higher brain centers, impairing judgment and other rational processes and lowering self-control. As behavioral restraints decline, a drinker may indulge in the satisfaction of impulses ordinarily held in check. Some degree of motor uncoordination soon becomes apparent, and the drinker’s discrimination and perception of cold, pain, and other discomforts are dulled. Typically the drinker experiences a sense of warmth, expansiveness, and well-being. In such a mood, unpleasant realities are screened out and the drinker’s feelings of self-esteem and adequacy rise. Casual acquaintances become the best and most understanding of friends, and the drinker enters a generally pleasant world of unreality in which worries are temporarily left behind.

In most U.S. states, when the alcohol content of the bloodstream reaches 0.08 percent, the individual is considered intoxicated, at least with respect to driving a vehicle. Muscular coordination, speech, and vision are impaired and thought processes are confused. Even before this level of intoxication is reached, however, judgment becomes impaired to such an extent that the person misjudges his or her condition. For example, drinkers tend to express confidence in their ability to drive safely long after such actions are in fact quite unsafe. When the blood alcohol level reaches approximately 0.5 percent (the level differs somewhat among individuals), the entire neural balance is upset and the individual passes out. Unconsciousness apparently acts as a safety device because concentrations above 0.55 percent are usually lethal.

In general, it is the amount of alcohol actually concentrated in the bodily fluids, not the amount consumed, that determines intoxication. The effects of alcohol vary for different drinkers, depending on their physical condition, the amount of food in their

stomach, and the duration of their drinking. In addition, alcohol users may gradually build up a tolerance for the drug so that ever-increasing amounts may be needed to produce the desired effects. Women metabolize alcohol less effectively than men and thus become intoxicated on lesser amounts (Gordis et al., 1995).

**DEVELOPMENT OF ALCOHOL DEPENDENCE** Excessive drinking can be viewed as progressing insidiously from early- to middle-to late-stage alcohol-related disorder, although some abusers do not follow this pattern. Many investigators have maintained that alcohol is a dangerous systemic poison even in small amounts, but others believe that in moderate amounts it is not harmful to most people. For pregnant women, however, even moderate amounts are believed to be dangerous; in fact, no safe level has been established, as is discussed in Developments in Research box below. The photos on page 374 show the differences between the brain of a normal teenager and those born with fetal alcohol syndrome

(FAS), a condition that is caused by excessive alcohol consumption during pregnancy and results in birth defects such as mental retardation.

**THE PHYSICAL EFFECTS OF CHRONIC ALCOHOL USE** For individuals who drink to excess, the clinical picture is highly unfavorable (Turner et al., 2006). Alcohol that is taken in must be assimilated by the body, except for about the 5 to 10 percent that is eliminated through breath, urine, and perspiration. The work of alcohol metabolism is done by the liver, but when large amounts of alcohol are ingested, the liver may be seriously overworked and eventually suffer irreversible damage (Lucey et al., 2009). In fact, from 15 to 30 percent of heavy drinkers develop cirrhosis of the liver, a disorder that involves extensive stiffening of the blood vessels. About 40 to 90 percent of the 26,000 annual cirrhosis deaths every year are alcohol related (Parrish et al., 1991). Some countries, for example Britain and Scotland, have

## developments in RESEARCH

### Fetal Alcohol Syndrome: How Much Drinking Is Too Much?

**R**esearch indicates that heavy drinking by expectant mothers can affect the health of unborn babies, particularly binge drinking and heavy drinking during the early days of pregnancy (Burd & Christensen, 2009; Calhoun & Warren, 2007)—a condition known as *fetal alcohol syndrome*. Newborn infants whose mothers drank heavily during pregnancy have been found to have frequent physical and behavioral abnormalities (Alison, 1994), including aggressiveness and destructiveness (Gardner, 2000), and may experience symptoms of withdrawal (Thomas & Riley, 1998). For example, such infants have shown growth deficiencies, facial and limb irregularities, damage to the central nervous system, and impairment in cognitive functioning (Kodituwakku et al., 2001). Neuroimaging research has shown that there is an overall reduction of brain size and prominent brain shape abnormalities, with narrowing in the parietal region along with reduced brain growth in portions of the frontal lobe (Spadoni et al., 2007). Moreover, children with FAS often show significant working memory deficits and altered activations patterns in some brain regions (Astley et al., 2009).

As noted in *The Third Report on Alcohol and Health* (HEW, 1978), alcohol abuse in pregnant women is the third-leading cause of birth defects—the first two being Down syndrome and spina bifida (the incomplete formation and fusion of the spinal canal). Although data on FAS are often difficult to obtain, the prevalence has been estimated at between 0.5 and 2 cases per 1,000 births (May & Gossage, 2001).

How much drinking endangers a newborn's health? The HEW report warns against drinking more than 1 ounce of alcohol per

The effects of FAS can be both dramatic and long-lasting. This young child who had been diagnosed with FAS shows some of the permanent physical abnormalities characteristic of the syndrome.

day (one 12-ounce can of beer or one 5-ounce glass of wine, for example). The actual amount of alcohol that can safely be ingested during pregnancy is not known, but existing evidence for FAS is strongest when applied to binge drinkers or heavy alcohol users rather than to light or moderate users (Kolata, 1981). Nonetheless the surgeon general and many medical experts have concurred that pregnant women should abstain from using alcohol as the "safest course" until the safest amount of alcohol consumption can be determined (Raskin, 1993).

MRIs of three teenagers: (left) normal control, 13-year-old female; (center) FAS, 13-year-old male with focal thinning of the corpus callosum; (right) FAS, 14-year-old male with complete agenesis (nondevelopment) of the corpus callosum.

shown an increase in cirrhosis-related deaths in the last two decades because of the increased use of alcohol in their populations (Leon & McCambridge, 2006).

Alcohol is also a high-calorie drug. A pint of whiskey—enough to make about eight to ten ordinary cocktails—provides about 1,200 calories, which is approximately half the ordinary caloric requirement for a day (Flier et al., 1995). Thus consumption of alcohol reduces a drinker's appetite for other food. Because alcohol has no nutritional value, the excessive drinker can suffer from malnutrition (Derr & Gutmann, 1994). Furthermore, heavy drinking impairs the body's ability to utilize nutrients, so the nutritional deficiency cannot be made up by popping vitamins. Many alcohol abusers also experience increased gastrointestinal symptoms such as stomach pains (Fields et al., 1994).

**PSYCHOSOCIAL EFFECTS OF ALCOHOL ABUSE AND DEPENDENCE** In addition to various physical problems, a heavy drinker usually suffers from chronic fatigue, oversensitivity, and depression. Initially, alcohol may seem to provide a useful crutch for dealing with the stresses of life, especially during periods of acute stress, by helping screen out intolerable realities and enhance the drinker's feelings of adequacy and worth. The excessive use of alcohol eventually becomes counterproductive, however, and can result in impaired reasoning, poor judgment, and gradual personality deterioration. Behavior typically becomes coarse and inappropriate, and the drinker assumes increasingly less responsibility,

loses pride in personal appearance, neglects spouse and family, and becomes generally touchy, irritable, and unwilling to discuss the problem.  Watch the Video *Chris: Alcoholism* on [MyPsychLab](#)

As judgment becomes impaired, an excessive drinker may be unable to hold a job and generally becomes unqualified to cope with new demands that arise (Frone, 2003). General personality disorganization and deterioration may be reflected in loss of employment and marital breakup. By this time, the drinker's general health is likely to have deteriorated, and brain and liver damage may have occurred. For example, there is some evidence that an alcoholic's brain is accumulating diffuse organic damage even when no

extreme organic symptoms are present (Sullivan, Deshmukh, et al., 2000), and even mild to moderate drinking can adversely affect memory and problem solving (Gordis, 2001). Other researchers have found extensive alcohol consumption to be associated with an increased amount of organic damage in later life (Lyvers, 2000); however, recent research using fMRI has shown that this damage is partially reversible if the person abstains from alcohol use (Wobrock et al., 2009).

### PSYCHOSES ASSOCIATED WITH SEVERE ALCOHOL ABUSE

Excessive use of alcohol can result in severe mental health problems. Several acute psychotic reactions fit the diagnostic classification of substance-induced disorders. These reactions may develop in people who have been drinking excessively over long periods of time or who have a reduced tolerance for alcohol for other reasons—for example, because of brain lesions from excessive long-term use. Such acute reactions usually last only a short time and generally consist of confusion, excitement, and delirium. There is some evidence that delirium may be associated with lower levels of thiamine in alcoholics (Holzbeck, 1996). These disorders are often called "alcoholic psychoses" because they are marked by a temporary loss of contact with reality.

Among those who drink excessively for a long time, a reaction called **alcohol withdrawal delirium** (formerly known as **delirium tremens**) may occur (Palmstienro, 2001). This reaction usually happens following a prolonged drinking spree when the person enters a state of withdrawal. Slight noises or suddenly moving objects may cause considerable excitement and agitation. The full-blown symptoms include (1) disorientation for time and place, in which, for example, a person may mistake the hospital for a church or jail, no longer recognize friends, or identify hospital attendants as old acquaintances; (2) vivid hallucinations, particularly of small, fast-moving animals like snakes, rats, and roaches; (3) acute fear, in which these animals may change in form, size, or color in terrifying ways; (4) extreme suggestibility, in which a person can be made to see almost any animal if its presence is merely suggested; (5) marked tremors of the hands, tongue, and lips; and (6) other symptoms including perspiration, fever, a rapid and weak heartbeat, a coated tongue, and foul breath.

The delirium typically lasts from 3 to 6 days and is generally followed by a deep sleep. When a person awakens, few symptoms—except for possibly slight remorse—remain, but frequently the individual is badly scared and may not resume drinking for several weeks or months. Usually, however, drinking is eventually resumed, followed by a return to the hospital with a new attack. The death rate from withdrawal delirium as a result of convulsions, heart failure, and other complications once approximated 10 percent (Tavel, 1962). With drugs such as chlordiazepoxide, however, the current death rate during withdrawal delirium and acute alcoholic withdrawal has been markedly reduced.

A second alcohol-related psychosis is persisting alcohol disorder or alcohol amnestic disorder (formerly known as Korsakoff's syndrome). This condition was first described by the Russian psychiatrist Korsakoff in 1887 and is one of the most severe alcohol-related disorders (d'Yewalle & Van Damme, 2007). The outstanding symptom is a memory defect (particularly with regard to recent events), which is sometimes accompanied by falsification of events (confabulation). Persons with this disorder may not recognize pictures, faces, rooms, and other objects that they have just seen, although they may feel that these people or objects are familiar. Such people increasingly tend to fill in their memory gaps with reminiscences and fanciful tales that lead to unconnected and distorted associations. These individuals may appear to be delirious, delusional, and disoriented for time and place, but ordinarily their confusion and disordered actions are closely related to their attempts to fill in memory gaps. The memory disturbance itself seems related to an inability to form new associations in a manner that renders them readily retrievable. Such a reaction usually occurs in long-time alcohol abusers after many years of excessive drinking. These patients have also been observed to show other cognitive impairments such as planning deficits (Brokate et al., 2003), intellectual decline, emotional deficits (Snitz et al., 2002), judgment deficits (Brand et al., 2003), and cortical lesions (Estruch et al., 1998).

The symptoms of alcohol amnestic disorder are now thought to be due to vitamin B (thiamine) deficiency and other dietary inadequacies. Although it had been believed that a diet rich in vitamins and minerals generally restores such a patient to more normal physical and mental health, some research evidence suggests otherwise. Lishman (1990) reports that alcohol amnestic disorder did not respond well to thiamine replacement. Some memory functioning appears to be restored with prolonged abstinence. However, some personality deterioration usually remains in the form of memory impairment, blunted intellectual capacity, and lowered moral and ethical standards.

→ **Alcohol Amnestic Disorder** Averill B. was brought into the detoxification unit of a local county hospital by the police after an incident at a crowded city park. He was arrested because of his assaultive behavior toward others (he was walking through the crowded groups of sunbathers muttering to himself, kicking at people). At admission to the hospital, Averill was disoriented (did

not know where he was), incoherent, and confused. When asked his name, he paused a moment, scratched his head, and said, "George Washington." When asked about what he was doing at the park, he indicated that he was "marching in a parade in his honor."

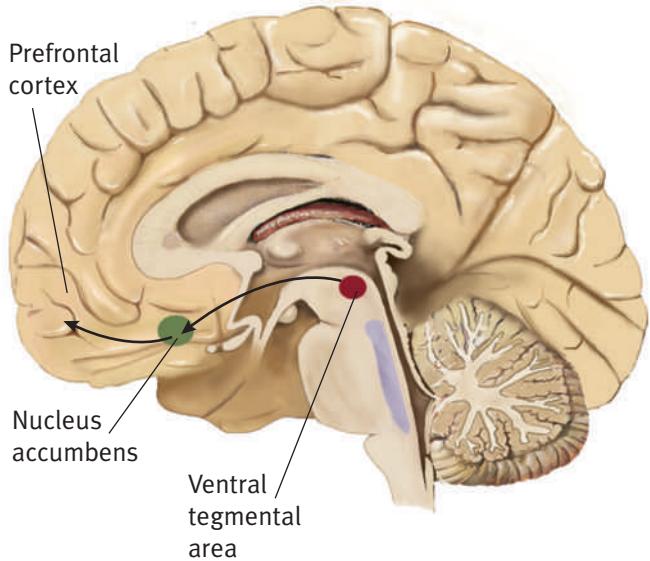

.....

## Biological Causal Factors in the Abuse of and Dependence on Alcohol

In trying to identify the causes of problem drinking, some researchers have stressed the role of genetic and biochemical factors (see Hartz, & Bierut, 2010); others have pointed to psycho-social factors, viewing problem drinking as a maladaptive pattern of adjustment to the stress of life; and still others have emphasized sociocultural factors such as the availability of alcohol and social approval of excessive drinking. As we will see, some combination of all of these factors seems to influence risk for developing alcohol abuse or alcohol dependency. As with most other forms of maladaptive behavior, there may be several types of alcohol abuse and dependency, each with somewhat different patterns of biological, psychosocial, and sociocultural causal factors.

How do substances such as alcohol, cocaine, and opium (discussed later in the chapter) come to have such powerful effects—an overpowering hold that occurs in some people after only a few uses of the drug? Although the exact mechanisms are not fully agreed on by experts in the field, two important factors are apparently involved. The first is the ability of most, if not all, addictive substances to activate areas of the brain that produce intrinsic pleasure and sometimes immediate, powerful reward. The second factor involves the person's biological makeup, or constitution, including his or her genetic inheritance and the environmental influences (learning factors) that enter into the need to seek mind-altering substances to an increasing degree as use continues. The development of an alcohol addiction is a complex process involving many elements—constitutional vulnerability and environmental encouragement, as well as the unique biochemical properties of certain psychoactive substances. Let's examine each of these elements in more detail.

**THE NEUROBIOLOGY OF ADDICTION** Let's first examine the role that substances like alcohol play in the process of addiction. Psychoactive drugs differ in their biochemical properties as well as in how rapidly they enter the brain. There are several routes of administration—oral, nasal, and intravenous. Alcohol is usually drunk, the slowest route, whereas cocaine is often self-administered by injection or taken nasally. Central to the neurochemical process underlying addiction is the role the drug plays in activating the "pleasure pathway." The **mesocorticolimbic dopamine pathway (MCLP)** is the center of psychoactive drug activation in the brain. The MCLP is made up of neuronal cells in the middle portion of the brain known as the ventral tegmental area (see Figure 11.1) and connects to other brain centers such as the nucleus accumbens and then to the prefrontal cortex. This neuronal system

**FIGURE 11.1**

**The Mesocorticolimbic Pathway.** The mesocorticolimbic pathway (MCLP), running from the ventral tegmental area to the nucleus accumbens to the prefrontal cortex, is central to the release of the neurotransmitter dopamine and in mediating the rewarding properties of drugs.

Source: Office of Technology Assessment, 1993.

Watch the Video In the Real World: Neurotransmitters on MyPsychLab

is involved in such functions as control of emotions, memory, and gratification. Alcohol produces euphoria by stimulating this area in the brain. Research has shown that direct electrical stimulation of the MCLP produces great pleasure and has strong reinforcing properties (Littrell, 2001). Other psychoactive drugs also operate to change the brain's normal functioning and to activate the pleasure pathway. Drug ingestion or behaviors that lead to activation of the brain reward system are reinforced, so further use is promoted. The exposure of the brain to an addictive drug alters its neurochemical structure and results in a number of behavioral effects. With continued use of the drug, neuroadaptation to or tolerance and dependence on the substance develop.

**GENETIC VULNERABILITY** The possibility of a genetic predisposition to developing alcohol-abuse problems has been widely researched. Many experts today agree that heredity probably plays an important role in a person's developing sensitivity to the addictive power of drugs like alcohol (Plomin & DeFries, 2003; Volk et al., 2007). Several lines of research point to the importance of genetic factors in substance-related disorders.

A review of 39 studies of the families of 6,251 alcoholics and of 4,083 nonalcoholics who had been followed over 40 years reported that almost one-third of alcoholics had at least one parent with an alcohol problem (Cotton, 1979). Likewise, a study of children of alcoholics by Cloninger and colleagues (1986) reported strong evidence for the inheritance of alcoholism. They found that for males, having one alcoholic parent increased the rate of alcoholism from 12.4 percent to 29.5 percent and

having two alcoholic parents increased the rate to 41.2 percent. For females with no alcoholic parents, the rate was 5.0 percent; for those with one alcoholic parent, the rate was 9.5 percent; and for those with two alcoholic parents, it was 25.0 percent.

Alcohol abuse problems clearly tend to run in families (Hartz & Beirut, 2010; Hasin & Katz, 2010). Research has shown that some people, such as the sons of alcoholics, have a high risk for developing problems with alcohol because of an inherent motivation to drink or sensitivity to the drug (Conrod et al., 1998). Research on the children of alcoholics who were adopted by other (nonalcoholic) families has also provided useful information. Studies have been conducted of alcoholics' children who were placed for adoption early in life and so did not come under the environmental influences of their biological parents. For example, Goodwin and colleagues (1973) found that children of alcoholic parents who had been adopted by nonalcoholic foster parents were nearly twice as likely to have alcohol problems by their late 20s as a control group of adopted children whose biological parents were not alcoholics. In another study, Goodwin and colleagues (1974) compared alcoholic parents' sons who were adopted in infancy by nonalcoholic parents and sons raised by their alcoholic parents. Both adopted and nonadopted sons later evidenced high rates of alcoholism—25 percent and 17 percent, respectively. These investigators concluded that being born to an alcoholic parent, rather than being raised by one, increases the risk of a son's becoming an alcoholic.

Another approach to understanding the precursors to alcohol-related disorders is to study prealcoholic personalities—individuals who are at high risk for substance abuse but who are not yet affected by alcohol. The heritability of personality characteristics has been widely explored (Bouchard & Loehlin, 2001). An alcohol-risk personality has been described as an individual (usually an alcoholic's child) who has an inherited predisposition toward alcohol abuse and who is impulsive, prefers taking high risks, and is emotionally unstable.

Research has shown that prealcoholic men (those who are genetically predisposed to developing drug or alcohol problems but who have not yet acquired the problem) show different physiological patterns than nonalcoholic men in several respects. Prealcoholic men tend to experience a greater lessening of feelings of stress with alcohol ingestion than do nonalcoholic men (Finn et al., 1997). Prealcoholic men also show different alpha wave patterns on EEGs (Stewart et al., 1990) and have been found to have larger conditioned physiological responses to alcohol cues than individuals who were considered at a low risk for alcoholism, according to Earleywine and Finn (1990). These results suggest that prealcoholic men may be more prone to developing tolerance for alcohol than low-risk men.

Some research suggests that certain ethnic groups, particularly Asians and Native Americans, have abnormal physiological reactions to alcohol—a phenomenon referred to as "alcohol flush reaction." Fenna and colleagues (1971) and Wolff (1972) found that Asian and Eskimo subjects showed a hypersensitive reaction

including flushing of the skin, a drop in blood pressure, heart palpitations, and nausea following the ingestion of alcohol (see also Gill et al., 1999). This physiological reaction is found in roughly half of all Asians (Chen & Yeh, 1997) and results from a mutant enzyme that fails to break down alcohol molecules in the liver during the metabolic process (Takeshita et al., 1993). Although cultural factors may also play a role, the relatively lower rates of alcoholism among Asian groups might be related to the extreme discomfort associated with the alcohol flush reaction (Higuci et al., 1994).

**GENETICS—THE WHOLE STORY?** As with the other disorders described in this book, genetics alone is not the whole story, and the exact role it plays in the development of alcohol-related disorders remains unclear. This issue continues to be debated, and some experts are not convinced of the primary role of genetics in substance-abuse disorders. The genetic mechanism or model for the generally agreed-upon observation that alcoholism is familial is insufficient to explain the behavior fully. That is, genetic transmission in the case of alcohol-related disorders does not follow the hereditary pattern found in strictly genetic disorders. Some investigators have employed the evidence that genetics appears to play a stronger role in men than in women (Merikangas & Swendsen, 1997) to question the relative power of genetics as an explanatory factor in substance abuse. Searles (1991) points to the ambiguous evidence for the genetics of alcohol-related disorders and cautions against interpreting genetics as a causal factor in its development. Negative results have been found in both twin and adoptive studies and in studies designed to follow up the behavior of high-risk individuals. The great majority of children who have parents with alcohol-related problems do not themselves develop substance-abuse disorders—whether or not they are raised by their biological parents. The children of substance abusers who make successful life adjustments have not been sufficiently studied. In one study of high-risk children of substance abusers, a group of young men 19 to 20 years of age who were presumably at high risk for developing substance-abuse problems were carefully studied for symptoms of psychopathology. Schulsinger and colleagues (1986) found that they did not differ in psychopathology or in alcohol-abuse behavior from a control sample similar to the general population. In another study of high-risk individuals, Alterman, Searles, and Hall (1989) failed to find differences in drinking behavior or alcohol-related symptoms between a group of high-risk subjects (those who had alcoholic fathers) and a group of non-high-risk subjects.

Although much evidence implicates genetic factors in the etiology of alcoholism, we do not know what precise role they play. At present, it appears that the genetic interpretation of alcoholism remains an attractive hypothesis; however, additional research is needed for us to hold this view with confidence. It is not likely that genetics alone will account for the full range of alcohol and drug problems. Social circumstances are still considered powerful forces in providing both the availability and the motivation to use alcohol and other drugs. McGue (1998)

notes that the mechanisms of genetic influence should be viewed as compatible, rather than competitive, with psychological and social determinants of this disorder.

**GENETIC INFLUENCES AND LEARNING** When we talk about familial or constitutional differences, we are not strictly limiting our explanation to genetic inheritance. Rather, learning factors appear to play an important part in the development of constitutional or predetermined tendencies to behave in particular ways. Having a genetic predisposition or biological vulnerability to substance abuse, of course, is not a sufficient cause of the disorder. The person must be exposed to the substance to a sufficient degree for the addictive behavior to appear. In the case of alcohol, almost everyone in America is exposed to the drug to some extent—in most cases through peer pressure, parental example, and advertising (Andrews & Hops, 2010). The development of alcohol-related problems involves living in an environment that promotes initial as well as continuing use of the substance. People become conditioned to stimuli and tend to respond in particular ways as a result of learning. Learning appears to play an important part in the development of substance abuse and antisocial personality disorders. There clearly are numerous reinforcements for using alcohol in our social environments and everyday lives. However, research has also shown that psychoactive drugs such as alcohol contain intrinsic rewarding properties—apart from the social context or the drug's operation to diminish worry or frustration. As we saw earlier, the drug stimulates pleasure centers in the brain and develops a reward system of its own.

### Psychosocial Causal Factors in Alcohol Abuse and Dependence

Not only do alcohol abusers become physiologically dependent on alcohol, they develop a powerful psychological dependence as well—they become socially dependent on the drug to help them enjoy social situations.

**FAILURES IN PARENTAL GUIDANCE** Stable family relationships and parental guidance are extremely important molding influences for children (Hasin & Katz, 2010), and this stability is often lacking in families of substance abusers. Children who have parents who are extensive alcohol or drug abusers are vulnerable to developing substance-abuse and related problems (Erblich et al., 2001). The experiences and lessons we learn from important figures in our early years have a significant impact on us as adults. Children who are exposed to negative role models and family dysfunction early in their lives or experience other negative circumstances because the adults around them provide limited guidance often falter on the difficult steps they must take in life (Fischer et al., 2005). These formative experiences can have a direct influence on whether a young person becomes involved in maladaptive behavior such as alcohol or drug abuse.

In one sophisticated program of research aimed at evaluating the possibility that negative socialization factors influence alcohol

Parent substance use is associated with early adolescent substance use, and negative parental models can have longer-range negative consequences once children leave home.

use, Chassin and colleagues (1993; Trim & Chassin, 2004) replicated findings that alcohol abuse in parents is associated with substance use in adolescents. They then evaluated several possible mediating factors that can affect whether adolescents start using alcohol. They found that parenting skills or parental behavior was associated with substance use in adolescents. Specifically, alcohol-abusing parents are less likely to keep track of what their children are doing, and this lack of monitoring often leads to the adolescents' affiliation with drug-using peers. In addition, Chassin and colleagues (1993) found that stress and negative affect (more prevalent in families with an alcoholic parent) are associated with alcohol use in adolescents. They reported that "parental alcoholism was associated with increases in negative uncontrollable life events which, in turn, were linked to negative affect, to associations with drug-using peers, and to substance use" (p. 16). In a follow-up study, Chassin and colleagues (1996) reported that the direct effect of fathers' alcohol abuse is strong, even after controlling for stress and negative affect. Extremely stressful childhood experiences such as physical abuse (Douglas et al., 2010; Kaufman et al., 2007) or child sexual abuse might also make a person vulnerable to later problems. Women who have a history of child sexual abuse are at risk for developing a wide range of psychological problems including substance abuse (Kendler et al., 2000).

**PSYCHOLOGICAL VULNERABILITY** Is there an "alcoholic personality"—a type of character organization that predisposes a person to use alcohol rather than adopt some other defensive pattern of coping with stress? Research has suggested that personality factors related to having a family history of alcoholism are associated with the development of alcohol-use disorders (Larkins & Sher, 2006). Research has shown that children of alcoholics progressed more quickly from initial alcohol use to the onset of disorder than did matched adolescents in the control sample (Hussong et al., 2008).

Do some individuals self-medicate or reduce their discomfort by excessive use of alcohol? In efforts to answer this question,

investigators have found that many potential alcohol abusers tend to be emotionally immature, expect a great deal of the world, require an inordinate amount of praise and appreciation, react to failure with marked feelings of hurt and inferiority, have low frustration tolerance, and feel inadequate and unsure of their abilities to fulfill expected male or female roles. Persons at high risk for developing alcohol-related problems have been found to be significantly more impulsive and aggressive than those at low risk for abusing alcohol (Morey et al., 1984).

In recent years, substantial research has focused on the link between alcohol-related disorders and such other disorders as antisocial personality, depression, and schizophrenia to determine whether some individuals are more vulnerable to substance-abuse disorders. About half of the persons with schizophrenia have either alcohol or drug abuse or dependence as well (Kosten, 1997). By far, most of the research on comorbidity has related antisocial personality and addictive disorders, where about 75 to 80 percent of the studies have shown a strong association (Alterman, 1988), and conduct disorder (Slutske et al., 1998). Interestingly, antisocial personality disorder, alcohol, and aggression are strongly associated (Moeller & Dougherty, 2001), and in a survey of eight alcohol-treatment programs, Morganstern and colleagues (1997) found that 57.9 percent of those in treatment had a personality disorder, with 22.7 percent meeting criteria for antisocial personality disorder. One study reports that substance abusers with antisocial personality disorder had lower expectations of remaining abstinent from alcohol use (Di Sclafani et al., 2007).

Considerable research has suggested that there is a relationship between depressive disorders and alcohol abuse, and there may be gender differences in the association between these disorders (Kranzler et al., 1997). One group of researchers (Moscato et al., 1997) found the degree of association between depression and alcohol-abuse problems stronger among women.

For whatever reason they co-occur, the presence of other mental disorders in alcohol- or drug-abusing patients is a very important consideration when it comes to treatment, as will be discussed later in this chapter.

#### STRESS, TENSION REDUCTION, AND REINFORCEMENT

Research studies on patients undergoing substance-abusing treatment have shown high levels of trauma in their prior histories—about 25 to 50 percent of PTSD patients also have substance-abuse disorders (Schafer & Najavits, 2007). In one study, Deters and colleagues (2006) found that 98 percent of the American Indian adolescents in their substance-abuse study reported having a history of trauma such as threat of personal injury, witnessing of injury, or sexual abuse. One recent controlled-treatment study of disaster workers who experienced PTSD following the World Trade Center trauma (Difede et al., 2007) found that excessive alcohol use was associated with dropout from treatment. Wilk and colleagues (2010) found that high exposure to threatening situations and atrocities (i.e., among Iraq war veterans) was associated with a positive screen for alcohol abuse.

A number of investigators have pointed out that the typical alcohol abuser is discontented with his or her life and is unable or unwilling to tolerate tension and stress (for example, Rutledge & Sher, 2001). Hussong and colleagues (2001) reported a high degree of association between alcohol consumption and negative affectivity such as anxiety and somatic complaints. In other words, alcoholics drink to relax. In this view, anyone who finds alcohol tension-reducing is in danger of abusing alcohol, even without an especially stressful life situation. However, the tension-reduction causal model is difficult to accept as a sole explanatory hypothesis. If this process were a main cause, we would expect substance-abuse disorder to be far more common than it is because alcohol tends to reduce tension for most people who use it. In addition, this model does not explain why some excessive drinkers are able to maintain control over their drinking and continue to function in society whereas others are not.

**EXPECTATIONS OF SOCIAL SUCCESS** Some research has explored the idea that cognitive expectation may play an important role both in the initiation of drinking and in the maintenance of drinking behavior once the person has begun to use alcohol (see, for example, Marlatt et al., 1998). Many people, especially young adolescents, expect that alcohol use will lower tension and anxiety and increase sexual desire and pleasure in life (Seto & Barbaree, 1995). According to the reciprocal-influence model, adolescents begin drinking as a result of expectations that using alcohol will increase their popularity and acceptance by their peers.

This view gives professionals an important and potentially powerful means of deterring drinking among young people or at least delaying its onset. From this perspective, alcohol use in teenagers can be countered by providing young people with more effective social tools and with ways of altering these expectancies before drinking begins. Smith and colleagues (1995) have suggested that prevention efforts should be targeted at children before they begin to drink so that the positive feedback cycle of reciprocal reinforcement between expectancy and drinking will never be established (see the discussion on prevention of alcohol use in Chapter 17).

Time and experience do have *moderating* influences on these alcohol expectancies, although heavy drinking in early college years can result in risky behavior and low academic

### research CLOSE-UP

#### Moderating

A moderating variable is a variable that influences the association between two other variables. For example, depression is common after bereavement. However, men who have lost a spouse tend to be more likely to be depressed than women who have lost a spouse. In this case, gender is a key moderating variable for the bereavement-depression relationship.

motivation (Hoepfner, et al., 2012). In a longitudinal study of college drinking, Sher and colleagues (1996) found that there was a significant decrease in outcome expectancy over time. That is, older students showed less expectation of the benefits of alcohol than beginning students (see *The World Around Us*).

**MARITAL AND OTHER INTIMATE RELATIONSHIPS** Adults with less intimate and supportive relationships tend to show greater drinking following sadness or hostility than those with close peers and with more positive relationships (Hussong et al., 2001). Excessive drinking often begins during crisis periods in marital or other intimate personal relationships, particularly crises that lead to hurt and self-devaluation. The marital relationship may actually serve to maintain the pattern of excessive drinking. (See the case study below.) Marital partners may behave toward each other in ways that promote or enable a spouse's excessive drinking. For example, a husband who lives with a wife who abuses alcohol is often unaware of the fact that, gradually and inevitably, many of the decisions he makes every day are based on the expectation that his wife will be drinking. These expectations, in turn, may make the drinking behavior more likely. Eventually an entire marriage may center on the drinking of a substance-abusing spouse. In some instances, the husband or wife may also begin to drink excessively. Thus one important concern in many treatment programs today involves identifying the personality or lifestyle factors in a relationship that tend to foster the drinking in the alcohol-abusing person. Of course, such relationships are not restricted to marital partners but may also occur in those involved in love affairs or close friendships.

→ **The Drunken Wife and Mother** Evelyn C., a 36-year-old homemaker and mother of two school-age children (from a previous marriage), began to drink to excess especially following intense disagreements with her husband, John, a manager of a retail business. For several months, she had been drinking during the day when her children were at school and on two occasions was inebriated when they came home. On one recent occasion, Evelyn failed to pick up her older daughter after an after-school event. Her daughter called John's cell phone (he was out of town on a business trip), and he had an assistant pick her up. When they arrived home, Evelyn (apparently unaware of the problem she had caused) created a scene and was verbally abusive toward the assistant. Her out-of-control drinking increased when her husband of 3 years began staying out all night. These emotionally charged encounters resulted in John's physically abusing her one morning when he came back home after a night away. John moved out of the house and filed for divorce.

Excessive use of alcohol is one of the most frequent causes of divorce in the United States (Perreira & Sloan, 2001) and is often a hidden factor in the two most common causes—financial and sexual problems. The deterioration in interpersonal relationships

## Binge Drinking in College

**T**wo alcohol-related student deaths shocked the Colorado college community in the fall of 2004. Lynn B., an entering freshman at the University of Colorado, drank so much whiskey and wine during a fraternity initiation that he became unconscious and died as a result of alcohol poisoning. This tragic incident occurred just 2 weeks after a 19-year-old sophomore at Colorado State University, Samantha S., died of alcohol poisoning after a party at which she had consumed an estimated 40 drinks (Sink, 2004).

How extensive is college binge drinking? In spite of the fact that alcohol use is illegal for most undergraduates, binge drinking on campus is widespread (Rabow & Duncan-Schill, 1995) and increased substantially between 1998 and 2005 (Mitka, 2009). Sher and Rutledge (2007) reported that college students who drank in high school are likely to continue drinking during their first year in college. According to a survey by Wechsler and colleagues (1994), 44 percent of college students in the United States are binge drinkers, and Goodwin (1992) reports that 98 percent of fraternity and sorority members drink some amount every week. Some research has suggested, however, that the pattern of drinking can vary widely, with binge drinking being more of an occasional rather than a regular event (Del Boca et al., 2004). Wechsler and colleagues (1994) conducted a nationwide survey of 140 college campuses in 40 states and obtained survey information pertaining to the drinking behavior and health consequences of drinking on 17,592 students (with approximately a 69 percent response rate). Students completed a 20-page survey of their drinking practices, including such information as recency of last drink, how many times they had five drinks or more in a row, and how many times they had four drinks in a row. They were also asked to provide information as to whether they experienced any of the following consequences after drinking: had a hangover, missed a class, got behind in schoolwork, did something they later regretted, forgot where they were or what they did, argued with friends, engaged in unplanned sexual activities, failed to use protection when having sex, damaged property, got into trouble with the campus police, got hurt, or required medical treatment for an alcohol overdose.

The colleges surveyed in the study varied widely in the extent of binge drinking among the student body. As one might expect—some colleges earn reputations as being “party schools”—some institutions had a large number of students (70 percent) heavily involved in alcohol and binge drinking, but the problem occurred to some degree across most college campuses. Recent research has suggested that heavier drinking students may self-select into certain study abroad programs with specific intentions to use alcohol (Pedersen et al. 2010).

What are the reasons for the widespread problem of binge drinking in college? Many factors can be cited, such as students'

expressing independence from parental influence (Turrisi et al., 2000); peer group and situational influences (Read et al., 2003); developing and asserting gender roles, particularly for men adopting a “macho” role (Capraro, 2000); and holding beliefs that alcohol can help make positive transformations, such as “having a few drinks to celebrate special occasions” (Turrisi, 1999). One recent study suggested that a family history of alcohol abuse was associated with problematic drinking among college students (LaBrie, et al. 2010).

The consequences of college binge drinking can be far-reaching and often involve disinhibited behavior (Carlson et al., 2010). In their survey, Wechsler and colleagues (1994) reported a strong association between the frequency of binge drinking and alcohol-related health and life problems. In fact, binge drinkers were nearly 10 times more likely than those who did not indulge in binge drinking to engage in unplanned sexual activity, not to use protection when having sex, to get into trouble with campus police, to damage property, and to get hurt after drinking. Men and women tended to report similar problems, except that men engaged in more property damage than women. Over 16 percent of the men and 9 percent of the women reported having gotten into trouble with the campus police. About 47 percent of the frequent binge drinkers, compared with 14 percent of the non-binge drinkers, indicated that they had experienced five or more of the problems surveyed. In a more recent follow-up survey of college drinking in 1997, Wechsler and colleagues (1998) reported strikingly similar results.

One recent study suggests that extensive drinking in college, even among the heaviest drinkers from sororities and fraternities, might be determined to a great extent by situational events, factors that change with graduation. In a follow-up study of drinking behavior a year after graduation, Sher, Bartholow, and Nanda (2001) reported that being a member of a fraternity or sorority did not predict postcollege drinking. Interestingly, a long-term follow-up of over 11 years has shown that the heavy drinking during college did not translate to heavy drinking during later years (Bartholow et al., 2003). These investigators found that heavy drinking that is associated with Greek society involvement does not generally lead to sustained heavy drinking in later life.

Some institutions provide a psychological intervention in an effort to reduce the extent of drinking among college students. One recent study reported that a procedure referred to as Brief Motivational Intervention, or BMI, produced greater self-regulation among a sample of binging college students by providing skills for them to moderate their drinking behavior (Carey et al., 2007). This procedure was more effective among students who also showed, in their pretreatment assessment, a readiness to change.

of the alcohol abuser or dependent, of course, further augments the stress and disorganization in her or his life. The breakdown of marital relationships can be a highly stressful situation for many people. The stress of divorce and the often erratic adjustment period that follows can lead to increased substance abuse.

Family relationship problems have also been found to be central to the development of alcoholism (Dooley & Praise, 2007). In a classic longitudinal study of possible etiologic factors in alcohol abuse, Vaillant and colleagues (1982) described six family relationship factors that were significantly associated with the development of alcoholism in the individuals they studied. The most important family variables that were considered to predispose an individual to substance-use problems were the presence of an alcoholic father, acute marital conflict, lax maternal supervision and inconsistent discipline, many moves during the family's early years, lack of "attachment" to the father, and lack of family cohesiveness.

### Sociocultural Causal Factors

Alcohol use is a pervasive component in the social life in Western civilization. Social events often revolve around alcohol use, and alcohol use before and during meals is commonplace. Alcohol is often seen as a "social lubricant" or tension reducer that enhances social events. Thus investigators have pointed to the role of sociocultural as well as biological and psychological factors in the high rate of alcohol abuse and dependence among Americans.

The effect of cultural attitudes toward drinking is well illustrated by Muslims and Mormons, whose religious values prohibit the use of alcohol, and by orthodox Jews, who have traditionally limited its use largely to religious rituals. The incidence of alcoholism among these groups is minimal. In comparison, the incidence of alcoholism is high among Europeans. For example, one survey showed the highest alcohol-use rates among young people to be in Denmark and Malta, where one in five students reported having drunk alcohol 10 times within the past 30 days (ESPAD, 2000). Interestingly, Europe and six countries that have been influenced by European culture—Argentina, Canada, Chile, Japan, the United States, and New Zealand—make up less than 20 percent of the world's population and yet consume 80 percent of the alcohol (Barry, 1982). Alcohol abuse continues to be a problem in Europe by, for example, contributing to accidents (Lehto, 1995), crime (Ritson, 1995), liver disease (Medical Council on Alcoholism, 1997), and the extent to which young people are developing substance-use problems (Anderson & Lehto, 1995). The French appear to have the highest rate of alcoholism in the world, involving approximately 15 percent of the population. France has both the highest per capita alcohol consumption and one of the highest death rates from cirrhosis of the liver (Noble, 1979). In addition, France shows the highest prevalence rates: In a broad survey of hospital patients, 18 percent (25 percent for men and 7 percent for women) were reported to have alcohol-use disorders even though only 6 percent of admissions were for alcohol problems (Reynaud et al., 1997).

In Sweden, another country with high rates of alcoholism, 13.2 percent of men's hospital admissions, and 1.1 percent of women's, are attributed to alcohol (Andreasson & Brandt, 1997). Thus it appears that religious sanctions and social customs can influence whether alcohol is one of the coping methods commonly used in a given group or society.

The behavior that is manifested under the influence of alcohol also seems to be influenced by cultural factors. Lindman and Lang (1994), in a study of alcohol-related behavior in eight countries, found that most people expressed the view that aggressive behavior frequently follows their drinking "many" drinks. However, the expectation that alcohol leads to aggression is related to cultural traditions and early exposure to violent or aggressive behavior.

In sum, we can identify many reasons why people drink—as well as many conditions that can predispose them to do so and reinforce their drinking behavior—but the exact combination of factors that results in a person's becoming an alcoholic is still unknown.

### Treatment of Alcohol-Related Disorders

Alcohol abuse and dependence are difficult to treat because many alcohol abusers refuse to admit that they have a problem before they "hit bottom," and many who do go into treatment leave before therapy is completed. DiClemente (1993) refers to the addictions as "diseases of denial." However, in a review of several large alcohol-treatment studies, Miller, Walters, and Bennett (2001) reported that two-thirds of studies show large and significant decreases in drinking and related problems. In this section, we will examine both biological and psychosocial treatment strategies. Some treatment approaches appear to reduce drinking-related problems more effectively than others (Miller & Wilbourne, 2002; Zweben, 2001). In general, a multidisciplinary approach to the treatment of drinking problems appears to be most effective because the problems are often complex, requiring flexibility and individualization of treatment procedures (Margolis & Zweben, 1998). Also, a substance abuser's needs change as treatment progresses. Treatment objectives usually include detoxification, physical rehabilitation, control over alcohol-abuse behavior, and the individual's realizing that he or she can cope with the problems of living and lead a much more rewarding life without alcohol.

Traditional treatment programs usually have as their goal abstinence from alcohol (Ambrogne, 2002). However, some programs attempt to promote controlled drinking as a treatment goal for problem drinkers. For example, one procedure referred to as Brief Motivational Intervention attempts to modify clients' behavior through providing information and advice about the consequences of the substance use in an effort to challenge the users about their use—but leaves the responsibility to the individual (Carey et al., 2007; Miller & Rollnik, 2002; Peterson et al., 2006). No matter what the treatment method, relapse is common, and many in the field see relapse as a factor that must be addressed in the treatment and recovery process.

## USE OF MEDICATIONS IN TREATING ALCOHOL ABUSE

**AND DEPENDENCY** Biological approaches include a variety of treatment measures such as medications to reduce cravings, to ease the detoxification process, and to treat co-occurring health (National Institutes of Health, 2001) and mental health problems that may underlie the drinking behavior.

**Medications to Block the Desire to Drink** Disulfiram (Antabuse), a drug that causes violent vomiting when followed by ingestion of alcohol, may be administered to prevent an immediate return to drinking (Grossman & Ruiz, 2004). However, such deterrent therapy is seldom advocated as the sole approach because pharmacological methods alone have not proved effective in treating many severe alcohol-abuse problems (Gorlick, 1993). For example, because the drug is usually self-administered, an alcohol-dependent person may simply discontinue the use of Antabuse when he or she is released from a hospital or clinic and begins to drink again. In fact, the primary value of drugs of this type seems to be their ability to interrupt the alcohol-abuse cycle for a period of time during which therapy may be undertaken. Uncomfortable side effects may accompany the use of Antabuse; for example, alcohol-based aftershave lotion can be absorbed through the skin, resulting in illness. Moreover, the cost of Antabuse treatment, which requires careful medical maintenance, is higher than that for many other, more effective treatments.

Another type of medication that has been used in a promising line of research (Kranzler et al., 2004) is naltrexone, an opiate antagonist that helps reduce the craving for alcohol by blocking the pleasure-producing effects of alcohol (Gueorguieva et al., 2007; Lee et al., 2010). O'Malley and colleagues (1996) have shown that naltrexone reduced the alcohol intake and lowered the incentive to drink for alcohol abusers compared with a control sample given a placebo. Some research has suggested that naltrexone is particularly effective with individuals who have a high level of craving (Monterosso et al., 2001) and show effects of binge drinking (Johnson, 2010). Other research, however, has failed to find naltrexone effective at reducing craving (Krystal et al., 2001), so confidence in its use for this purpose must await further research.

## Medications to Reduce the Side Effects of Acute Withdrawal

**Withdrawal** In cases of acute intoxication, the initial focus is on detoxification (the elimination of alcoholic substances from an individual's body), on treatment of the withdrawal symptoms described earlier, and on a medical regimen for physical rehabilitation. One of the primary goals in treatment of withdrawal symptoms is to reduce the physical symptoms characteristic of withdrawal such as insomnia, headache, gastrointestinal distress, and tremulousness. Central to the medical treatment approaches are the prevention of heart arrhythmias, seizures, delirium, and death. These steps can usually best be handled in a hospital or clinic, where drugs such as Valium have largely revolutionized

the treatment of withdrawal symptoms. Such drugs overcome motor excitement, nausea, and vomiting; prevent withdrawal delirium and convulsions; and help alleviate the tension and anxiety associated with withdrawal. Pharmacological treatments with long-lasting benzodiazepines, such as diazepam, to reduce the severity of withdrawal symptoms have been shown to be effective (Malcolm, 2003).

Concern is growing, however, that the use of tranquilizers—drugs that depress the CNS, resulting in calmness, relaxation, reduction of anxiety, and sleeping—does not promote long-term recovery and may simply transfer the addiction to another substance. Accordingly, some detoxification clinics are exploring alternative approaches including a gradual weaning from alcohol instead of a sudden cutoff. Maintenance doses of mild tranquilizers are sometimes given to patients withdrawing from alcohol to reduce anxiety and help them sleep. Such use of medications may be less effective than no treatment at all, however. Usually patients must learn to abstain from tranquilizers as well as from alcohol because they tend to misuse both. Further, under the influence of medications, patients may even return to alcohol use.

**PSYCHOLOGICAL TREATMENT APPROACHES** Once the patient has her or his drinking under control, detoxification is optimally followed by psychological treatment, including family counseling and the use of community resources related to employment and other aspects of a person's social readjustment. Although individual psychotherapy is sometimes effective, the focus of psychosocial measures in the treatment of alcohol-related problems often involves group therapy, environmental intervention, behavior therapy, and the approach used by Alcoholics Anonymous and family groups such as Al-Anon and Alateen.

**Group Therapy** Group therapy has been shown to be effective for many clinical problems (Galanter et al., 2005), especially substance-related disorders (Velasquez et al., 2001). In the confrontational give-and-take of group therapy, alcohol abusers are often forced (perhaps for the first time) to face their problems and their tendencies to deny or minimize them. These group situations can be extremely difficult for those who have been engrossed in denial of their own responsibilities, but such treatment also helps them see new possibilities for coping with circumstances that have led to their difficulties. Often this paves the way for them to learn more effective ways of coping and other positive steps toward dealing with their drinking problem.

In some instances, the spouses of alcohol abusers and even their children may be invited to join in group therapy meetings. In other situations, family treatment is itself the central focus of therapeutic efforts. In that case, the alcohol abuser is seen as a member of a disturbed family in which all members have a responsibility for cooperating in treatment. Because family members are frequently the people most victimized by the alcohol abuser's addiction, they often tend to be judgmental and

punitive, and the person in treatment, who has already passed harsh judgment on himself or herself, may tolerate this further source of devaluation poorly. In other instances, family members may unwittingly encourage an alcohol abuser to remain addicted—for example, a man with a need to dominate his wife may find that a continually drunken and remorseful spouse best meets his needs.

**Environmental Intervention** As with other serious maladaptive behaviors, a total treatment program for alcohol abuse or dependency usually requires measures to alleviate a patient's aversive life situation. Environmental support has been shown to be an important ingredient of an alcohol abuser's recovery. People often become estranged from family and friends because of their drinking and either lose or jeopardize their jobs. As a result, they are often lonely and live in impoverished neighborhoods. Typically, the reaction of those around them is not as understanding or as supportive as it would be if the alcohol abuser had a physical illness of comparable magnitude. Simply helping people with alcohol-abuse problems learn more effective coping techniques may not be enough if their social environment remains hostile and threatening. For those who have been hospitalized, halfway houses—designed to assist them in their return to family and community—are often important adjuncts to their total treatment program.

**Behavioral and Cognitive-Behavioral Therapy** An interesting and often effective form of treatment for alcohol-related disorders is behavioral therapy, of which several types exist. One is aversive conditioning therapy, which involves the presentation of a wide range of noxious stimuli with alcohol consumption in order to suppress drinking behavior. For example, the ingestion of alcohol might be paired with an electric shock or a drug that produces nausea. A variety of pharmacological and other deterrent measures can be used in behavioral therapy after detoxification. One approach involves an intramuscular injection of emetine hydrochloride, an emetic. Before experiencing the nausea that results from the injection, a patient is given alcohol, so that the sight, smell, and taste of the beverage become associated with severe retching and vomiting. That is, a conditioned aversion to the taste and smell of alcohol develops. With repetition, this classical conditioning procedure acts as a strong deterrent to further drinking—probably in part because it adds an immediate and unpleasant physiological consequence to the more general socially aversive consequences of excessive drinking.

One of the most effective contemporary procedures for treating alcohol abusers has been the cognitive-behavioral approach recommended by Alan Marlatt (1985) and Witkiewitz and Marlatt (2004). This approach combines cognitive-behavioral strategies of intervention with social-learning theory and modeling of behavior. The approach, often referred to as a "skills training procedure," is usually aimed at younger problem drinkers who are considered to be at risk for developing more severe drinking

problems because of an alcohol-abuse history in their family or their current heavy consumption. This approach relies on such techniques as imparting specific knowledge about alcohol, developing coping skills in situations associated with increased risk of alcohol use, modifying cognitions and expectancies, acquiring stress-management skills, and providing training in life skills (Connors & Walitzer, 2001). Cognitive-behavioral treatments have been shown to be effective; for example, O'Farrell and colleagues (2004) report that partner violence was significantly reduced following cognitive-behavioral treatment.

Self-control training techniques, such as the Brief Motivational Intervention noted earlier, in which the goal of therapy is to get alcoholics to reduce alcohol intake without necessarily abstaining altogether, have a great deal of appeal for some drinkers. For example, one recent approach to improve drinking outcomes by altering the drinker's social networks was found to be successful (Litt et al., 2007) and motivational interviewing with adolescents was found to be promising (Macgowan & Engle, 2010). There is now even a computer-based self-control training program available that has been shown to reduce problem drinking in a controlled study (Fals-Stewart & Lam, 2010; Neighbors et al., 2004). It is difficult, of course, for individuals who are extremely dependent on the effects of alcohol to abstain totally from drinking. Thus many alcoholics fail to complete traditional treatment programs.

**CONTROLLED DRINKING VERSUS ABSTINENCE** Other psychological techniques have also received attention in recent years, partly because they are based on the hypothesis that some problem drinkers need not give up drinking altogether but rather can learn to drink moderately (Miller, Walters, & Bennett, 2001; Sobell & Sobell, 1995). Several approaches to learning controlled drinking have been attempted (McMurran & Hollin, 1993), and research has suggested that some alcoholics can learn to control their alcohol intake (Senft et al., 1997). Miller and colleagues (1986) evaluated the results of four long-term follow-up studies of controlled-drinking treatment programs. Although they found a clear trend of increased numbers of abstainers and relapsed cases at long-term follow-up, they also found that a consistent percentage (15 percent) of subjects across the four studies controlled their drinking. The researchers concluded that controlled drinking was more likely to be successful in persons with less severe alcohol problems. The finding that some individuals are able to maintain some control over their drinking after treatment (without remaining totally abstinent) was also reported in a classic study by Polich et al. (1981). These researchers found that 18 percent of the alcoholics they studied had reportedly been able to drink socially without problems during the 6-month follow-up of treatment.

Many people in the field have rejected the idea that alcohol abusers can learn to control their drinking, and some recent research has found that controlled drinking is not effective (Bottlender et al., 2007). And some groups, such as Alcoholics

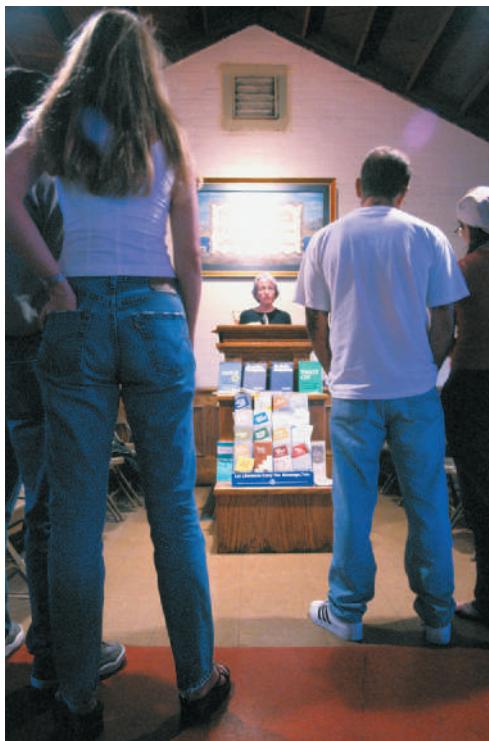

Anonymous, are adamant in their opposition to programs aimed at controlled drinking for alcohol-dependent individuals.

**ALCOHOLICS ANONYMOUS** A practical approach to alcoholism that has reportedly met with considerable success is that of Alcoholics Anonymous (AA). This organization was started in 1935 by two men, Dr. Bob and Bill W., in Akron, Ohio. Bill W. recovered from alcoholism through a “fundamental spiritual change” and immediately sought out Dr. Bob, who, with Bill’s assistance, also achieved recovery. They in turn began to help other alcoholics. Since that time, AA has grown to over 52,000 groups in the United States, with an annual growth rate of about 6 to 7 percent (Alcoholics Anonymous, 2007). In addition, there are nearly 5,000 AA groups in Canada and over 45,000 groups in many other countries.

Alcoholics Anonymous operates primarily as a self-help counseling program in which both person-to-person and group relationships are emphasized. AA accepts both teenagers and adults with drinking problems, has no dues or fees, does not keep records or case histories, does not participate in political causes, and is not affiliated with any religious sect, although spiritual development is a key aspect of its treatment approach. To ensure anonymity, only first names are used. Meetings are devoted partly to social activities, but they consist mainly of discussions of the participants’ problems with alcohol, often with testimonials from those who have stopped drinking. Such members usually contrast their lives before they broke their alcohol dependence with the lives they now live without alcohol. We should point out here that the term alcoholic is used by AA and its affiliates to refer either to persons who currently are drinking excessively or to people who have stopped drinking but must, according to AA philosophy, continue to abstain from alcohol consumption in the future. That is, in the AA view, one is an alcoholic for life, whether or not one is drinking; one is never “cured” of alcoholism but is instead “in recovery.”

An important aspect of AA’s rehabilitation program is that it appears to lift the burden of personal responsibility by helping alcoholics accept that alcoholism, like many other problems, is bigger than they are. Henceforth, they can see themselves not as weak willed or lacking in moral strength but rather simply as having an affliction—they cannot drink—just as other people may not be able to tolerate certain types of medication. Through mutual help and reassurance from group members who have had similar experiences, many alcoholics acquire insight into their problems, a new sense of purpose, greater ego strength, and more effective coping techniques. Continued participation in the group, of course, can help prevent the crisis of a relapse. Affiliated movements such as Al-Anon family groups and Alateen (which has over 35,000 groups in the United States and Canada) are designed to bring family members together to share experiences and problems, to gain understanding of the nature of alcoholism, and to learn techniques for dealing with their own problems living in a family with one or more affected individuals.

The reported success of Alcoholics Anonymous is based primarily on anecdotal information rather than on objective study of treatment outcomes because AA does not directly participate in external comparative research efforts. However, several studies have found AA conditions effective in helping people avoid drinking (Kelly, Stout et al., 2010). In a classic study, Brandsma and colleagues (1980) included an AA program in their extensive comparative study of alcoholism treatments. The success of this treatment method with severe alcoholics was found to be quite limited. Another important finding was that the AA method had high dropout rates compared with other therapies. About half of the people who go to AA drop out of the program within 3 months. Chappel (1993) attributes the very high dropout rate to alcoholics’ denial that they have problems, resistance to external pressure, and resistance to AA itself. Apparently many alcoholics are unable to accept the quasireligious quality of the sessions and the group-testimonial format that is so much a part of the AA program. In the Brandsma study, the participants who were assigned to the AA group subsequently encountered more life difficulties and drank more than the people in the other treatment groups. On the positive side, however, a study by Morganstern and colleagues (1997) reports that affiliation with AA after alcohol treatment was associated with better outcomes than without such involvement, and a study by Tonigan and colleagues (1995) found that AA involvement was strongly associated with success in outpatient samples.

These people are participating in an Alcoholics Anonymous (AA) meeting. AA accepts both teenagers and adults, has no dues or fees, does not keep records or case histories, does not participate in political causes, and is not affiliated with any religious sect, although spiritual development is a key aspect of its treatment approach. To ensure anonymity, only first names are used at meetings. AA is one of the most popular alcohol-treatment programs, promoting total abstinence rather than controlled drinking.

**OUTCOME STUDIES AND ISSUES IN TREATMENT** The outcome of treatment for alcohol-related disorders varies considerably, depending on the population studied and on the treatment facilities and procedures employed. Results range from low rates of success for hard-core substance abusers to recovery rates of 70 to 90 percent when modern treatment and aftercare procedures are used. Substance abusers who are also diagnosed as having a personality disorder or mood disorder tend to have poorer outcomes in alcohol treatment than those for whom the diagnosis is simply alcohol-abuse problems (Woelwer et al., 2001). Treatment is most likely to be effective when an individual realizes that she or he needs help, when adequate treatment facilities are available, and when the individual attends treatment regularly. Having a positive relationship with the therapist is also associated with better treatment outcome (Connors et al., 1997). One important treatment strategy is aimed at reinforcing treatment motivation and abstinence early in the treatment process by providing “check-up” follow-ups on drinking behavior. Miller and colleagues (1993) report that “Drinking Check-Up” sessions during the early stages of therapy resulted in a reduction of drinking in the first 6 weeks of therapy compared with clients who did not have check-up sessions.

Some researchers have maintained that treatment for alcohol-use and -abuse disorders would be more effective if important patient characteristics were taken into account (Mattson et al., 1994). That is, patients with certain personality characteristics or with differing degrees of severity might do better with one specific therapeutic approach rather than with another. This view was evaluated in a study of patient-treatment matching (referred to as “Project MATCH”) that was sponsored by the National Institute on Alcohol Abuse and Alcoholism (NIAAA, 1997). This extensive study, initiated in 1989, involved 1,726 patients who were treated in 26 alcohol-treatment programs in the United States by 80 different therapists representing three treatment approaches. The research design included both inpatient and outpatient treatment components. The results of this study were unexpected: Matching the patients to particular treatments did not appear to be important to having an effective outcome because the treatments studied all had equal outcomes. Gordis (1997) concludes that patients from competently run alcoholism-treatment programs will do as well in any of the three treatments studied.

**RELAPSE PREVENTION** One of the greatest problems in the treatment of addictive disorders is maintaining abstinence or self-control once the behavioral excesses have been checked (Tims et al., 2001). Most alcohol-treatment programs show high success rates in “curing” the addictive problems, but many programs show lessening rates of abstinence or controlled drinking at various periods of follow-up. Many treatment programs do not pay enough attention to maintaining effective behavior and preventing relapse into previous maladaptive patterns (Miller & Rollnick, 2003).

Given that alcohol-dependent people are highly vulnerable to relapse, some researchers have focused on the need to help
