them remain abstinent. In one cognitive-behavioral approach, relapse behavior is a key factor in alcohol treatment (Witkiewitz & Marlatt, 2007). One recent study (Nattala et al., 2010) found that relapse prevention treatment worked most effectively when family members were involved in the treatment.

The behaviors underlying relapse are seen as “indulgent behaviors” that are based on an individual’s learning history. When an individual is abstinent or has an addiction under control, she or he gains a sense of personal control over the indulgent behavior. The longer the person is able to maintain this control, the greater the sense of achievement—the self-efficacy or confidence—and the greater the chance that she or he will be able to cope with the addiction and maintain control. However, a person may violate this rule of abstinence through a gradual, perhaps unconscious, process rather than through the sudden “falling off the wagon” that constitutes the traditional view of craving and relapse. In the cognitive-behavioral view, a person may, even while maintaining abstinence, inadvertently make a series of mini-decisions that begin a chain of behaviors that render relapse inevitable. For example, an abstinent alcohol abuser who buys a quart of bourbon just in case his friends drop by is unconsciously preparing the way for relapse.

Another type of relapse behavior involves the “abstinence violation effect,” in which even minor transgressions are seen by the abstainer as having drastic significance. The effect works this way: An abstinent person may hold that she or he should not, under any circumstance, transgress or give in to the old habit. Abstinence-oriented treatment programs are particularly guided by this prohibitive rule. What happens, then, when an abstinent person becomes somewhat self-indulgent and takes a drink offered by an old friend or joins in a wedding toast? He or she may lose some of the sense of self-efficacy—confidence—needed to control his or her drinking. Feeling guilty about having technically violated the vow of abstinence, the person may rationalize that he or she “has blown it and become a drunk again, so why not go all the way?”

In *relapse prevention treatment*, clients are taught to recognize the apparently irrelevant decisions that serve as early warning signals of the possibility of relapse. High-risk situations such as parties or sports events are targeted, and the individuals

Appealing advertisements and displays that encourage drinking can make abstinence particularly difficult and can contribute, at the very least on a subconscious level, to a relapse.

learn to assess their own vulnerability to relapse. Clients are also trained not to become so discouraged that if they do relapse they lose their confidence. Some cognitive-behavioral therapists have even incorporated a “planned relapse” phase into the treatment. Research with relapse prevention strategies has shown them to be effective in providing continuing improvement over time (Rawson et al., 2002). In other words, when patients are taught to expect a relapse, they are better able to handle it.

### in review

- What is the difference between alcohol abuse and alcohol dependence?
- What are the major physiological effects of alcohol?
- Identify the physical, interpersonal, and social/occupational problems that can result from chronic alcohol use.
- What neurobiological processes underlie addiction?
- What are the five major psychosocial causal factors that may contribute to alcohol abuse and dependence?
- Describe four psychosocial interventions used to treat alcohol dependence.

## Drug Abuse and Dependence

Aside from alcohol, the psychoactive drugs most commonly associated with abuse and dependence in our society appear to be (1) narcotics such as opiates or opioids, including opium and heroin; (2) sedatives such as barbiturates; (3) stimulants such as cocaine and amphetamines; (4) antianxiety drugs such as benzodiazepines; (5) pain medications such as OxyContin (Whoriskey, 2013); (6) hallucinogens such as LSD (the effects of these and other drugs are summarized in Table 11.2); and (7) caffeine and nicotine, which are also drugs of dependence (disorders associated with tobacco withdrawal and caffeine intoxication are included in the *DSM-5* diagnostic classification system).

An estimated 20.1 million Americans who are 12 years of age or older reported using an illicit drug during the month before a recent survey. This represents 8.0 percent of the population (Substance Abuse and Mental Health Services Administration, 2009). According to the Monitoring the Future Study, in 2008 the annual prevalence rate of using any illicit drug was 37 percent for 12th graders, 35 percent for college students, 34 percent for 19- to 28-year-olds, 27 percent for

**TABLE 11.2**  
**Psychoactive Drugs Commonly Involved in Drug Abuse**

Classification	Drug	Effect
Sedatives	Alcohol (ethanol)	Reduce tension Facilitate social interaction “Blot out” feelings or events Reduce tension
	Barbiturates Nembutal (pentobarbital) Seconal (secobarbital) Veronal (barbital) Tuinal (secobarbital and amobarbital)	
Stimulants	Amphetamines Benzedrine (amphetamine) Dexedrine (dextroamphetamine) Methedrine (methamphetamine) Cocaine (coca)	Increase feelings of alertness and confidence  Decrease feelings of fatigue Stay awake for long periods Increase endurance Stimulate sex drive Alleviate physical pain Induce relaxation and pleasant reverie Alleviate anxiety and tension
	Opium and its derivatives Opium Morphine Codeine Heroin	
Hallucinogens	Methadone (synthetic narcotic) Cannabis Marijuana Hashish Mescaline (peyote) Psilocybin (psychedelic mushrooms) LSD (lysergic acid diethylamide-25) PCP (phencyclidine)	Treatment of heroin dependence Induce changes in mood, thought, and behavior  “Expand” one’s mind Induce stupor
	Librium (chlordiazepoxide) Miltown (meprobamate) Valium (diazepam) Xanax	Alleviate tension and anxiety Induce relaxation and sleep

Note: This list is by no means complete; for example, it does not include drugs such as Ritalin, which are designed to produce multiple effects; it does not include the less commonly used volatile hydrocarbons such as glue, paint thinner, gasoline, cleaning fluid, and nail polish remover, which are highly dangerous when sniffed for their psychoactive effects; and it does not include the antipsychotic and antidepressant drugs, which are abused, but relatively rarely. We shall deal with these and the antianxiety drugs in our discussion of drug therapy in Chapter 16.

10th graders, and 14 percent for 8th graders (Johnston et al., 2009). The extent of drug abuse in the population is likely to be underestimated because many abusers do not seek help (Compton et al., 2007). Although they may occur at any age, drug abuse and dependence are most common during adolescence and young adulthood (Campbell, 2010) and vary according to metropolitan area, race and ethnicity, labor force status, and other demographic characteristics (Hughes, 1992). Substance-abuse problems are relatively more prominent in economically depressed minority communities (Akins et al., 2003).

The extent to which drug abuse has become a problem for society is reflected in a study of drug involvement among applicants for employment at a large teaching hospital in Maryland (Lange et al., 1994). Beginning in 1989, and for a 2-year period, all applicants for employment were screened through a preemployment drug-screening program (individuals were not identified in the initial study). Of 593 applicants, 10.8 percent were found to have detectable amounts of illicit drugs in their systems. The most frequently detected drug was marijuana (55 percent of those who tested positively), followed by cocaine (36 percent) and opiates (28 percent).

The impact of drug use among employed people has also been reported to be significant. In an extensive survey of illegal drug use among 40,000 currently employed workers, researchers found the following rates of illicit drug use within the month prior to the survey: 19 percent for those age 18 or younger, 10.3 percent for those between 18 and 25, 7 percent for those between 26 and 34, 7 percent for those between 35 and 49, and 2.6 percent for those between 50 and 64 (Larson et al., 2007). The overall frequency of illegal drug use rate in this work sample was 8.2 percent. The high rate of drug use in this population (many reported actually using drugs on the job) is problematic. For example, among those workers who reported current illicit drug use, 12.3 percent reported that they had worked for three or more employers in the past year, compared with 5.1 percent for nonabusing workers.

Among people who abuse drugs, behavior patterns vary markedly depending on the type, amount, and duration of drug use; on the physiological and psychological makeup of the individual; and, in some instances, on the social setting in which the drug experience occurs. Thus it appears most useful to deal separately with some of the drugs that are more commonly associated with abuse and dependence in contemporary society.

## Opium and Its Derivatives (Narcotics)

**OPIUM** People have used opium and its derivatives for centuries. Galen (A.D. 130–201) considered theriaca, whose principal ingredient was opium, to be a panacea:

It resists poison and venomous bites, cures inveterate headache, vertigo, deafness, epilepsy, apoplexy, dimness of sight, loss of voice, asthma, coughs of all kinds, spitting of blood, tightness of breath, colic, the iliac poisons, jaundice, hardness of the spleen, stone, urinary complaints, fevers, dropsies, leprosies, the trouble to which women are subject,

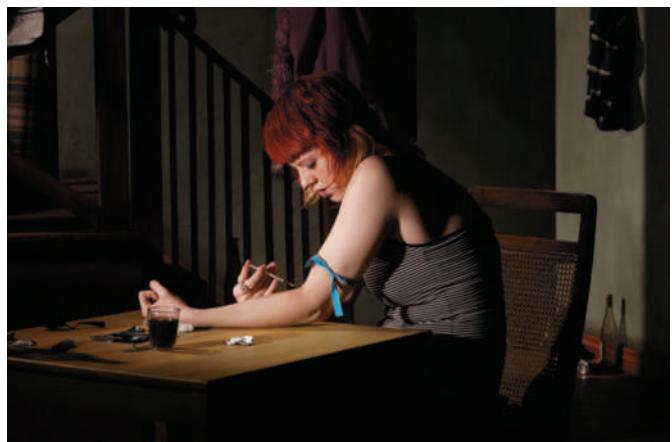

melancholy and all pestilences. (See Brock, 1979, for a discussion of Galen.)

Even today, opiates are still used for some of the conditions Galen mentioned.

**Opium** is a mixture of about 18 chemical substances known as alkaloids. In 1805, the alkaloid present in the largest amount (10 to 15 percent) was found to be a bitter-tasting powder that could serve as a powerful sedative and pain reliever; it was named **morphine** after Morpheus, the god of sleep in Greek mythology. The hypodermic needle was introduced in America around 1856, allowing morphine to be widely administered to soldiers during the Civil War—not only to those wounded in battle but also to those suffering from dysentery. As a consequence, many Civil War veterans returned to civilian life addicted to the drug, a condition euphemistically referred to as “soldier’s illness.”

Scientists concerned with the addictive properties of morphine hypothesized that one part of the morphine molecule might be responsible for its analgesic properties (that is, its ability to eliminate pain without inducing unconsciousness) and another for its addictiveness. At about the turn of the century, it was discovered that if morphine was treated with an inexpensive and readily available chemical called acetic anhydride, it would be converted into another powerful analgesic called **heroin**. Heroin was hailed enthusiastically by its discoverer, Heinrich Dreser (Boehm, 1968). Leading scientists of his time agreed on the merits of heroin, and the drug came to be widely prescribed in place of morphine for pain relief and related medicinal purposes. However, heroin was a cruel disappointment, for it proved to be an even more dangerous drug than morphine, acting more rapidly and more intensely and being equally, if not more addictive. Eventually, heroin was removed from use in medical practice.

As it became apparent that opium and its derivatives—including codeine, which is used in some cough syrups—were perilously addictive, the U.S. Congress enacted the Harrison Act in 1914. Under this and later legislation, the unauthorized sale and distribution of certain drugs became a federal offense;

The adolescent shown here is injecting the drug heroin—a dangerous and highly addictive substance that is widely available to adolescents today.

physicians and pharmacists were held accountable for each dose they dispensed. Thus, overnight, the role of a chronic narcotic user changed from that of addict—whose addiction was considered a vice, but was tolerated—to that of criminal. Unable to obtain drugs through legal sources, many turned to illegal channels, and eventually to other criminal acts, as a means of maintaining their suddenly expensive drug supply.

In one survey, about 2.4 million Americans acknowledged having tried heroin, and almost a quarter of a million people admitted to using it within the previous 12 months (U.S. Department of Health and Human Services, 1997). In 2005, heroin overdose accounted for 10 percent of all drug-abuse-related emergency room admissions (DAWN Report, 2010).

**BIOLOGICAL EFFECTS OF MORPHINE AND HEROIN** Morphine and heroin are commonly introduced into the body by smoking, snorting (inhaling the powder), eating, “skin popping,” or “mainlining,” the last two being methods of introducing the drug via hypodermic injection. Skin popping is injecting the liquefied drug just beneath the skin, while mainlining is injecting the drug directly into the bloodstream. In the United States, a young addict usually moves from snorting to mainlining.

Among the immediate effects of mainlined or snorted heroin is a euphoric spasm (the rush) lasting 60 seconds or so, which many addicts compare to a sexual orgasm. However, vomiting and nausea have also been known to be part of the immediate effects of heroin and morphine use. This rush is followed by a high, during which an addict typically is in a lethargic, withdrawn state in which bodily needs, including needs for food and sex, are markedly diminished; pleasant feelings of relaxation and euphoria tend to dominate. These effects last from 4 to 6 hours and are followed—in addicts—by a negative phase that produces a desire for more of the drug.

The use of opiates over a period of time generally results in a physiological craving for the drug. The time required to establish the drug habit varies, but it has been estimated that continual use over a period of 30 days is sufficient. Users then find that they have become physiologically dependent on the drug in the sense that they feel physically ill when they do not take it. In addition, users of opiates gradually build up a tolerance to the drug so increasingly larger amounts are needed to achieve the desired effects.

When people addicted to opiates do not get a dose of the drug within approximately 8 hours, they start to experience withdrawal symptoms. The character and severity of these reactions depend on many factors including the amount of the narcotic habitually used, the intervals between doses, the duration of the addiction, and especially the addict’s health and personality.

Withdrawal from heroin is not always dangerous or even very painful. Many addicted people withdraw without assistance. Withdrawal can, however, be an agonizing experience for some people, with symptoms including runny nose, tearing eyes, perspiration, restlessness, increased respiration rate, and an intensified desire for the drug. As time passes, the symptoms

may become more severe. Typically, a feeling of chilliness alternates with flushing and excessive sweating, vomiting, diarrhea, abdominal cramps, pains in the back and extremities, severe headache, marked tremors, and varying degrees of insomnia. Beset by these discomforts, an individual refuses food and water, and this, coupled with the vomiting, sweating, and diarrhea, results in dehydration and weight loss. Occasionally, symptoms include delirium, hallucinations, and manic activity. Cardiovascular collapse may also occur and can result in death. If morphine is administered, the subjective distress experienced by an addict temporarily ends and physiological balance is quickly restored.

Withdrawal symptoms are usually on the decline by the third or fourth day and by the seventh or eighth day have disappeared. As the symptoms subside, the person resumes normal eating and drinking and rapidly regains lost weight. After withdrawal symptoms have ceased, the individual’s former tolerance for the drug is reduced; as a result, there is a risk that taking the former large dosage might result in overdose.

**SOCIAL EFFECTS OF MORPHINE AND HEROIN** Typically, the life of a person addicted to opiates becomes increasingly centered on obtaining and using drugs, so the addiction usually leads to socially maladaptive behavior as the individual is eventually forced to lie, steal, and associate with undesirable contacts to maintain a supply of drugs. Many addicts resort to petty theft to support their habits, and some addicts turn to prostitution as a means of financing their addictions.

Along with the lowering of ethical and moral restraints, addiction has adverse physical effects on an individual’s well-being—for example, disruption of the immune system (Theodorou & Haber, 2005). Lifestyle factors can lead to further problems; an inadequate diet, for example, may lead to ill health and increased susceptibility to a variety of physical ailments. The use of unsterile equipment may also lead to various problems including liver damage from hepatitis (Lucey et al. 2009) and transmission of the AIDS virus. In addition, the use of such a potent drug without medical supervision and government controls to ensure its strength and purity can result in fatal overdose. Injection of too much heroin can cause coma and death. In fact, heroin-related deaths have shown an increase in cities where data are collected (DAWN Report, 2006) and among soldiers in Afghanistan where eight deaths were recorded from opiates in 2011 (Martinez, 2011). The most common drug-related deaths in the United States involve combinations of heroin, cocaine, and alcohol. Women who use heroin during pregnancy subject their unborn children to the risk of dire consequences. One tragic outcome is premature babies who are themselves addicted to heroin and vulnerable to a number of diseases.

Addiction to opiates usually leads to a gradual deterioration of well-being (Brown & Lo, 2000). For example, some research has shown that opiates actively alter the immune system, rendering the person vulnerable to organ damage (McHugh & Kreek, 2004). The ill health and general personality degeneration often found in opiate addiction do not always result directly from

the pharmacological effects of the drug, however; rather, they are often products of the sacrifices of money, proper diet, social position, and self-respect as an addict becomes more desperate to procure the required daily dosage.

### CAUSAL FACTORS IN OPIATE ABUSE AND DEPENDENCE

No single causal pattern fits all addictions to opiate drugs.

Kendler and Sundquist (2012) recently reported that drug abuse is etiologically complex involving both genetic and environmental influences. A study by Fulmer and Lapidus (1980) concludes that the three most frequently cited reasons for beginning to use heroin were pleasure, curiosity, and peer pressure. Pleasure was, by far, the single most widespread reason—given by 81 percent of addicts. Other reasons such as a desire to escape life stress, personal maladjustment, and sociocultural conditions also play a part. Zuckerman (2007) provided the view that substance abuse such as smoking, drinking, and the use of drugs are all related to a personality characteristic he refers to as “sensation seeking.” He considered this trait to be mediated through genetic and biological mechanisms as well as through peer influences.

**NEURAL BASES FOR PHYSIOLOGICAL ADDICTION** Research teams have isolated and studied receptor sites for narcotic drugs in the brain (Goldstein et al., 1974). Such receptor sites are specific nerve cells into which given psychoactive drugs fit like keys into the proper locks. This interaction of drug and brain cells apparently results in a drug’s action and, in the case of narcotic drugs, may lead to addiction. The repeated use of opiates results in changes in the neurotransmitter systems that regulate incentive and motivation and the ability to manage stress (DeVries & Shippenberg, 2002). Research has demonstrated that heroin users show a number of CNS dysfunctions including slowed reaction time, impaired learning and attention, impaired cognitive processing, and impulse control problems (Angelucci et al., 2007).

The human body produces its own opium-like substances, called **endorphins**, in the brain and pituitary gland. These substances are produced in response to stimulation and are believed to play a role in an organism’s reaction to pain. Some investigators have suspected that endorphins play a role in drug addiction, speculating that chronic underproduction of endorphins leads to a craving for narcotic drugs. Research on the role of endorphins in drug addiction has generally been inconclusive, and no effective treatment has resulted from this line of research.

### ADDICTION ASSOCIATED WITH PSYCHOPATHOLOGY

A high incidence of antisocial personality has been found among heroin addicts (Alterman, et al., 1998; Feske et al., 2006). In a comparison between a group of 45 young institutionalized male addicts and a control group of nonaddicts, Gilbert and Lombardi (1967) found that the distinguishing features were “the addict’s antisocial traits, his depression, tension, insecurity, and feelings of inadequacy, and his difficulty in forming warm and lasting interpersonal relationships” (p. 536). Meyer and Mirin (1979) found that opiate addicts are highly impulsive and unable to delay gratification. Kosten and Rounsaville (1986) reported that about 68 percent of heroin abusers are also diagnosed as having a personality disorder. As in the case of alcoholism, however, it is essential to exercise caution in distinguishing between personality traits present before and those present after addiction; the high incidence of psychopathology among narcotics addicts may in part result from, rather than precede, the long-term effects of addiction.

### DRUG USE ASSOCIATED WITH SOCIOCULTURAL FACTORS

In our society, a so-called narcotics subculture exists in which addicts can obtain drugs and protect themselves against society’s sanctions (Johnson, 2007). The decision to join this culture has important future implications, for from that point on, addicts’ activities will revolve around their drug-user role. In short,

Celebrities Lindsay Lohan and Paris Hilton have received jail terms for substance-related driving offenses.

addiction becomes a way of life. In a survey of three large cities in Texas, Maddux and colleagues (1994) found that the majority of illicit drug injectors were undereducated and unemployed individuals from minority groups.

With time, most young addicts who join the drug culture become increasingly withdrawn, indifferent to their friends (except those in the drug group), and apathetic about sexual activity (Tremble et al., 1994). They are likely to abandon scholastic and athletic endeavors and to show a marked reduction in competitive and achievement strivings. Most of these addicts appear to lack clear sex-role identification and to experience feelings of inadequacy when confronted with the demands of adulthood. They feel progressively isolated from the broader culture, but their feelings of group belongingness are bolstered by continued association with the addict milieu. At the same time, they come to view drugs both as a means of revolt against authority and conventional values and as a device for alleviating personal anxieties and tensions.

**TREATMENTS AND OUTCOMES** Treatment for opiate addiction is initially similar to that for alcoholism in that it involves building up an addict both physically and psychologically and providing help through the withdrawal period. Addicts often dread the discomfort of withdrawal, but in a hospital setting it is less abrupt and usually involves the administration of medication that eases the distress.

After physical withdrawal has been completed, treatment focuses on helping a former addict make an adequate adjustment to his or her community and abstain from the further use of opiates. Traditionally, however, the prognosis has been unfavorable, with many clients dropping out of treatment (Katz et al., 2004). Withdrawal from heroin does not remove the craving for the drug. Thus a key target in treatment of heroin addiction must be the alleviation of this craving. One approach to dealing with the physiological craving for heroin was pioneered by a research team at Rockefeller University in New York. It involved the use of the drug **methadone** in conjunction with a rehabilitation program (counseling, group therapy, and other procedures) directed toward the “total resocialization” of addicts. Methadone hydrochloride is a synthetic narcotic that is related to heroin and is equally addictive physiologically. Its usefulness in treatment lies in the fact that it satisfies an addict’s craving for heroin without producing serious psychological impairment, if only because it is administered as a “treatment” in a formal clinical context and can result in reduced drug use and improved cognitive performance (Gruber et al., 2006; Kreek et al., 2010). (See the Unresolved Issues section at the end of this chapter.)

Other medications, such as buprenorphine, have also been used to treat heroin addiction (Meier & Patkar, 2007). Buprenorphine promises to be as effective a substitute for heroin as methadone but with fewer side effects (Ling et al., 2010). It operates as a partial antagonist to heroin and produces the feelings of contentment associated with heroin use (Mendelson &

Mello, 1992). Yet the drug does not produce the physical dependence that is characteristic of heroin (Grant & Sonti, 1994) and can be discontinued without severe withdrawal symptoms. Like methadone, buprenorphine appears to work best at maintaining abstinence if it is provided along with behavior therapy (Bickel et al., 1997).

## Cocaine and Amphetamines (Stimulants)

In contrast to narcotics, which depress (slow down) the action of the CNS, cocaine and amphetamines stimulate it (speed it up).

**COCAINE** Like opium, **cocaine** is a plant product discovered in ancient times and used ever since. It was widely used in the pre-Columbian world of Mexico and Peru (Guerra, 1971). Because for many years it was typically very costly in the United States, cocaine was considered as the “high” for the affluent. However, with more widespread availability and lowering of prices, the drug’s use increased significantly in the United States during the 1980s and 1990s—to the point where its use was considered epidemic, especially among middle- and upper-income groups. “Crack” is the street name that is applied to cocaine that has been processed from cocaine hydrochloride to a free base for smoking. The name refers to the crackling sound emitted when the mixture is heated.

In 2008, cocaine use was reported in 1.5 percent of young adults (Substance Abuse and Mental Health Services Administration, 2009). In 2005, there was a substantial increase in cocaine-related emergency room visits per 100,000 drug-related admissions (about 29 percent of drug-related emergencies). This amount is about three times greater than heroin-related admissions (DAWN Report, 2010).

Like the opiates, cocaine may be ingested by sniffing, swallowing, or injecting. Also like the opiates, it precipitates a euphoric state of 4 to 6 hours’ duration, during which a user experiences feelings of confidence and contentment. However, this blissful state may be preceded by headache, dizziness, and restlessness. When cocaine is chronically abused, acute toxic psychotic symptoms may occur, including frightening visual, auditory, and tactual hallucinations similar to those in acute schizophrenia.

Unlike the opiates, cocaine stimulates the cortex of the brain, inducing sleeplessness and excitement as well as stimulating and accentuating sexual feelings. Dependence on cocaine also differs somewhat from dependence on opiates. It was formerly believed that tolerance was not increased appreciably with cocaine use. However, acute tolerance has now been demonstrated, and some chronic tolerance may occur as well. Moreover, cognitive impairment associated with cocaine abuse is likely to be an important consideration in long-term effects of the drug (Abi-Saab et al., 2005; Mann, 2004). The previous view that cocaine abusers did not develop physiological dependence on the drug also has changed. Gawin and Kleber (1986) demonstrated that chronic abusers who become abstinent develop uniform, depression-like symptoms, but the symptoms are transient. Our

broadened knowledge about cocaine abuse, particularly with respect to the many health and social problems resulting from dependence on the drug, has resulted in considerable modification of professional views of cocaine over the past 20 years. For example, the modifications in the *DSM-5* diagnostic classification reflect a significant increase in our knowledge of cocaine's addictive properties. A new disorder is described—cocaine withdrawal—that involves symptoms of depression, fatigue, disturbed sleep, and increased dreaming (Foltin & Fischman, 1997). The psychological and life problems experienced by cocaine users are often great. Employment, family, psychological, and legal problems are all more likely to occur among cocaine and crack users than among nonusers. Many life problems experienced by cocaine abusers result in part from the considerable amounts of money that are required to support their habits. Increased sexual activity, often trading sex for drugs, has been associated with crack cocaine use (Weatherby et al., 1992), as has engaging in sexual activity with anonymous partners (Balshem et al., 1992). However, problems in sexual functioning have been reported to be associated with crack cocaine use. Kim and colleagues (1992) report that most users lose interest in sex and develop sexual dysfunction with prolonged usage.

Women who use cocaine when they are pregnant place their babies at risk for both health and psychological problems. Although research has suggested that there is no "fetal crack syndrome" similar to what has been shown with alcohol-abusing mothers (Azar, 1997), children of crack-using mothers are at risk of being maltreated as infants as well as of losing their mothers during infancy. Wasserman and Leventhal (1993) studied a group of cocaine-exposed children and a control sample of non-exposed children for a 24-month period following their birth. They found that children who were regularly exposed to cocaine *in utero* were more likely to be mistreated (23 percent compared with only 4 percent of controls).

**TREATMENT AND OUTCOMES** Treatment for dependence on cocaine does not differ appreciably from that for other drugs that involve physiological dependence (see Kosten et al., 1992; Schmitz et al., 2004). In order to reduce cravings as part of psychological therapy and to ensure treatment compliance, drugs such as naltrexone have been used to reduce cocaine use (Carroll et al., 2004). The feelings of tension and depression that accompany absence of the drug have to be dealt with during the immediate withdrawal period. One recent study reported that methadone was effective in promoting abstinence among individuals with less severe cocaine use (Weinstock et al., 2010).

Some success in the treatment of cocaine abusers has been reported. For example, Siqueland and colleagues (2002) found that patients who remained in drug treatment longer used drugs less often after treatment than those who dropped out; and Stewart, Gossop, and Marsden (2002) found that patients who completed therapy had lower rates of drug overdose than those who failed to complete treatment. Carroll and colleagues (1993)

have shown that many cocaine abusers do well in maintaining treatment goals, and one-third are abstinent at a 12-month follow-up. They found several factors associated with poorer outcomes: severity of abuse, poorer psychiatric functioning, and presence of concurrent alcoholism. Higgins, Badger, and Budney (2000) found that people who were not able to sustain abstinence during the treatment had poorer outcomes following therapy.

One of the problems clinicians face in working with cocaine abusers is their "dropping out": Only 42 percent of those in one study remained in treatment for six or more sessions (Kleinman et al., 1992). Another problem encountered in drug treatment is that many of the cocaine-dependent patients have severe antisocial personality disorder—a situation resulting in treatment resistance (Poling et al., 2007)—or are "psychosis-prone" personalities (Kwapil, 1996). Arndt and colleagues (1994) found that cocaine-dependent patients with antisocial personality characteristics made few therapeutic gains, whereas those without antisocial features made significant progress. Gallop and colleagues (2007) report a study in which gender differences were found for being able to maintain abstinence from cocaine use; men tended to have more problems transitioning to abstinence after cocaine abuse.

Is treatment always necessary for cocaine abusers to recover? An interesting study suggests that some abusers can improve without therapy. Toneatto and colleagues (1999) describe a study of natural (nontreated) recovery among cocaine abusers. They report that abusers who resolved their dependence on cocaine were similar to those who did not resolve their cocaine problems in terms of demographic characteristics, substance abuse, and psychiatric history. The successful abstainers considered their "improved self-concept" crucial to their success.

**AMPHETAMINES** The earliest **amphetamine** to be introduced—Benzedrine, or amphetamine sulfate—was first synthesized in 1927 and became available in drugstores in the early 1930s as an inhalant to relieve stuffy noses. However, the manufacturers soon learned that some customers were chewing the wicks in the inhalers for "kicks." Thus the stimulating effects of amphetamine sulfate were discovered by the public before the drug was formally prescribed as a stimulant by physicians. In the late 1930s, two newer amphetamines were introduced—Dexedrine (dextroamphetamine) and Methedrine (methamphetamine hydrochloride, also known as "speed"). The latter preparation is a far more potent stimulant of the CNS than either Benzedrine or Dexedrine and hence is considered more dangerous. In fact, its abuse can be lethal.

Initially these preparations were considered to be "wonder pills" that helped people stay alert and awake and function temporarily at a level beyond normal. During World War II, military interest was aroused in the stimulating effects of these drugs, and they were used by both Allied and German soldiers to ward off fatigue (Jarvik, 1967). Similarly, among civilians,

amphetamines came to be widely used by night workers, long-distance truck drivers, students cramming for exams, and athletes striving to improve their performances. It was also discovered that amphetamines tend to suppress appetite, and they became popular with people trying to lose weight. In addition, they were often used to counteract the effects of barbiturates or other sleeping pills that had been taken the night before. As a result of their many uses, amphetamines were widely prescribed by doctors.

Today amphetamines are occasionally used medically for curbing the appetite when weight reduction is desirable; for treating individuals suffering from narcolepsy, a disorder in which people cannot prevent themselves from continually falling asleep during the day; and for treating hyperactive children. Curiously enough, amphetamines have a calming rather than a stimulating effect on many of these young people. Amphetamines are also sometimes prescribed for alleviating mild feelings of depression, relieving fatigue, and maintaining alertness for sustained periods of time. By far, however, the most frequent use of amphetamines is for recreational purposes, the most typical user being a young person interested in the high that the drug induces (Klee, 1998).

Since the passage of the Controlled Substance Act of 1970 (Drug Enforcement Administration, 1979), amphetamines have been classified as Schedule II controlled substances—that is, drugs with high abuse potential that require a prescription for each purchase. As a result, medical use of amphetamines has declined in the United States in recent years, and they are more difficult to obtain legally. However, it is often easy to find illegal sources of amphetamines, which thus remain among the most widely abused drugs. Amphetamines are among the most widely used illicit drugs in other countries as well, for example, in Australia (Lintzeris, Holgate et al., 1996). In 2007, about 5 percent of drug-related emergency room visits involved amphetamines or methamphetamine (DAWN Report, 2010).

**EFFECTS OF AMPHETAMINE ABUSE** Despite their legitimate medical uses, amphetamines are not a magical source of extra mental or physical energy. Instead, they push users toward greater expenditures of their own resources—often to the point of hazardous fatigue. Amphetamines are psychologically and physically addictive, and the body rapidly builds up tolerance to them (Wise, 1996). Thus habituated abusers may use the drugs in amounts that would be lethal to nonusers. In some instances, users inject the drug to get faster and more intense results.

For a person who exceeds prescribed dosages, amphetamine consumption results in heightened blood pressure, enlarged pupils, unclear or rapid speech, profuse sweating, tremors, excitability, loss of appetite, confusion, and sleeplessness. Injected in large quantities, Methedrine can raise blood pressure enough to cause immediate death. In addition, chronic abuse of amphetamines can result in brain damage and a wide range of psychopathology, including a disorder known as “amphetamine psychosis,” which appears similar to paranoid schizophrenia.

Suicide, homicide, assault, and various other acts of violence are also associated with amphetamine abuse.

**TREATMENTS AND OUTCOMES** Research on the effectiveness of various treatments for withdrawing patients from amphetamines is scarce (Baker & Lee, 2003). Although withdrawal from amphetamines is usually safe, some evidence suggests that physiological dependence upon the drug is an important factor to consider in treatment (Wise & Munn, 1995). In some instances, abrupt withdrawal from the chronic, excessive use of amphetamines can result in cramping, nausea, diarrhea, and even convulsions. Moreover, abrupt abstinence commonly results in feelings of weariness and depression. The depression usually peaks in 48 to 72 hours, often remains intense for a day or two, and then tends to lessen gradually over a period of several days. Mild feelings of depression and lassitude may persist for weeks or even months. If brain damage has occurred, the residual effects may include impaired ability to concentrate, learn, and remember, with resulting social, economic, and personality deterioration.

## Methamphetamine

Methamphetamine, referred to on the streets as “crystal” or “ice” because of its appearance, is a highly addictive stimulant drug that can provide a quick and long-lasting “high.” However, it is one of the most dangerous illegal drugs because of its treacherous properties and its unwelcome results (Covey, 2007).

Methamphetamine is a form of amphetamine that can be “cooked” in large quantities in makeshift laboratories in out-of-the-way places that defy and frustrate detection. This drug is relatively cheap to manufacture and is often referred to as “poor people’s cocaine.” It can be manufactured, for example, in a portable cooler with ingredients that can be legally obtained from any drugstore. The drug can be ingested in a variety of ways, through smoking, snorting, swallowing, or injecting. The drug’s effects can be almost instantaneous if it is smoked or injected.

Methamphetamine operates by increasing the level of dopamine in the brain, and prolonged use of the drug produces structural changes in the brain (Chang, Alicata et al., 2007). The severity of psychiatric symptoms associated with the drug is significantly related to the duration of use (Yoshimoto et al., 2002).

Methamphetamine, known as “crystal” or “ice,” can be “cooked” in large quantities in makeshift laboratories. The man shown in this photo was arrested in a police raid on one such laboratory.

## Can changes to the diagnostic criteria result in increased drug use?

DSM-5

There are a number of modifications in the way some disorders are diagnosed in *DSM-5* that will likely influence medical treatment with many more patients being treated with stimulant drugs. One of these modified disorders, Attention Deficit/Hyperactivity Disorder or ADHD (see Chapter 15 for details), results in an expanded population of patients who can receive this diagnosis across the adult years. Although, the diagnostic criteria for ADHD in *DSM-5* are similar to those in *DSM-IV* for young people, several changes have been introduced in *DSM-5* that expands the application among adults. This change will likely result in many more adults being treated with prescription drugs for ADHD symptoms.

One of the most popular treatments for ADHD in children and adolescents is the drug Methylphenidate (Morton, Gwendolyn, & Stockton, 2000), classified as a CNS stimulant.

Methylphenidate, when used intranasally, has receptor effects similar to those of cocaine. These frequently prescribed drugs (Ritalin, Adderall, and Quillivant) are also FDA approved for treatment of adults. The side effects of these medications can result in long-term problems such as sleep problems, headaches, decreased appetite and jitteriness. Moreover, Methylphenidate drugs are addicting and can result in long-term use.

The concern over expanded medication use and potential for abuse has been raised by Batstra & Frances (2012) in their review of the *DSM-5* committee's changes. They pointed out that *DSM-5* will likely trigger a fad of diagnosing Adult Attention Deficit Disorder and lead to widespread misuse of stimulant drugs for performance enhancement and recreation use and will contribute substantially to the already extensive problem of stimulant abuse.

Moreover, discontinuing the drug after the person has become habituated can result in problems with learning, memory, and cognitive dysfunction (Cretzmeyer et al., 2003; Rothman et al., 2000) and severe mental health problems such as paranoid thinking and hallucinations (Brecht et al., 2004; Srisurapanont et al., 2003). This drug is metabolized more slowly than other drugs such as cocaine and produces a high for a longer period of time. When the drug wears off or when users "come down from the high," they are likely to feel extremely weak, lethargic, sleepy, and depressed.

Use of the drug increased substantially during the 1990s; 4.9 million people in the United States (2.3 percent of the population) had tried methamphetamine by 1998 (NIDA, 2003). In one survey of almost 630,000 high school students, Oetting and colleagues (2000) report that methamphetamine use more than doubled between 1989 and 1996. The number of people starting to use methamphetamine decreased in 2008 and was significantly lower than it was in 2007 (Substance Abuse and Mental Health Services Administration, 2009). Interestingly, the use of methamphetamine in the United States has been somewhat of a regional phenomenon; most use has occurred in the Southwest, on the West Coast, and in Hawaii, with very little use in the North, South, and Midwest (DAWN, 2007). This situation results from the fact that meth labs have been concentrated in Mexico, California, and Hawaii.

There is some evidence that people become more quickly addicted to methamphetamine and require treatment sooner than those using cocaine (Castro et al., 2000). Addicted methamphetamine users are highly resistant to treatment, and post-treatment relapse is common. In one California study of 98 methamphetamine abusers, the investigators reported that over

half of the participants had returned to methamphetamine use by the time they were interviewed 2 to 3 years following therapy; 36 percent reported that they had returned to methamphetamine use within 6 months of therapy (Brecht et al., 2000).

### Barbiturates (Sedatives)

For over a hundred years, powerful sedatives called **barbiturates** have been available as an aid to falling asleep (Lopez-Munoz et al., 2005). Although barbiturates have legitimate medical uses, they are extremely dangerous drugs commonly associated with both physiological and psychological dependence and lethal overdoses.

**EFFECTS OF BARBITURATES** Barbiturates were once widely used by physicians to calm patients and induce sleep. They act as depressants—somewhat like alcohol—to slow down the action of the CNS (Nemeroff, 2003) and significantly reduce performance on cognitive tasks (Pickworth et al., 1997). Shortly after taking a barbiturate, or "downer," an individual experiences a feeling of relaxation in which tensions seem to disappear, followed by a physical and intellectual lassitude and a tendency toward drowsiness and sleep—the intensity of such feelings depends on the type and amount of barbiturate taken. Strong doses produce sleep almost immediately; excessive doses are lethal because they result in paralysis of the brain's respiratory centers. Impaired decision making and problem solving, sluggishness, slow speech, and sudden mood shifts are also common effects of barbiturates (Lemmer, 2007).

Excessive use of barbiturates leads to increased tolerance as well as to physiological and psychological dependence. It can also lead to brain damage and personality deterioration. Unlike tolerance

for opiates, tolerance for barbiturates does not increase the amount needed to cause death. This means that users can easily ingest fatal overdoses, either intentionally or accidentally.

### CAUSAL FACTORS IN BARBITURATE ABUSE AND DEPENDENCE

Although many young people experiment with barbiturates, most do not become dependent. In fact, the people who do become dependent on barbiturates tend to be middle-aged and older people who often rely on them as “sleeping pills” and who do not commonly use other classes of drugs (except possibly alcohol and minor tranquilizers). These people have been referred to as “silent abusers” because they take the drugs in the privacy of their homes and ordinarily do not become public nuisances. Barbiturates are often used with alcohol. Some users claim they can achieve an intense high by combining barbiturates, amphetamines, and alcohol. However, one possible effect of combining barbiturates and alcohol is death because each drug potentiates (increases the action of) the other.

**TREATMENTS AND OUTCOMES** As with many other drugs, it is often essential in treatment to distinguish between barbiturate intoxication, which results from the toxic effects of overdose, and the symptoms associated with drug withdrawal, because different procedures are required. With barbiturates, withdrawal symptoms are more dangerous, severe, and long-lasting than in opiate withdrawal. A patient going through barbiturate withdrawal becomes anxious and apprehensive and manifests coarse tremors of the hands and face; additional symptoms commonly include insomnia, weakness, nausea, vomiting, abdominal cramps, rapid heart rate, elevated blood pressure, and loss of weight. An acute delirious psychosis may develop.

For persons accustomed to taking large dosages, withdrawal symptoms may last for as long as a month, but usually they tend to abate by the end of the first week. Fortunately, the withdrawal symptoms in barbiturate addiction can be minimized by administering increasingly smaller doses of the barbiturate itself or another drug that produces similar effects. The withdrawal program is still a dangerous one, however, especially if barbiturate addiction is complicated by alcoholism or dependence on other drugs.

## Hallucinogens: LSD and Related Drugs

The **hallucinogens** are drugs that are thought to induce hallucinations. However, these preparations usually do not in fact “create” sensory images but distort them so that an individual sees or hears things in different and unusual ways. These drugs are often referred to as psychedelics. The major drugs in this category are LSD (lysergic acid diethylamide) or “acid,” mescaline, and psilocybin.

**LSD** The most potent of the hallucinogens, the odorless, colorless, and tasteless drug **LSD** can produce intoxication with an amount smaller than a grain of salt. It is a chemically synthesized substance first discovered by the Swiss chemist Albert Hoffman

in 1938. Hoffman was not aware of the potent hallucinatory qualities of LSD until he swallowed a small amount. This is his report of the experience:

*Last Friday, April 16, 1943, I was forced to stop my work in the laboratory in the middle of the afternoon and to go home, as I was seized by a peculiar restlessness associated with a sensation of mild dizziness. On arriving home, I lay down and sank into a kind of drunkenness which was not unpleasant and which was characterized by extreme activity of imagination. As I lay in a dazed condition with my eyes closed (I experienced daylight as disagreeably bright) there surged upon me an uninterrupted stream of fantastic images of extraordinary plasticity and vividness and accompanied by an intense kaleidoscope-like play of colors. This condition gradually passed off after about 2 hours. (Hoffman, 1971, p. 23)*

Hoffman followed up this experience with a series of planned self-observations with LSD, some of which he described as “harrowing.” Researchers thought LSD might be useful for the induction and study of hallucinogenic states or “model psychoses,” which were thought to be related to schizophrenia. About 1950, LSD was introduced into the United States for purposes of such research and to ascertain whether it might have medical or therapeutic uses. Despite considerable research, however, LSD did not prove to be therapeutically useful.

After taking LSD, a person typically goes through about 8 hours of changes in sensory perception, mood swings, and feelings of depersonalization and detachment. The LSD experience is not always pleasant. It can be extremely traumatic, and the distorted objects and sounds, the illusory colors, and the new thoughts can be menacing and terrifying. For example, while under the influence of LSD, a British law student tried to continue time by using a dental drill to bore a hole in his head (Rorvik, 1970). In other instances, people undergoing bad trips have set themselves aflame, jumped from high places, and taken other drugs that proved lethal in combination with LSD.

An interesting and unusual phenomenon that may occur sometime following the use of LSD is the **flashback**, an involuntary recurrence of perceptual distortions or hallucinations weeks or even months after the individual has taken the drug. Flashbacks appear to be relatively rare among people who have taken LSD only once—although they do sometimes occur. Even if no flashbacks occur, one study found that continued effects on visual function were apparent at least 2 years after LSD use. In this study, Abraham and Wolf (1988) report that individuals who had used LSD for a week had reduced visual sensitivity to light during dark adaptation and showed other visual problems compared with controls.

Although the widespread use of LSD during the 1960s and 1970s has waned in recent years with the availability of other drugs, it is still used among young people associated with the “rave culture” or club scene. One recent study reported that in a sample of 782 youths in treatment for substance abuse, 42 percent had used LSD (Hopfer et al., 2006).

**MESCALINE AND PSILOCYBIN** Two other hallucinogens are **mescaline**, which is derived from the small, disc-like growths (mescal buttons) at the top of the peyote cactus, and **psilocybin**, which is obtained from a variety of “sacred” Mexican mushrooms known as *Psilocybe mexicana*. These drugs have been used for centuries in the ceremonial rites of Native peoples living in Mexico, the American Southwest, and Central and South America. In fact, they were used by the Aztecs for such purposes long before the Spanish invasion. Both drugs have mind-altering and hallucinogenic properties, but their principal effect appears to be enabling an individual to see, hear, and otherwise experience events in unaccustomed ways—transporting him or her into a realm of “non-ordinary reality.” As with LSD, no definite evidence shows that mescaline and psilocybin actually “expand consciousness” or create new ideas; rather, they mainly alter or distort experience.

## Ecstasy

The drug **Ecstasy**, or MDMA (3,4-methylenedioxymethylamphetamine), is both a hallucinogen and a stimulant that is popular as a party drug among young adults. The drug was originally patented in 1914 by the pharmaceutical company Merck, supposedly to be sold as a diet pill, but the company decided against marketing the drug because of its side effects. The drug was further evaluated and tested during the 1970s and 1980s as a potential medication for use in psychological treatment for a wide range of conditions such as posttraumatic stress, phobias, psychosomatic disorders, depression, suicidality, drug addiction, and relationship difficulties (Grob, 2000). However, its value in this capacity was not supported. At present, this drug is considered a “dangerous” drug and is listed in the most restricted category by the Drug Enforcement Administration (Murray, 2001). It is currently available in the United States only through illicit means.

Ecstasy is chemically similar to methamphetamine and to the hallucinogen mescaline and produces effects similar to those of other stimulants, although some research has suggested that the

The Ecstasy drug (MDMA—3,4-methylenedioxymethylamphetamine) is taken in pill form and is often used at “raves” or nightclubs to enhance mood. Ecstasy is an illegal substance, and manufacturers do not follow regulation and quality control.

drug's hallucinogenic properties exceed those of mescaline (Kovar, 1998; Parrott & Stuart, 1997). Usually about 20 minutes after ingesting Ecstasy (typically in pill form), the person experiences a “rush” sensation followed by a feeling of calmness, energy, and well-being. The effects of Ecstasy can last for several hours. People who take the drug often report an intense experience of color and sound and mild hallucinations (Fox et al., 2001; Lieb et al., 2002; Soar et al., 2001) in addition to the high levels of energy and excitement that are produced. The drug MDMA is an addictive substance, but it is not thought to be as addictive as cocaine (Degenhardt et al., 2010). Use of the drug is accompanied by a number of adverse consequences such as nausea, sweating, clenching of teeth, muscle cramps, blurred vision, and hallucinations (Parrott, 2001).

Ecstasy has been used increasingly among college students and young adults as a party enhancement or “rave” drug at dances (Hopfer et al., 2006). In a survey of 14,000 college students, Strote and colleagues (2002) found that between 1997 and 1999, Ecstasy use increased 69 percent, from 2.8 percent to 4.7 percent. Ecstasy reportedly grew in use among 8th, 10th, and 12th graders, as noted by the Monitoring the Future study, in which nearly 5 percent of 10th and 12th graders and about 2 percent of 8th graders reportedly had used MDMA in the past year. In a recent survey of Americans over the age of 12, .02 percent of the sample reported using Ecstasy (Substance Abuse and Mental Health Services Administration, 2009).

As with many other illicit drugs, the recreational use of Ecstasy has been associated with personality characteristics of impulsivity and poor judgment (Morgan, 1998). Ecstasy users have been found to be more likely to use marijuana, engage in binge drinking, smoke cigarettes, and have multiple sexual partners (Strote et al., 2002). However, Ecstasy use is also found among naïve partygoers who are provided the drug as a means of staying awake while socializing (Boys et al., 2001).

The negative psychological and health consequences (including death) of using Ecstasy have been widely reported in the literature. One study reported on the case of a 21-year-old man who developed panic disorder after taking Ecstasy (Windhaber et al., 1998); in another case study, an 18-year-old woman reportedly developed a prolonged psychosis after a single recreational use of Ecstasy (Van Kampen & Katz, 2001). The use of Ecstasy has also been found to be associated with memory impairment (Parrott et al., 1998) and obstructive sleep apnea (Chamberlin & Saper, 2009; McCann et al. 2009). Severe organic brain problems have also been reported. Granato and colleagues (1997) describe a case in which a 20-year-old male suffered from cerebrovascular injury after taking Ecstasy. The youth went into a coma about a minute or so after taking the drug. Upon awakening, he was found to have dissociation, delirium, visual hallucinations, and poor memory for past events. Subsequent examination showed damage to his frontal lobes and his right temporal lobe. Ecstasy users have consistently shown memory deficits (Roberts et al., 2009). A recent study by Schilt and colleagues (2010) found long-term harmful neurological

effects in middle-aged Ecstasy users. Moderate to heavy Ecstasy users showed moderate memory loss compared to controls.

## Marijuana

**Marijuana** comes from the leaves and flowering tops of the hemp plant, *Cannabis sativa*, which grows in mild climates throughout the world. In its prepared state, marijuana consists chiefly of dried green leaves—hence the colloquial name grass. It is ordinarily smoked in the form of cigarettes (variously referred to as “pot,” “reefers,” “joints,” “stash,” “weed,” etc.) or in pipes. In some cultures the leaves are steeped in hot water and the liquid is drunk, much as one might drink tea. Marijuana is related to a stronger drug, **hashish**, which is derived from the resin exuded by the cannabis plant and made into a gummy powder. Hashish, like marijuana, is usually smoked. Although marijuana can be considered a mild hallucinogen, there are significant differences between the nature, intensity, and duration of its effects and those induced by drugs like LSD, mescaline, and other major hallucinogens.

Both marijuana use and hashish use can be traced far back into history. Cannabis was apparently known in ancient China (Blum, 1969) and was listed in the herbal compendiums of the Chinese Emperor Shen Nung, written about 2737 B.C. Until the late 1960s, marijuana use in the United States was confined largely to members of lower-socioeconomic-status and minority groups and to people in entertainment and related fields, but marijuana use is commonplace today. Now marijuana is the most frequently used illicit drug. In 2008, 6.7 percent of the U.S. population between 12 and 17 years of age used marijuana; 16.5 percent of young adults did as well (Substance Abuse and Mental Health Services Administration, 2009), although according to the most recent Monitoring the Future study, college students have begun to show some decline in marijuana use in recent years (Johnston et al., 2009).

Minority group members and Caucasians have been shown to have comparable rates of use (Brown et al., 2004), however, one recent survey found that Hispanic American adults had lower rates of current illicit drug use (Substance Abuse and Mental Health Services Administration, 2010). Cannabis is

Marijuana can produce extreme euphoria, hilarity, and hypertalkativeness, but it can also produce intense anxiety and depression as well as delusions, hallucinations, and other psychotic-like behavior.

the most commonly used drug by people with schizophrenia (Coulston et al., 2007). Marijuana use is likely to show an increase in the future, given that it has been legalized in some states even though it is illegal according to U.S. legal standards.

In a recent survey of drug-related visits to the emergency room (DAWN, 2010), 16 percent were for marijuana abuse. Many of these emergency room visits, as one might suspect, involved the use of other substances along with marijuana.

**EFFECTS OF MARIJUANA** The specific effects of marijuana vary greatly, depending on the quality and dosage of the drug, the personality and mood of the user, the user's past experiences with the drug, the social setting, and the user's expectations. However, considerable consensus exists among regular users that when marijuana is smoked and inhaled, a state of slight intoxication results. This state is one of mild euphoria distinguished by increased feelings of well-being, heightened perceptual acuity, and pleasant relaxation, often accompanied by a sensation of drifting or floating away. Sensory inputs are intensified. Marijuana has the effect on the brain of altering one's internal clock (O'Leary et al., 2003). Often a person's sense of time is stretched or distorted so that an event that lasts only a few seconds may seem to cover a much longer span. Short-term memory may also be affected, as when one notices that a bite has been taken out of a sandwich but does not remember having taken it. For most users, pleasurable experiences, including sexual intercourse, are reportedly enhanced. When smoked, marijuana is rapidly absorbed, and its effects appear within seconds to minutes but seldom last more than 2 to 3 hours. Marijuana has also been used to relieve pain or nausea; see The World Around Us box on page 397 for a discussion of the controversy over medical marijuana.

**TREATMENT** Some research has reported that many marijuana users who abstain report having uncomfortable withdrawal-like symptoms such as nervousness, tension, sleep problems, and appetite change (Budney et al., 2003; Zickler, 2002). One study of substance abusers showed that marijuana users were more ambivalent and less confident about stopping use than were cocaine abusers (Budney et al., 1998).

Psychological treatment methods have been shown to be effective in reducing marijuana use in adults who are dependent on the drug (Marijuana Treatment Project Research Group, 2004). In a comparative review of psychological treatment studies of marijuana users, Nordstrom and Levin (2007) conclude that a number of therapies have been found to be effective in treating cannabis dependency, but no specific treatment approach has been found to be more effective than the others. Some investigators have also reported that many patients do not show a positive treatment response. No pharmacotherapy treatment for cannabis dependency has been shown to be very effective (Nordstrom and Levin, 2007); however, one recent study using busiprone for treatment of marijuana dependency showed slight improvement over a placebo group (McRae et al., 2009).

As with other addictive drugs, there may be among the users many individuals with serious antisocial or “psychosis-prone”

## Should Marijuana Be Marketed and Sold Openly as a Medication?

**A**lthough marijuana is a Schedule 1 Drug according to the 1970 Controlled Substances Act, and U. S. Government drug control agencies have strongly opposed legalization of the drug (Walters, 2006), there have been substantial efforts to broaden its use and availability. In recent years marijuana has been distributed for pain or nausea relief from medical conditions such as cancer, AIDS, glaucoma, multiple sclerosis, migraines, and epilepsy. Proponents of medical marijuana cite its value in the treatment of these conditions, and some have pointed out that medical marijuana treatment is consistent with participation in other forms of drug treatment and may not adversely affect the outcome (Swartz, 2010). Marijuana does not cure any illness; it only reduces pain for which other medications exist (Watson, Benson et al., 2000).

Proponents of medical marijuana have made considerable inroads in securing legalization of marijuana as a treatment in 14 states and the District of Columbia. Although many professional researchers and practitioners discourage the use of marijuana because of the ill effects, others, including mental health professionals, politicians, and lay persons, press society to change the rigid control over the drug and make it legal.

States vary in how medical marijuana is made available to the public. Some locations, such as the District of Columbia, have approved medical marijuana use by a limited and controlled number of dispensaries (Southall, 2010) while others have allowed a broad and less controlled environment to develop. A recent article by Vick (2009) pointed out that California's medical marijuana law (Proposition 215) enabled the opening of more than 400 public dispensaries of medical marijuana in the Los Angeles area and resulted in marijuana becoming "mainstream." The ready access to marijuana heightened concerns over the drug serving as an "entry level" drug for more addictive and dangerous illicit substances. This problem has been a focus of the U.S. government's opposition to legalizing marijuana since it has become more widely available (Walters, 2006). In 2012, the Los Angeles City Council rescinded its early approval of the sale of medical marijuana and closed down the numerous "clinics" that provided open access to the drug (Zahniser, 2012). It is uncertain as to what the future access to medical marijuana will be as various states may change their positions on marijuana use and availability.

A number of problems with the use of medical marijuana have been reported, in part because of the unregulated availability of the drug; for example, one can get a "prescription" for the drug by walking into one of the many "treatment centers" and talking with a salesperson. A recent article by Moore (2009) describes the sentencing of an owner of a marijuana dispensary to a year in prison for distributing marijuana. Thus, providers of medical marijuana to the public can still face the possibility of jail time in some situations. Yardley (2010) recently pointed out a number of crimes that resulted from the medical marijuana users having had large amounts of marijuana in their homes. Mascia (2010) highlighted

another problem in using medical marijuana in employment settings. A number of people have lost jobs or have not been offered a position as a result of drug screening—a requirement for employment in many positions such as security personnel, police applicants, pilots, and even some corporations such as Walmart.

Iversen (2008) makes a strong case for the research supporting the use of medical marijuana, but others continue to question the scientific basis of the medical use (Walters, 2006). Others have also pointed out that medical use of cannabis has been shown to be significantly associated with nonmedical use and could result in adverse consequences (Parakh, 2010).

Should "medical marijuana" be considered a legitimate pharmaceutical treatment? Is marijuana an effective drug based on the research, or is it without any medical value? Is marijuana being unfairly criminalized by the federal government, or does its potential as an entry drug and its medical side effects counter its value as a treatment? Should cannabis be approved for medical use by a vote of the people, as already has been done in many states, or should medical marijuana be scientifically evaluated and its use be guided by science? The controversy is likely to continue as more states vote to legalize medical marijuana and as other problems with the broadened availability of the drug emerge.

Marijuana may lead to unpleasant as well as pleasant experiences. For example, if a person uses the drug while in an unhappy, angry, suspicious and paranoid, or frightened mood, these feelings may be magnified. With higher dosages and with certain unstable or susceptible individuals, marijuana can produce extreme euphoria, hilarity, and overt talkativeness, but it can also produce intense anxiety (Zvolensky et al., 2010) and depression as well as delusions, hallucinations, and other psychotic-like experiences. Evidence suggests a strong relationship between daily marijuana use and the occurrence of psychotic symptoms (Raphael et al., 2005).

Marijuana's short-range physiological effects include a moderate increase in heart rate, a slowing of reaction time, a slight contraction of pupil size, bloodshot and itchy eyes, a dry mouth, and increased appetite. Furthermore, marijuana induces memory dysfunction and a slowing of information processing (Pope et al., 2001). Continued use of high dosages over time tends to produce lethargy and passivity along with reduced life success (Lane et al., 2005). In such cases marijuana appears to have a depressant and a hallucinogenic effect. The effects of long-term and habitual marijuana use are still under investigation, although a number of possible adverse side effects have been found to be related to the prolonged, heavy use of marijuana (Earleywine, 2002). For example, marijuana use tends to diminish self-control. One study exploring past substance-use history in incarcerated murderers reported that among men who had committed murder, marijuana was the most commonly used drug. One-third indicated that they had used the drug before the homicide, and two-thirds were experiencing some effects of the drug at the time of the murder (Spunt et al., 1994).

personalities (Kwapisil, 1996). Treatment of marijuana use is hampered by the fact that there might be an underlying personality disorder. One study compared the effectiveness of two treatments, Relapse Prevention and Support Group, with marijuana-dependent adults (Stephens et al., 1994). Both treatment conditions resulted in substantial reduction in marijuana use in the 12 months following treatment. Relapse Prevention and Support Group discussion sessions were equally effective in bringing about changes in marijuana use.

**SYNTHETIC MARIJUANA** Not all discoveries or product developments today are innovations that contribute to the public good. An example of a recent chemical that is widely marketed and can result in harm for the consumers is a marijuana substitute that goes under the name of “Spice.” Spice is an herbal compound that is touted as an incense blend (as are several other chemical brands such as “K2,” “Blaze,” and “Red X Dawn”) and marketed on the Internet and in specialty shops. These products are advertised as a legal alternative to controlled substances such as marijuana. Spice is typically smoked along with tobacco; however, it tends to take longer to feel the effects than marijuana.

Many people who use Spice report that it has effects equal to or stronger than those obtained by smoking cannabis. Very little is known at this point about the make-up of Spice or its long-term effects. Reports suggest that it may contain up to 15 different herbs, of which wild dagga (*Leonotis leonurus*) and Indian warrior (*Pedicularis densiflora*) are considered to be the most likely candidates for producing a psychoactive effect. In addition, other synthetic chemicals may have been added to the drug (Griffiths et al., 2010). Although there is a limited amount of research and clinical information about synthetic marijuana, there are reports that the **toxicity** lasts 3 to 4 hours and often has adverse effects such as anxiety, tachycardia, hypertension, abnormally fast breathing, chest pain, heart palpitations,

Bath salts are becoming a widely used and dangerous stimulant drug and are now considered an illegal substance even though they are often available in bath products or fertilizers. The drug's effects are very similar to ecstasy or cocaine. Bath salts contain amphetamine or cocaine-like chemicals, such as methylenedioxypyrovalerone (MPDV). They tend to cause intense euphoria and make the user very talkative and sexually aroused and often produce bizarre results.

hallucinations, racing thoughts, and seizures (Wells & Ott, 2011).

Spice has come under the attention of drug control agencies because of the extreme and damaging side effects. A number of efforts are being made to place legal restrictions on its use and availability (McLachlan, 2009). In November 2010, the United States Drug Enforcement Administration (DEA) used its emergency scheduling authority to temporarily control five chemicals that are used to make fake marijuana products. In March of 2011, the DEA declared these chemicals to be illegal substances (Kraft, 2011).

### Stimulants: Caffeine and Nicotine

*DSM-5* includes addictions to two legally available and widely used substances: **caffeine** and **nicotine**. Although these substances do not involve the extensive and self-destructive problems found in alcohol- and drug-use disorders, they can create important physical and mental health problems in our society for several reasons:

- These drugs are easy to abuse. It is easy to become addicted to them because they are widely used and most people are exposed to them early in life.
- These drugs are readily available to anyone who wants to use them; in fact, because of peer pressure, it is usually difficult to avoid using them in our society.
- Both caffeine and nicotine have clearly addictive properties; use of them promotes further use, until one craves a regular “fix” in one’s daily life.
- It is difficult to quit using these drugs both because of their addictive properties and because they are so embedded in the social context. (Nicotine use, however, is falling out of favor in many settings.)
- The extreme difficulty most people have in dealing with the withdrawal symptoms when trying to “break the habit” often produces considerable frustration.
- The health problems and side effects of these drugs, particularly nicotine, have been widely noted (USDHHS, 1994). One in seven deaths in the United States is associated with cigarette consumption.

Because of their tenacity as habits and their contributions to many major health problems, we will examine each of these addictions in more detail.

**CAFFEINE** The chemical compound caffeine is found in many commonly available drinks and foods. Although the consumption of caffeine is widely practiced and socially promoted in contemporary society, problems can result from excessive caffeine intake. The negative effects of caffeine involve intoxication rather than withdrawal. Unlike addiction to drugs such as alcohol or nicotine, withdrawal from caffeine does not produce severe symptoms, except for headache, which is usually mild.

Because they are socially acceptable and readily available, caffeine and nicotine can be insidiously addictive substances. Though they do not result in the same kind of extensive, self-destructive problems as alcohol and drug disorders, caffeine and nicotine addiction can cause a myriad of health problems and are now included in the *DSM-5*.

As described in *DSM-5* caffeine-related disorder involves symptoms of restlessness, nervousness, excitement, insomnia, muscle twitching, and gastrointestinal complaints. It follows the ingestion of caffeine-containing substances such as coffee, tea, cola, and chocolate. The amount of caffeine that results in intoxication differs among individuals.

**NICOTINE** The poisonous alkaloid nicotine is the chief active ingredient in tobacco; it is found in such items as cigarettes, chewing tobacco, and cigars, and it is even used as an insecticide. The use of tobacco is a significant problem in the general population. The number of Americans aged 12 and older who use some form of tobacco is estimated at 70.9 million people, or about 28.4 percent of the population (Substance Abuse and Mental Health Services Administration, 2009). However, an estimated 63 percent of women and 53 percent of men have never smoked (Pleis et al., 2009). The *DSM-5* contains a diagnostic category for nicotine abuse. The criteria for tobacco use disorder are the same for other addictive disorders.

Strong evidence exists for a nicotine-dependence syndrome (Malin, 2001; Watkins et al., 2000), which nearly always begins during the adolescent years and may continue into adult life as a difficult-to-break and health-endangering habit. Supporting the finding that nicotine may have an antianxiety property, nicotine use has been observed as being highly prevalent among those with anxiety disorders (Morissette et al., 2007). Recent evidence from stroke-related brain injury suggests that nicotine

addiction might be controlled by a portion of the brain near the ear called the insula (Naqvi et al., 2007). A stroke patient with damage to that area of the brain reported that his craving for cigarettes vanished. This result suggests that the insula might be an important center for addiction to smoking, but more research is needed to support this conclusion.

The “Tobacco Withdrawal disorder,” as it is called in *DSM-5*, results from ceasing or reducing the intake of nicotine-containing substances after an individual has developed physical dependence on them. The diagnostic criteria for nicotine withdrawal include (1) the daily use of nicotine for at least several weeks, and (2) the following symptoms after nicotine ingestion is stopped or reduced: craving for nicotine; irritability, frustration, or anger; anxiety; difficulty concentrating; restlessness; decreased heart rate; and increased appetite or weight gain. Several other physical concomitants are associated with withdrawal from nicotine including decreased metabolic rate, headaches, insomnia, tremors, increased coughing, and impairment of performance on tasks requiring attention.

These withdrawal symptoms usually continue for several days to several weeks, depending on the extent of the nicotine habit. Some individuals report a desire for nicotine continuing for several months after they quit smoking. In general, nicotine withdrawal symptoms operate in a manner similar to those of withdrawal from other addictions—they are time limited and are reduced over time as the drug intake stops, (Hughes, 2007).

**TREATMENT OF NICOTINE WITHDRAWAL** Over the past three decades, numerous treatment programs have been developed to help smokers quit (Hughes, 2007). Available programs use many different methods including social support groups; various pharmacologic agents that replace cigarette consumption with safer forms of nicotine such as candy, gum, or patches; self-directed change that involves giving individuals guidance in changing their own behaviors; and professional treatment using psychological procedures such as behavioral or cognitive-behavioral interventions. One recent study provided smokers with ultrasound photographs of their carotid and femoral arteries along with quit-smoking counseling. This group showed higher quit rates than controls (Bovet et al., 2002).

In general, tobacco dependence can be successfully treated, and most of the quit-smoking programs enjoy some success. They average only about a 20- to 25-percent success rate, however, although rates have been reported to be higher with treatment (Hays et al., 2001). This same level of success appears to result from the use of nicotine replacement therapy (NRT). Shiffman and colleagues (2006) point out that high-dose NRT reduces withdrawal symptoms. Treatment with active patches reduced withdrawal and craving during cessation and completely eliminated deprivation-related changes in affect or concentration. Recently, encouraging results have been reported on the use of the drug bupropion (Zyban) in preventing relapse for smokers trying to quit. The

drug reduced relapse as long as the person was taking it, but relapse rates were similar to those of other treatments once the drug was discontinued (Barringer & Weaver, 2002). The highest self-reported quit rates for smokers were reportedly among patients who were hospitalized for cancer (63 percent), cardiovascular disease (57 percent), or pulmonary disease (46 percent; Smith, Reilly, et al., 2002).

Not all addictive disorders involve the use of substances with chemical properties that induce dependence. As discussed in the next section, people can develop “addictions” to certain activities that can be just as life-threatening as severe alcoholism and just as damaging, psychologically and socially, as drug abuse. One such addiction, **pathological gambling**, is in many ways similar to substance abuse. The maladaptive behaviors involved and the treatment approaches shown to be effective suggest that these addictive disorders are quite similar to the various drug-use and drug-induced disorders.

### in review

- What are the major biological and psychological effects of using opiates such as morphine and heroin?
- What are the three major causal factors in the development of opiate abuse and dependence?
- What is methamphetamine? What are the major health factors related to methamphetamine use?
- What are the physical risks of taking Ecstasy?
- Describe the effects of cannabis.
- Describe the effects of nicotine and caffeine use, and explain why these commonly available substances are included in this chapter on substance abuse.

## Gambling Disorder

Although pathological gambling does not involve a chemically addictive substance, it is considered by many to be an addictive disorder because of the personality factors that tend to characterize compulsive gamblers (Petry & Madden, 2010). Like the substance abuse disorders, pathological gambling involves behavior maintained by short-term gains despite long-term disruption of an individual’s life. There is a high comorbidity between pathological gambling and alcohol abuse disorders (Blanco, Cohen et al., 2010) and with personality disorders (Sacco et al., 2008). Pathological gambling, also known as “compulsive gambling” or disordered gambling, is a progressive disorder characterized by continuous or periodic loss of control over gambling, a preoccupation with gambling and with obtaining money for gambling, and continuation of the gambling behavior in spite of adverse consequences.

Estimates place the number of pathological gamblers worldwide at between 1 and 2 percent of the adult population (Petry, 2005). Both men and women appear to be vulnerable to pathological gambling (Hing & Breen, 2001). However, rates differ by subpopulation; for example, in some high-risk populations, such as alcoholics, the rates are higher. One study of elderly African Americans from two senior citizen centers documented the extent of gambling problems in this population; 17 percent were found to be people with gambling disorders (Bazargan et al., 2001). Pietrzak and colleagues (2007) found that older, disordered gamblers were significantly more likely than nongambling older adults to have alcohol-abuse problems, nicotine addiction, and health problems.

### criteria for Gambling Disorder

DSM-5

- A. Persistent and recurrent problematic gambling behavior leading to clinically significant impairment or distress, as indicated by the individual exhibiting four (or more) of the following in a 12-month period:
1. Needs to gamble with increasing amounts of money in order to achieve the desired excitement.
  2. Is restless or irritable when attempting to cut down or stop gambling.
  3. Has made repeated unsuccessful efforts to control, cut back, or stop gambling.
  4. Is often preoccupied with gambling (e.g., having persistent thoughts of reliving past gambling experiences, handicapping or planning the next venture, thinking of ways to get money with which to gamble).

5. Often gambles when feeling distressed (e.g., helpless, guilty, anxious, depressed).
  6. After losing money gambling, often returns another day to get even (“chasing” one’s losses).
  7. Lies to conceal the extent of involvement with gambling.
  8. Has jeopardized or lost a significant relationship, job, or educational or career opportunity because of gambling.
  9. Relies on others to provide money to relieve desperate financial situations caused by gambling.
- B. The gambling behavior is not better explained by a manic episode.

Cultural factors also appear to be important in the development of gambling problems. Pathological gambling is a particular problem among Southeast Asian refugees, especially those from Laos. Surveys of mental health problems have reported almost epidemic compulsive gambling among such groups (Aronoff, 1987; Ganju & Quan, 1987).

Gambling in our society takes many forms including casino gambling, betting on horse races or sports (legally or otherwise), Internet gaming, numbers games, lotteries, dice, bingo, and cards. Whatever an individual gambler's situation, compulsive gambling significantly affects the social, psychological, and economic well-being of the gambler's family. In fact, studies have found that a high proportion of pathological gamblers commit crimes that are related to gambling (Blaszczynski et al., 1989), family violence (Afifi et al., 2010) and other crimes of aggression (Folino & Abait, 2009).

Pathological gambling seems to be a learned pattern that is highly resistant to extinction. Some research suggests that control over gambling is related to duration and frequency of playing (Scannell et al., 2000). However, many people who become pathological gamblers won a substantial sum of money the first time they gambled; chance alone would dictate that a certain percentage of people would have such "beginner's luck." The reinforcement a person receives during this introductory phase may be a significant factor in later pathological gambling. Because everyone is likely to win from time to time, the principles of intermittent reinforcement—the most potent reinforcement schedule for operant conditioning—could explain an addict's continued gambling despite excessive losses.

Despite their awareness that the odds are against them, and despite the fact that they rarely or never repeat their early success, compulsive gamblers continue to gamble avidly. To "stake" their gambling, they often dissipate their savings, neglect their families, default on bills, and borrow money from friends and loan companies. Some resort to embezzlement, writing bad checks, or other illegal means of obtaining money. In a pioneering study of former pathological gamblers, Rosten (1961) found that they tended to be rebellious, unconventional individuals who did not seem to understand fully the ethical norms of society. Half of the group described themselves as "hating regulations." Often they had the unshakable feeling that "tonight is my night." Typically, they had also followed the so-called "Monte Carlo fallacy"—that after so many losses, their turn was coming up and they would hit it big. Many of the men discussed the extent to which they had "fooled themselves" by elaborate rationalizations.

Later studies also describe pathological gamblers as typically immature, rebellious, thrill-seeking, superstitious, basically antisocial, and compulsive (Hollander et al., 2000). Research has shown that pathological gambling frequently co-occurs with other disorders, particularly substance abuse such as alcohol and cocaine dependence (Kausch, 2003; Welte et al., 2004) and impulse disorders (Grant & Potenza, 2010). Those with

co-occurring substance-abuse disorders typically have the most severe gambling problems (Ladd & Petry, 2003).

The causes of impulse-driven behavior in pathological gambling are complex. Some research has suggested that early trauma might contribute to the development of compulsive gambling (Scherrer et al., 2007). Although learning undoubtedly plays an important part in the development of personality factors underlying the "compulsive" gambler, recent research in brain mechanisms that are involved in motivation, reward, and decision making indicates that these mechanisms could influence the underlying impulsivity in personality (Chambers & Potenza, 2003). These investigators have suggested that important neurodevelopmental events during adolescence occur in brain regions associated with motivation and impulsive behavior. Recent research has also suggested that genetic factors might play a part in developing pathological gambling habits (Slutske et al., 2010).

Treatment of pathological gamblers has tended to parallel that of other addictive disorders. The most extensive treatment approach used with pathological gamblers is cognitive-behavioral therapy (Okuda et al., 2009). For example, Sylvain, Ladouceur, and Boisvert (1997) provided cognitive-behavioral therapy for 58 pathological gamblers recruited through the media. Although 18 participants dropped out at the start and 11 quit during therapy, those who remained in treatment showed significant improvement. Of those who completed therapy, 86 percent were considered "no longer" pathological gamblers at a 1-year follow-up. However, one study (Hodgins & el-Guebaly, 2004) reports very high relapse rates among pathological gamblers—only 8 percent were free of gambling 12 months after treatment. Even studies that show improvement during treatment also report participants' difficulty remaining abstinent. In a study of 231 gamblers (Petry et al., 2006), some improved when receiving cognitive-behavioral therapy and when attending at Gambler's Anonymous (GA), an organization modeled after Alcoholics Anonymous, or when attending GA and receiving a workbook. The patients tended not to remain abstinent, although incidents were less than they usually reported. Most participants reported some gambling during the follow-up period. More positive outcomes in treating pathological gambling have been found when family relationship problems are addressed in the treatment (McComb et al., 2009).

Pathological gambling is on the increase in the United States (Potenza, 2002), particularly with the widely available gambling opportunities on the Internet (Griffiths, 2003). Liberalized gambling legislation has permitted state-operated lotteries, horse racing, and gambling casinos in an effort to increase state tax revenues. In the context of this apparent environmental support and "official" sanction for gambling, it is likely that pathological gambling will increase substantially as more and more people "try their luck." Given that pathological gamblers are resistant to treatment, future efforts to develop more effective preventive and treatment approaches will need to be increased as this problem continues to grow.

## Exchanging Addictions: Is This an Effective Treatment Approach?

Withdrawal from heroin can be extremely difficult because of the intense craving that develops for the drug. Wouldn't it be great if we had a magic bullet—a medication—that would allow people who are addicted to heroin to withdraw from it painlessly? One approach that has been used for several decades involves the administration of methadone (methadone hydrochloride, a synthetic narcotic that is as addictive as heroin), often in conjunction with a psychological or social rehabilitation program that is aimed at resocialization of the abuser. The value of this treatment comes from the fact that methadone satisfies an addict's craving for heroin without producing serious psychological impairment.

Many researchers have concluded that in addition to facilitating psychological or social rehabilitation, this drug is effective at reducing the dependence on heroin (Kreek et al., 2010). Thus, it enables many people to experience reduced craving, allowing them to alter somewhat the often desperate life circumstances they find themselves in through trying to support their expensive and all-consuming habit. In addition, opiate addicts who remain on methadone have a substantially lower death rate than those discharged from methadone maintenance programs (Fugelstad et al., 2007).

The idea that addicts may need to be maintained for life on methadone, itself a powerful and addicting drug, has been questioned both on moral and practical grounds. Methadone advocates, however, point out that addicts on methadone can function normally and hold jobs, which is not possible for most heroin addicts. In addition, methadone is available legally, and its quality is controlled by government standards. Advocates for methadone programs point out that it is not necessary to increase the dosage over time as it is with heroin use. In fact, some patients can eventually stop taking methadone without danger of relapse to heroin addiction.

However, negative consequences are sometimes associated with the use of methadone (Miller & Lyon, 2003). Methadone patients

are at increased risk for health problems such as hepatitis (McCarthy & Flynn, 2001) and cognitive impairment (Scheurich, 2005; Verdejo et al., 2005). In addition, many social problems, such as trading sex for drugs, persist (El-Bassel et al., 2001); some addicts get involved with other drugs such as cocaine (Avants et al. 1998; Silverman et al., 1996); suicide attempts are common (Darke & Ross, 2001); and violent deaths and drug overdoses are common among methadone patients (Sunjic & Zabor, 1999).

A great deal of research has shown that administering psychotherapy along with methadone increases the effectiveness of treatment (Marsch et al., 2005). However, a persistent problem of methadone maintenance programs has been the relatively high dropout rate. Several variations in methadone maintenance programs have been aimed at keeping addicts in therapy. These variations include the use of such additional drugs as clonidine (an antihypertensive drug used to treat essential hypertension and prevent headache), which aid in the detoxification process and reduce the discomfort of withdrawal symptoms. In one study, the joint use of tranquilizers such as diazepam was shown to decrease the amount of methadone consumed (Spiga et al., 2001). Another approach involves the use of behavioral shaping through contingent reinforcers (monetary vouchers) to reward abstinent patients (Preston et al., 2001).

A new approach to treating opiate dependence is one that promotes drug abstinence for addicts rather than permanent maintenance on methadone (Kosten, 2003). This program, referred to as methadone transition treatment (MTT), involves several elements over its 180-day duration. During the first 100 days, the addict is provided a stable dose of methadone to begin the withdrawal from heroin. During this period the addict also receives a psychosocial intervention that includes weekly psychoeducational classes, biweekly group therapy, and 6 months of individual therapy that continues after drug maintenance has terminated. The program ends with 80 days of phaseout in which the addict is "weaned" from methadone through systematically decreasing the doses (Piotrowski et al., 1999).

## summary

### 11.1 What is alcohol abuse and dependence?

- Substance-related disorders such as alcohol or drug abuse and dependency are among the most widespread and intransigent mental health problems facing us today.

- Many problems of alcohol or drug use involve difficulties that stem solely from the intoxicating effects of the substances.
- Dependence occurs when an individual develops a tolerance for the substance or exhibits withdrawal symptoms when the substance is not available.
- Several psychoses related to alcoholism have been identified: withdrawal delirium, chronic alcoholic hallucinosis, and dementia associated with alcoholism.
- Drug-related abuse disorders may involve physiological dependence on substances such as opiates—particularly heroin—or

- barbiturates; however, psychological dependence may also occur with any of the drugs that are commonly used today—for example, marijuana.
- A number of factors are considered important in the etiology of substance-abuse disorders. Some substances, such as alcohol and opiates, stimulate brain centers that produce euphoria—which then becomes a desired goal.
  - It is widely believed that genetic factors play some role in causing susceptibility to alcohol-abuse problems through such biological avenues as metabolic rates and sensitivity to alcohol.
  - Psychological factors—such as psychological vulnerability, stress, and the desire for tension reduction—and disturbed marital relationships or failure in parental guidance are also seen as important etiologic elements in substance-use disorders.
  - Although the existence of an “alcoholic personality type” has been disavowed by most theorists, a variety of personality factors apparently play an important role in the development and expression of addictive disorders.
  - Sociocultural factors such as attitudes toward alcohol may predispose individuals to alcohol-related disorders.

### **11.2 What is drug abuse and dependence?**

- Possible causal factors in drug abuse include the influence of peer groups, the existence of a so-called “drug culture,” and the availability of drugs as tension reducers or pain relievers.
- Some recent research has explored a possible physiological basis for drug abuse. The discovery of endorphins, opium-like substances produced by the body, has led to speculation that a biochemical basis of drug addiction may exist.
- The so-called “pleasure pathway”—the mesocorticolimbic pathway (MCLP)—has come under a great deal of study in recent years as the possible potential anatomic site underlying the addictions.

- The treatment of individuals who abuse alcohol or drugs is generally difficult and often fails. The abuse may reflect a long history of psychological difficulties; interpersonal and marital distress may be involved; and financial and legal problems may be present.
- In addition, all such problems must be dealt with by an individual who may deny that the problems exist and who may not be motivated to work on them.
- Several approaches to the treatment of chronic substance-related disorders have been developed—for example, medication to deal with withdrawal symptoms and withdrawal delirium, and dietary evaluation and treatment for malnutrition.
- Psychological therapies such as group therapy and behavioral interventions may be effective with some alcohol- or drug-abusing individuals. Another source of help for alcohol abusers is Alcoholics Anonymous; however, the extent of successful outcomes with this program has not been sufficiently studied.
- Most treatment programs require abstinence; however, some research has suggested that some alcohol abusers can learn to control their drinking while continuing to drink socially. The controversy surrounding controlled drinking continues.
- Relapse prevention strategies have proved successful in helping substance-abusing patients to deal with the challenges encountered in abstinence-based treatment approaches.

### **11.3 Are there addictive disorders other than alcohol and drugs?**

- This chapter also includes discussion of several addictive disorders that are different than alcohol or drug abuse, caffeine, tobacco and gambling.

## learning objectives

### 12.1

Why is it difficult to define boundaries between normality and psychopathology in the area of variant sexuality?

### 12.2

What do we mean by sexual and gender variants?

### 12.3

What are the three primary types of sexual abuse?

### 12.4

What is a sexual dysfunction?

Loving, sexually satisfying relationships contribute a great deal to our happiness, and if we are not in such relationships, we are apt to spend a great deal of time, effort, and emotional energy looking for them. Sexuality is a central concern of our lives, influencing with whom we fall in love and mate and how happy we are with our partner and with ourselves.

In this chapter we shall first look at the psychological problems that make sexual fulfillment especially difficult for some people—the vast majority of them men—who develop unusual sexual interests that are difficult to satisfy in a socially acceptable manner. For example, exhibitionists are sexually aroused by showing their genitals to strangers, who are likely to be disgusted, frightened, and potentially traumatized. Other sexual or gender variants may be problematic primarily to the individual: Transsexualism, for example, is a disorder involving discomfort with one's biological sex and a strong desire to be of the opposite sex. Still other variants such as fetishism, in which sexual interest centers on some inanimate object or body part, involve behaviors that, although bizarre and unusual, do not clearly harm anyone. Perhaps no other area covered in this book exposes the difficulties in defining boundaries between normality and psychopathology as clearly as variant sexuality does.

The second issue we shall consider is sexual abuse, a pattern of pressured, forced, or inappropriate sexual contact. During the last few decades, there has been a tremendous increase in attention to the problem of sexual abuse of both children and adults. A great deal of research has addressed its causes and consequences. As we shall see, some related issues, such as the reality of recovered memories of sexual abuse, are extremely controversial.

The third category of sexual difficulties examined in this chapter is sexual dysfunctions, which include problems that impede satisfactory performance of sexual acts. People who have sexual dysfunctions (or their partners) typically view them as problems. Premature ejaculation, for example, causes men to reach orgasm much earlier than they and their partners find satisfying. And women with orgasmic disorder get sexually aroused and enjoy sexual activity but have a persistent delay, or absence, of orgasm following a normal sexual excitement or **arousal phase**.

Much less is known about sexual deviations, abuse, and dysfunctions than is known about many of the other disorders we have considered thus far in this book. There are also fewer sex researchers than researchers for many other disorders, so fewer articles related to research on sexual deviations and dysfunctions are published compared with the number of articles on anxiety and mood disorders or schizophrenia. One major reason is the sex taboo. Although sex is an important concern for most people, many have difficulty talking about it openly—especially when the relevant behavior is socially stigmatized, as homosexuality has often been historically. This makes it hard to obtain knowledge about even the most basic facts, such as the frequency of various sexual practices, feelings, and attitudes.

A second reason why sex research has progressed less rapidly is that many issues related to sexuality—including homosexuality, teenage sexuality, abortion, and childhood sexual abuse—are among our most divisive and controversial. In fact, sex research is itself controversial and not well funded. In the 1990s, two large-scale sex surveys were halted because of political opposition even after the surveys had been officially approved and deemed scientifically meritorious (Udry, 1993). Conservative former senator Jesse Helms and others had argued that sex researchers tended to approve of premarital sex and homosexuality and that this would likely bias the results of the surveys. Fortunately, one of these surveys was funded privately, though on a much smaller scale, and it is still considered definitive even though it was conducted in the 1990s (Laumann et al., 1994, 1999). Another attack led by social conservatives occurred in 2003, when several federal grants were criticized because they focused on sex (Kempner, 2008). A legislative attempt to defund five of the grants barely failed.

Despite these significant barriers, significant progress has been made in the past half-century in understanding some important things about sexual and gender variants and dysfunctions. The contemporary era of sex research was first launched by Alfred Kinsey in the early 1950s (Kinsey et al., 1948, 1953).

Kinsey and his pioneering work are portrayed in a fascinating way in the 2004 award-winning movie *Kinsey*. However, before we discuss this progress, we first examine sociocultural influences on sexual behavior and attitudes in general. We do so to provide some perspective about cross-cultural variability in standards of sexual conduct and how these perspectives have changed over

Loving, sexually satisfying relationships contribute a great deal to our happiness, but our understanding of them has advanced slowly, largely because they are so difficult for people to talk about openly and because funding for research is often hard to come by.

time. Such examples will remind us that we must exercise special caution in classifying sexual practices as “abnormal” or “deviant.”

## Sociocultural Influences on Sexual Practices and Standards

Although some aspects of sexuality and mating, such as men’s greater emphasis on their partner’s attractiveness, are cross-culturally universal (Buss, 1989, 2012), others are quite variable. For example, all known cultures have taboos against sex between close relatives, but attitudes toward premarital sex have varied considerably across history and around the world. Ideas about acceptable sexual behavior also change over time. Less than 100 years ago, for example, sexual modesty in Western cultures was such that women’s arms and legs were always hidden in public. Although this is by no means the case in Western cultures today, it remains true in many Muslim countries.

Despite the substantial variability in sexual attitudes and behavior in different times and places, people typically behave as though the sexual standards of their own time and place are obviously correct, and they tend to be intolerant of sexual nonconformity. Sexual nonconformists are often considered evil or sick. We do not mean to suggest that such judgments are always arbitrary. There has probably never existed a society in which Jeffrey Dahmer, who was sexually aroused by killing men, having sex with them, storing their corpses, and sometimes eating them, would be considered psychologically normal. Nevertheless, it is useful to be aware of historical and cultural influences on sexuality. When the expression or the acceptance of a certain behavior varies considerably across eras and cultures, we should at least pause to consider the possibility that our own stance is not the only appropriate one.

Because the influences of time and place are so important in shaping sexual behavior and attitudes, we begin by exploring three cases that illustrate how opinions about “acceptable” and

“normal” sexual behavior may change dramatically over time and may differ dramatically from one culture to another. In the first case, America during the mid-1800s, “degeneracy theory”—a set of beliefs about sexuality—led to highly conservative sexual practices and dire warnings about most kinds of sexual “indulgence.” In the second case, we look briefly at the Sambia tribe in New Guinea, in which a set of beliefs about sexuality prescribe that all normal adolescent males go through a stage of homosexuality before switching rather abruptly to heterosexuality in adulthood. Finally, in the third case, we consider changes across time in the status of homosexuality in Western culture.

### Case 1: Degeneracy and Abstinence Theory

During the 1750s, Swiss physician Simon Tissot developed *degeneracy theory*, the central belief of which was that semen is necessary for physical and sexual vigor in men and for masculine characteristics such as beard growth (Money, 1985, 1986). He based this theory on observations about human eunuchs and castrated animals. We now know, of course, that loss of the male hormone testosterone, and not of semen, is responsible for the relevant characteristics of eunuchs and castrated animals. On the basis of his theory, however, Tissot asserted that two practices were especially harmful: masturbation and patronizing prostitutes. Both of these practices wasted the vital fluid, semen, as well as (in his view) overstimulating and exhausting the nervous system. Tissot also recommended that married people engage solely in procreative sex to avoid the waste of semen.

A descendant of degeneracy theory, abstinence theory was advocated in America during the 1830s by the Reverend Sylvester Graham (Money, 1985, 1986). The three cornerstones of his crusade for public health were healthy food (graham crackers were named for him), physical fitness, and sexual abstinence. In the 1870s Graham’s most famous successor, Dr. John Harvey Kellogg, published a paper in which he ardently disapproved of masturbation and urged parents to be wary of signs that their children were indulging in it. He wrote about the 39 signs of “the secret vice,” which included weakness, dullness of the eyes, sleeplessness, untrustworthiness, bashfulness, love of solitude, unnatural boldness, mock piety, and round shoulders.

As a physician, Kellogg was professionally admired and publicly influential, and he earned a fortune publishing books discouraging masturbation. His recommended treatments for “the secret vice” were quite extreme. For example, he advocated that persistent masturbation in boys be treated by sewing the foreskin with silver wire or, as a last resort, by circumcision without anesthesia. Female masturbation was to be treated by burning the clitoris with carbolic acid. Kellogg, like Graham, was also very concerned with dietary health—especially with the idea that consumption of meat increased sexual desire. Thus, he urged people to eat more cereals and nuts and invented Kellogg’s cornflakes “almost literally, as anti-masturbation food” (1986, p. 186).

Given the influence of physicians like Kellogg, it should come as no surprise that many people believed that

masturbation caused insanity (Hare, 1962). This hypothesis had started with the anonymous publication in the early eighteenth century in London of a book entitled *Onania, or the Heinous Sin of Self-Pollution*. It asserted that masturbation was a common cause of insanity. This idea probably arose from observations that many patients in mental asylums masturbated openly (unlike sane people, who are more likely to do it in private) and that the age at which masturbation tends to begin (at puberty in adolescence) precedes by several years the age when the first signs of insanity often appear (in late adolescence and young adulthood) (Abramson & Seligman, 1977). The idea that masturbation may cause insanity appeared in some psychiatry textbooks as late as the 1940s.

Although abstinence theory and associated attitudes seem highly puritanical by today's standards, they have had a long-lasting influence on attitudes toward sex in American and other Western cultures. It was not until 1972 that the American Medical Association declared, "Masturbation is a normal part of adolescent sexual development and requires no medical management" (American Medical Association Committee on Human Sexuality, 1972, p. 40). Around the same time, the Boy Scout Manual dropped its antimasturbation warnings. Nonetheless, in 1994 Jocelyn Elders was fired as U.S. Surgeon General for suggesting publicly that sex education courses should include discussion of masturbation. Moreover, the Roman Catholic Church still holds that masturbation is sinful.

## Case 2: Ritualized Homosexuality in Melanesia

Melanesia is a group of islands in the South Pacific that has been intensively studied by anthropologists, who have uncovered cultural influences on sexuality unlike any known in the West. Between 10 and 20 percent of Melanesian societies practice a form of homosexuality within the context of male initiation rituals, which all male members of society must experience.

The best-studied society has been the Sambia of Papua New Guinea (Herdt, 2000; Herdt & Stoller, 1990). Two beliefs reflected in Sambian sexual practices are semen conservation and female pollution. Like Tissot, the Sambians believe that semen is important for many things including physical growth, strength, and spirituality. Furthermore, they believe that it takes many inseminations (and much semen) to impregnate a woman. Finally, they believe that semen cannot easily be replenished by the body and so must be conserved or obtained elsewhere. The female pollution doctrine is the belief that the female body is unhealthy to males, primarily because of menstrual fluids. At menarche, Sambian women are secretly initiated in the menstrual hut forbidden to all males.

In order to obtain or maintain adequate amounts of semen, young Sambian males practice semen exchange with each other. Beginning as boys, they learn to practice fellatio (oral sex) in order to ingest sperm, but after puberty they can also take the penetrative role, inseminating younger boys. Ritualized homosexuality among the young Sambian men is seen as an exchange

of sexual pleasure for vital semen. (It is ironic that although both the Sambians and the Victorian-era Americans believed in semen conservation, their solutions to the problem were radically different.) When Sambian males are well past puberty, they begin the transition to heterosexuality. At this time the female body is thought to be less dangerous because the males have ingested protective semen over the previous years. For a time, they may begin having sex with women and still participate in fellatio with younger boys, but homosexual behavior stops after the birth of a man's first child. Most of the Sambian men make the transition to exclusive adult heterosexuality without problems, and those who do not are viewed as misfits.

Ritualized homosexuality among the Melanesians is a striking example of the influence of culture on sexual attitudes and behavior. A Melanesian adolescent who refuses to practice homosexuality would be viewed as abnormal, and such adolescents are apparently absent or rare. In the United States ritualized homosexuality of this type would be stigmatized as homosexual pedophilia, but Melanesian boys who practice it appear neither to have strong objections nor to be derailed from eventual heterosexuality. Obviously, homosexuality in Sambia is not the same as homosexuality in contemporary America, with the possible exception of those Sambian men who have difficulty making the transition to heterosexuality.

## Case 3: Homosexuality and American Psychiatry

During the past half-century, the status of homosexuality has changed enormously, both within psychiatry and psychology and for many Western societies in general. In the not-too-distant past, homosexuality was a taboo topic. Now, movies, talk shows, and television sitcoms and dramas address the topic explicitly by including gay men and lesbians in leading roles. As we shall see, developments in psychiatry and psychology have played an important part in these changes. Homosexuality was officially removed from the *DSM* (where it had previously been classified as a sexual deviation) in 1973 and today is no longer regarded as a mental disorder. A brief survey of attitudes toward homosexuality within the mental health profession itself will again illustrate how attitudes toward various expressions of human sexuality may change over time.

**HOMOSEXUALITY AS SICKNESS** Reading the medical and psychological literature on homosexuality written before 1970 can be a jarring experience, especially if one subscribes to views prevalent today. Relevant articles included "Effeminate homosexuality: A disease of childhood" and "On the cure of homosexuality." It is only fair to note, however, that the view that homosexual people are mentally ill was relatively tolerant compared with some earlier views—for example, the idea that homosexual people are criminals in need of incarceration (Bayer, 1981). British and American cultures had long taken punitive approaches to homosexual behavior. In the sixteenth century, King Henry VIII of England declared "the detestable and

abominable vice of buggery [anal sex]" a felony punishable by death, and it was not until 1861 that the maximum penalty was reduced to 10 years' imprisonment. Similarly, laws in the United States were very repressive until recently, with homosexual behavior continuing to be a criminal offense in some states (Eskridge, 2008) until the 2003 Supreme Court ruling that struck down a Texas state law banning sexual behavior between two people of the same sex (*Lawrence & Garner v. Texas*). For the first time, this ruling established a broad constitutional right to sexual privacy in the United States.

During the late nineteenth and early twentieth centuries, several prominent sexologists such as Havelock Ellis and Magnus Hirschfeld suggested that homosexuality is natural and consistent with psychological normality. Freud's own attitude toward homosexual people was also remarkably progressive for his time and is well expressed in his touching "Letter to an American Mother" (1935).

*Dear Mrs. . . .*

*I gather from your letter that your son is a homosexual. I am most impressed by the fact that you do not mention this term yourself in your information about him. May I question you, why you avoid it? Homosexuality is assuredly no advantage, but it is nothing to be ashamed of, no vice, no degradation, it cannot be classified as an illness. . . . Many highly respectable individuals of ancient and modern times have been homosexuals, several of the greatest men among them (Plato, Michelangelo, Leonardo da Vinci, etc.). It is a great injustice to persecute homosexuality as a crime, and cruelty too. . . .*

*By asking me if I can help, you mean, I suppose, if I can abolish homosexuality and make normal heterosexuality take its place. The answer is, in a general way, we cannot promise to achieve it. . . .*

*Sincerely yours with kind wishes,  
Freud*

Beginning in the 1940s, however, other psychoanalysts, led by Sandor Rado, began to take a more pessimistic view of the mental health of homosexual people—and a more optimistic view of the possible success of therapy to induce heterosexuality (Herek, 2010). Rado (1962) believed that homosexuality develops in people whose heterosexual desires are too psychologically threatening; thus, in this view, homosexuality is an escape from heterosexuality and therefore incompatible with mental health (see also Bieber et al., 1962). In the case of male homosexuality, one argument was that domineering, emotionally smothering mothers and detached, hostile fathers played a causal role. Unfortunately, these psychoanalysts based their opinions primarily on their experiences seeing gay men in therapy, who are obviously more likely than other gay men to be psychologically troubled (Herek, 2010).

## HOMOSEXUALITY AS NONPATHOLOGICAL VARIATION

Around 1950, the view of homosexuality as sickness began to be challenged by both scientists and homosexual people themselves (e.g., Herek, 2010). Scientific blows to the pathology position

included Alfred Kinsey's finding that homosexual behavior was more common than had been previously believed (Kinsey et al., 1948, 1953). Influential studies also demonstrated that trained psychologists could not distinguish the psychological test results of homosexual subjects from those of heterosexual subjects (e.g., Hooker, 1957).

Gay men and lesbians also began to challenge the psychiatric orthodoxy that homosexuality is a mental disorder. The 1960s saw the birth of the radical gay liberation movement, which took the more uncompromising stance that "gay is good." The decade closed with the famous Stonewall riot in New York City, sparked by police mistreatment of gay men, which sent a clear signal that homosexual people would no longer tolerate being treated as second-class citizens. By the 1970s, openly gay psychiatrists and psychologists were working from within the mental health profession to have homosexuality removed from *DSM-II* (American Psychiatric Association, 1968).

After acrimonious debate in 1973 and 1974, the American Psychiatric Association (APA) voted in 1974 by a vote of 5,854 to 3,810 to remove homosexuality from *DSM-II*. This episode was a milestone for gay rights. We believe the APA made a correct decision here because the vast majority of evidence shows that homosexuality is compatible with psychological health (e.g., Herek, 2010). Challenges by gay and lesbian people forced mental health professionals to confront the issue explicitly, and these professionals made the correct determination that homosexuality is not a psychological disorder.

After mental health professionals stopped merely assuming that homosexuality was pathological, research began systematically to address mental health concerns of gay men and lesbians. Several large and careful surveys have examined rates of mental problems in people with and without homosexual feelings or behavior (Chakraborty et al., 2011; Sandfort et al., 2001; see Herek & Garnets, 2007, for a review). Homosexual people do appear to have elevated risk for some mental problems. For example, compared with heterosexual men and women, gay-identified men and lesbian-identified have higher rates of anxiety disorders and depression (Bostwick et al., 2010). Whether gay and lesbian people are at increased risk for suicide remains controversial (Savin-Williams, 2006), with a recent population study finding no increased risk for gay men (Cochran & Mays, 2011). Lesbians also have a higher rate of substance abuse (Herek & Garnets, 2007; Sandfort et al., 2001). Although it remains unclear why homosexual people have higher rates of certain problems (Bailey, 1999; Cochran, 2012), one plausible explanation is that such problems result from stressful life events related to societal stigmatizing of homosexuality (Herek & Garnets, 2007). Regardless, homosexuality is compatible with psychological health—most gay men and lesbians do not have mental disorders.

During the past 50 years gay men and lesbians have made momentous progress toward legal rights and social acceptance in much of the developed world. For example, in 2010 for the first time a majority of Americans viewed homosexual relations

between adults as morally acceptable (Gallup, 2010). A plurality of Americans now support marriage for same-sex couples (Smith, 2011), and in many nations and in several U.S. states, gay men and lesbians have the legal right to marry. In some parts of the world, however, progress toward equal rights and acceptance has lagged far behind. In some countries in Africa and the Middle East, large majorities disapprove of homosexuality (Pew Research Center, 2007), and in a few of those countries homosexual people may be subject to capital punishment. The marked cross-cultural and historical variation in treatment of homosexual people should remind us to be cautious in assuming that a currently unpopular or uncommon trait is pathological without careful and persuasive analysis. Sometimes it is culture that is the problem.

### in review

- What does each of the three examples of sociocultural influences on sexual practices and standards reveal about cultural differences and historical changes in what is considered acceptable and normal sexual behavior?
- How has the psychiatric view of homosexuality changed over time? Identify a few key historical events that propelled this change.

## Gender Dysphoria

In *DSM-5*, there is a new classification for the *DSM-IV-TR* “Sexual and Gender Variants” referred to as Gender Dysphoria. This reflects a change in the way these diagnostic groups are defined. The phenomenon of “gender incongruence” is emphasized instead of “cross-gender identification” that was emphasized in *DSM-IV* Gender Identity Disorder. We will examine two general categories: the paraphilic disorders and gender identity disorders.

## The Paraphilic Disorders

People with **paraphilic disorders** have recurrent, intense sexually arousing fantasies, sexual urges, or behaviors that generally involve (1) nonhuman objects, (2) the suffering or humiliation of oneself or one's partner, or (3) children or other nonconsenting persons. Paraphilic disorders have challenged authors of past *DSM* editions for two main reasons. First, some paraphilic disorders—especially pedophilia—are widely considered pathological even if the paraphilic individual does not experience distress. For example, consider a pedophile who has molested children but does not feel guilty. Most people believe that such a man has a mental disorder. In the past, pedophilia has been diagnosed even in the absence of distress; so have frotteurism and exhibitionism, both of which typically involve nonconsenting individuals in sexual acts. A second challenge has been that some other categories of paraphilic disorders may be compatible with psychological health and happiness. For example, some men who have a foot fetish are comfortable with their sexual interest and even find willing partners who happily indulge them, while some others feel substantial shame and guilt (Bergner, 2009). In the past, only foot fetishists with intense shame and guilt (or other problems related to their fetish) would be diagnosed as paraphilic. But surely, both happy and distressed

foot fetishists have the same paraphilia. A useful distinction to be included in *DSM-5* is that between paraphilic interests and paraphilic disorders (Blanchard, 2010). Paraphilic interests are unusual sexual interests, but they need not cause harm either to the individual or to others. Only if they cause such harm do they become paraphilic disorders. Thus, foot fetishists have a paraphilia, but only those who suffer due to their sexual interest have a paraphilic disorder.

Although mild forms of these conditions probably occur in the lives of many normal people, a paraphilic person is distinguished by the insistence, and in some cases the relative exclusivity, with which his sexuality focuses on the acts or objects in question—without which orgasm is sometimes impossible. Paraphilic interests also frequently have a compulsive quality, and some individuals with paraphilic interests require orgasmic release as often as 4 to 10 times per day (Garcia & Thibaut, 2010). Individuals with paraphilic interests may or may not have persistent desires to change their sexual preferences. Because nearly all such persons are male (a fact whose etiological implications we consider later), we use masculine pronouns to refer to them (see Fedoroff et al., 1999, for some possible examples of women with paraphilic interests).

No one knows how common different paraphilic interests are. Good prevalence data do not exist, in part because people are often reluctant to disclose such deviant behavior (Griffiths, 2012). The *DSM-5* recognizes eight specific paraphilic disorders: (1) fetishism, (2) transvestic fetishism, (3) voyeurism, (4) exhibitionism, (5) sexual sadism, (6) sexual masochism, (7) pedophilia, and (8) frotteurism (rubbing one's genital area against a nonconsenting person). An additional category, paraphilic disorders not otherwise specified, includes several rarer disorders such as telephone scatology (obscene phone calls), necrophilia (sexual desire for corpses), zoophilia (sexual interest in animals; Aggrawal, 2011), apotemnophilia (sexual excitement and desire about having a limb amputated), and coprophilia (sexual arousal to feces). Although some of different paraphilic disorders tend to co-occur together, we will discuss each of them separately. In addition, our discussion of pedophilia is postponed until a later section concerning sexual abuse.

**FETISHISTIC DISORDER** In **fetishism**, the individual has recurrent, intense sexually arousing fantasies, urges, and behaviors involving the use of some inanimate object or a part of the body not typically found erotic (e.g., feet) to obtain sexual gratification (see “*DSM-5 Criteria for Several Different Paraphilic Disorders*”). As is generally true for the paraphilic disorders, reported cases of female fetishists are extremely rare (Mason, 1997). Usually the fetishistic object is required or strongly preferred during sexual arousal and activity. Many men have a strong sexual fascination for paraphernalia such as bras, garter belts, hose, and high heels, but most do not typically meet diagnostic criteria for fetishism because the paraphernalia are not necessary or strongly preferred for sexual arousal. Nevertheless, they do illustrate the relatively high frequency of fetish-like preferences among men. Fetishism occurs frequently in the context of sadomasochistic activity but is relatively rare among sexual offenders (Kafka, 2010).

**Fetishistic Disorder**

- A. Over a period of at least 6 months, recurrent and intense sexual arousal from either the use of nonliving objects or a highly specific focus on nongenital body part(s), as manifested by fantasies, urges, or behaviors.
- B. The fantasies, sexual urges, or behaviors cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- C. The fetish objects are not limited to articles of clothing used in cross-dressing (as in transvestic disorder) or devices specifically designed for the purpose of tactile genital stimulation (e.g., vibrator).

**Transvestic Disorder**

- A. Over a period of at least 6 months, recurrent and intense sexual arousal from cross-dressing, as manifested by fantasies, urges, or behaviors.
- B. The fantasies, sexual urges, or behaviors cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

**Voyeuristic Disorder**

- A. Over a period of at least 6 months, recurrent and intense sexual arousal from observing an unsuspecting person who is naked, in the process of disrobing, or engaging in sexual activity, as manifested by fantasies, urges, or behaviors.
- B. The individual has acted on these sexual urges with a nonconsenting person, or the sexual urges or fantasies cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- C. The individual experiencing the arousal and/or acting on the urges is at least 18 years of age.

**Exhibitionistic Disorder**

- A. Over a period of at least 6 months, recurrent and intense sexual arousal from the exposure of one's genitals to an unsuspecting person, as manifested by fantasies, urges, or behaviors.
- B. The individual has acted on these sexual urges with a nonconsenting person, or the sexual urges or fantasies cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

**Sexual Sadism Disorder**

- A. Over a period of at least 6 months, recurrent and intense sexual arousal from the physical or psychological suffering of another person, as manifested by fantasies, urges, or behaviors.
- B. The individual has acted on these sexual urges with a nonconsenting person, or the sexual urges or fantasies cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

**Sexual Masochism Disorder**

- A. Over a period of at least 6 months, recurrent and intense sexual arousal from the act of being humiliated, beaten, bound, or otherwise made to suffer, as manifested by fantasies, urges, or behaviors.
- B. The fantasies, sexual urges, or behaviors cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

**Pedophilic Disorder**

- A. Over a period of at least 6 months, recurrent, intense sexually arousing fantasies, sexual urges, or behaviors involving sexual activity with a prepubescent child or children (generally age 13 years or younger).
- B. The individual has acted on these sexual urges, or the sexual urges or fantasies cause marked distress or interpersonal difficulty.
- C. The individual is at least age 16 years and at least 5 years older than the child or children in Criterion A.

**Note:** Do not include an individual in late adolescence involved in an ongoing sexual relationship with a 12- or 13-year-old.

**Frotteuristic Disorder**

- A. Over a period of at least 6 months, recurrent and intense sexual arousal from touching or rubbing against a nonconsenting person, as manifested by fantasies, urges, or behaviors.
- B. The individual has acted on these sexual urges with a nonconsenting person, or the sexual urges or fantasies cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

The mode of using these objects to achieve sexual excitation and gratification varies considerably, but it commonly involves masturbating while kissing, fondling, tasting, or smelling the objects. In the context of consensual sexual relationships, fetishism does not normally interfere with the rights of others. However, some partners who do not share an erotic fascination with a fetishistic object may understandably object to participating. Some paraphilic men are so ashamed of their desires that they

cannot bring themselves to ask partners. Bergner (2009) relates the case of a foot fetishist who chooses chemical castration to suppress his desire rather than tell his wife.

To obtain the required object, some men with fetishes may commit burglary, theft, or even assault. The articles most commonly stolen by such individuals are probably women's undergarments. In such cases, the excitement and suspense of the criminal act itself typically reinforce the sexual stimulation and sometimes

actually constitute the fetish, the stolen article itself being of little importance. One example of this pattern of fetishism is provided in the case of a man whose fetish was women's panties:

→ **Panties** A single, 32-year-old male freelance photographer . . . related that although he was somewhat sexually attracted by women, he was far more attracted by "their panties." . . . [His] sexual excitement began about age 7, when he came upon a pornographic magazine and felt stimulated by pictures of partially nude women wearing "panties." His first ejaculation occurred at 13 via masturbation to fantasies of women wearing panties. He masturbated into his older sister's panties, which he had stolen without her knowledge. Subsequently he stole panties from her friends and from other women he met socially. . . . The pattern of masturbating into women's underwear had been his preferred method of achieving sexual excitement and orgasm from adolescence until the present consultation.

One common hypothesis regarding the etiology of fetishism emphasizes the importance of classical conditioning and social learning (e.g., Hoffmann, 2012). For example, it is not difficult to imagine how women's underwear might become eroticized via its close association with sex and the female body. But only a small number of men develop fetishes, so even if the hypothesis has merit there must be individual differences in conditionability of sexual responses (just as there are differences in the conditionability of fear and anxiety responses, as discussed in Chapter 6). Men high in sexual conditionability would be prone to developing one or more fetishes. We will return later to the role of conditioning in the development of paraphilic disorders more generally.

**TRANSVESTIC DISORDER** According to *DSM-5*, heterosexual men who experience recurrent, intense sexually arousing fantasies, urges, or behaviors that involve cross-dressing as a female may be diagnosed with **transvestic disorder**, if they experience significant distress or impairment due to the condition (see "DSM-5 Criteria" on p. 410). Although some gay men dress "in drag" on occasion, they do not typically do this for sexual pleasure and hence do not have the paraphilia transvestism. Typically, the onset of transvestism is during adolescence and involves masturbation while wearing female clothing or undergarments. Blanchard (1989, 2010) has hypothesized that the psychological motivation of most heterosexual transvestites includes **autogynephilia**: paraphilic sexual arousal by the thought or fantasy of being a woman (Blanchard, 1991, 1993; Lawrence, 2013). The great sexologist Magnus Hirschfeld first identified a class of cross-dressing men who are sexually aroused by the image of themselves as women: "They feel attracted not by the women outside them, but by the woman inside them" (Hirschfeld,

1948, p. 167). Not all men with transvestic fetishism show clear evidence of autogynephilia (Blanchard, 2010). The others seem quite similar to typical fetishists, focusing on specifics of their preferred female clothing and without having clearly apparent fantasies of becoming women. Among transvestic fetishists, strength of autogynephilic fantasies strongly predicts **gender dysphoria** and desire for sex reassignment surgery (Blanchard, 2010). Like other kinds of fetishism, transvestic fetishism causes overt harm to others only when accompanied by such an illegal act as theft or destruction of property. Such acts are rare, and the vast majority of transvestites are harmless.

One large survey of over 2,400 men and women in Sweden estimated that almost 3 percent of the men and 0.4 percent of the women reported having engaged in at least one episode of erotic cross-dressing, but the actual prevalence of the disorder is likely much lower (Langstrom & Zucker, 2005). This same study reported on various demographic and experiential differences between the men who had cross-dressed and those who had not. Among the most interesting findings were that the men who had cross-dressed had experienced more sexual abuse before age 10, were more easily sexually aroused, had a higher frequency of masturbation, made greater use of pornography, and had other paraphilic interests. An earlier survey of over 1,000 men who frequently crossed-dressed reported that the vast majority (87 percent) were heterosexual, 83 percent had married, and 60 percent were married at the time of the survey (Docter & Prince, 1997). Many managed to keep their cross-dressing a secret, at least for a while. However, wives often found out and had a wide range of reactions, from accepting to being extremely disturbed. The following case illustrates both the typical early onset of transvestic fetishism and the difficulties the condition may raise in a marriage.

→ **A Transvestite's Dilemma** Mr. A., a 65-year-old security guard, formerly a fishing-boat captain, is distressed about his wife's objections to his wearing a nightgown at home in the evening now that his youngest child has left home. His appearance and demeanor, except when he is dressing in women's clothes, are always appropriately masculine, and he is exclusively heterosexual. Occasionally, over the past 5 years, he has worn an inconspicuous item of female clothing even when dressed as a man, sometimes a pair of panties. . . . He always carries a photograph of himself dressed as a woman.

His first recollection of an interest in female clothing was putting on his sister's bloomers at age 12, an act accompanied by sexual excitement. He continued periodically to put on women's underpants—an activity that invariably resulted in an erection, sometimes a spontaneous emission, sometimes masturbation. . . . He was competitive and aggressive with other boys and always acted "masculine." During his single years he was always attracted to girls. . . .

His involvement with female clothes was of the same intensity even after his marriage. Beginning at age 45, after a chance

exposure to a magazine called *Transvestia*, he began to increase his cross-dressing activity. He learned there were other men like himself, and he became more and more preoccupied with female clothing in fantasy and progressed to periodically dressing completely as a woman. More recently he has become involved in a transvestite network . . . occasionally attending transvestite parties.

Although still committed to his marriage, sex with his wife has dwindled over the past 20 years as his waking thoughts and activities have become increasingly centered on cross-dressing. . . . He always has an increased urge to dress as a woman when under stress; it has a tranquilizing effect. If particular circumstances prevent him from cross-dressing, he feels extremely frustrated. . . .

Because of disruptions in his early life, the patient has always treasured the steadfastness of his wife and the order of his home. He told his wife about his cross-dressing practice when they were married, and she was accepting so long as he kept it to himself. Nevertheless, he felt guilty . . . and periodically he attempted to renounce the practice, throwing out all his female clothes and makeup. His children served as a barrier to his giving free rein to his impulses. Following his retirement from fishing, and in the absence of his children, he finds himself more drawn to cross-dressing, more in conflict with his wife, and more depressed.

**VOYEURISTIC DISORDER** A person is diagnosed with **voyeurism** according to *DSM-5* if he has recurrent, intense sexually arousing fantasies, urges, or behaviors involving the observation of unsuspecting females who are undressing or of couples engaging in sexual activity (see “*DSM-5 Criteria*” on p. 410). Frequently, such individuals masturbate during their peeping activity. Peeping Toms, as they are commonly called, commit these offenses primarily as young men. Voyeurism often co-occurs with exhibitionism, and it is also associated with interest in sadomasochism and cross-dressing (Langstrom & Seto, 2006). Voyeurism is probably the most common illegal sexual activity (Langstrom, 2010).

How do some young men develop this pattern? First, viewing the body of an attractive female is sexually stimulating for most heterosexual men. In addition, the privacy and mystery that have traditionally surrounded sexual activities tend to increase curiosity about them. Third, if a young man with such curiosity feels shy and inadequate in his relations with the opposite sex, he may accept the substitute of voyeurism, which satisfies his curiosity and to some extent meets his sexual needs without the trauma of actually approaching a female. He thus avoids the rejection and lowered self-status that such an approach might bring. In fact, voyeuristic activities often provide important compensatory feelings of power and secret

domination over an unsuspecting victim, which may contribute to the maintenance of this pattern. If a voyeur manages to find a wife in spite of his interpersonal difficulties, as many do, he is rarely well-adjusted sexually in his relationship with his wife, as the following case illustrates.

→ **A Peeping Tom** A young, married college student had an attic apartment that was extremely hot during the summer months. To enable him to attend school, his wife worked; she came home at night tired and irritable and not in the mood for sexual relations. In addition, “the damned springs in the bed squeaked.” In order “to obtain some sexual gratification,” the youth would peer through his binoculars at the room next door and occasionally saw the young couple there engaged in erotic activities. This stimulated him greatly, and he decided to extend his peeping to a sorority house. During his second venture, however, he was reported and was apprehended by the police. This offender was quite immature for his age, rather puritanical in his attitude toward masturbation, and prone to indulge in rich but immature sexual fantasies.

More permissive laws concerning “adult” movies, videos, and magazines in recent years have removed some of the secrecy about sexual behavior and also have provided an alternative source of gratification for would-be voyeurs. However, for many voyeurs, these movies and magazines probably do not provide an adequate substitute for secretly watching the sexual behavior of an unsuspecting couple or the “real-life” nudity of a woman who mistakenly believes she enjoys privacy. Moreover, the actual effect of these “adult materials” on voyeurism is a matter of speculation because there never have been good epidemiological data on the prevalence of this paraphilia, although it is thought to be one of the most common paraphilic disorders (Langstrom, 2010). The large Swedish survey mentioned earlier that was conducted with over 2,400 men and women found that 11.5 percent of the men and 3.0 percent of the women had at some time engaged in voyeuristic activity (Langstrom & Seto, 2006). Among those who did report such activity, they also reported more psychological problems, less satisfaction with life, higher rates of masturbation, greater use of pornography, and greater ease of sexual arousability.

Although a voyeur may become reckless in his behavior and thus may be detected or even apprehended by the police, voyeurism does not ordinarily have any other serious criminal or anti-social behaviors associated with it. In fact, many people probably have some voyeuristic inclinations, which are checked by practical considerations such as the possibility of being caught and by ethical attitudes concerning the right to privacy.

**EXHIBITIONISTIC DISORDER** **Exhibitionistic disorder** (*indecent exposure* in legal terms) is diagnosed in a person with recurrent, intense urges, fantasies, or behaviors that involve exposing his genitals to others (usually strangers) in inappropriate circumstances

Men who engage in exhibitionism often cause emotional distress in the viewers because of the intrusive quality of the act, along with its explicit violation of propriety norms.

and without their consent (see “*DSM-5 Criteria*” on p. 410). Frequently the element of shock in the victim is highly arousing to these individuals. The exposure may take place in some secluded location such as a park or in a more public place such as a department store, church, theater, or bus. In cities, an exhibitionist (also known as a flasher) often drives by schools or bus stops, exhibits himself while in the car, and then drives rapidly away. In many instances the exposure is repeated under fairly constant conditions, such as only in churches or buses or in the same general vicinity and at the same time of day. In one case, a youth exhibited himself only at the top of an escalator in a large department store. For a male offender, the typical victim is ordinarily a young or middle-aged female who is not known to the offender, although children and adolescents may also be targeted (Murphy, 1997).

Exhibitionism, which usually begins in adolescence or young adulthood, is the most common sexual offense reported to the police in the United States, Canada, and Europe, accounting for about one-third of all sexual offenses (McAnulty et al., 2001; Murphy, 1997). According to some estimates, as many as 20 percent of women have been the target of either exhibitionism or voyeurism (Kaplan & Krueger, 1997; Meyer, 1995). Although there are no good epidemiological data on the prevalence of this paraphilia, the large Swedish survey of over 2,400 people mentioned earlier reported that 4.1 percent of the men and 2.1 percent of the women had had at least one episode of exhibitionistic behavior (Langstrom & Seto, 2006). It commonly co-occurs with voyeurism and also tends to co-occur with sadomasochistic interests and cross-dressing (Langstrom, 2010). Exhibitionism is associated with greater psychological problems, lower life satisfaction, greater use of pornography, and more frequent masturbation.

In some instances, exposure of the genitals is accompanied by suggestive gestures or masturbation, but more often there is only exposure. A significant minority of exhibitionists commit aggressive acts, sometimes including coercive sex crimes against

adults or children. Some men who expose themselves may do so because they have antisocial personality disorder, as described in Chapter 10, rather than a paraphilia (Langstrom, 2010).

Despite the rarity of aggressive or assaultive behavior in these cases, an exhibitionistic act nevertheless takes place without the viewer’s consent and may be emotionally upsetting, as is indeed the perpetrator’s intent. This intrusive quality of the act, together with its explicit violation of propriety norms about “private parts,” ensures condemnation. Thus society considers exhibitionism a criminal offense.

**FROTTEURISTIC DISORDER** **Frotteurism** is sexual excitement at rubbing one’s genitals against, or touching, the body of a nonconsenting person. As with voyeurism, frotteurism reflects inappropriate and persistent interest in something that many people enjoy in a consensual context. Frotteurism commonly co-occurs with voyeurism and exhibitionism (Langstrom, 2010). Being the victim of a frotteuristic act is fairly common among regular riders of crowded buses or subway trains. Some have speculated that frotteurs’ willingness to touch others sexually without their consent means that they are at risk for more serious sexual offending, but there is currently no evidence supporting this concern (Langstrom, 2010). Because frotteurism typically requires unwilling participation of others, frotteuristic disorder is diagnosed if frotteuristic acts occur, whether or not the frotteurer is, himself, bothered by his urges.

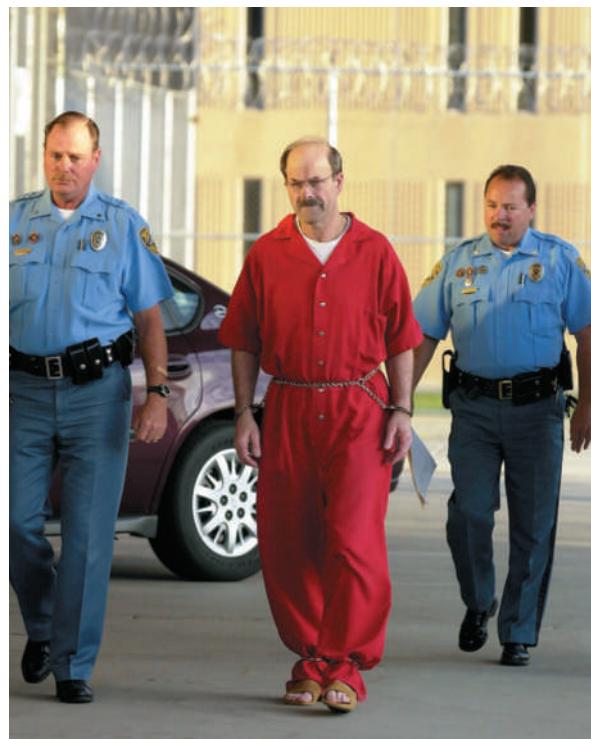

**SEXUAL SADISM DISORDER** The term **sadism** is derived from the name of the Marquis de Sade (1740–1814), who for sexual purposes, inflicted such cruelty on his victims that he was eventually committed as insane. In *DSM-5*, for a diagnosis of sadism, a person must have recurrent, intense sexually arousing fantasies, urges, or behaviors that involve inflicting psychological or physical pain on another individual (see “*DSM-5 Criteria*” on p. 410). Sadistic fantasies often include themes of dominance, control, and humiliation (Kirsh & Becker, 2007). A closely related, but less severe, pattern is the practice of “bondage and discipline” (B & D), which may include tying a person up, hitting or spanking, and so on to enhance sexual excitement. The large majority of sexually sadistic acts probably occur in the context of a consensual sexual relationship without any evident harm. In large urban communities, there is often a BDSM subculture consisting of individuals who enjoy mild sadism, masochism, bondage, and discipline. It is thus important to distinguish transient or occasional interest in sadomasochistic practices from sadism as a paraphilia. Surveys have found that perhaps 5 to 15 percent of men and women enjoy sadistic and/or masochistic activities voluntarily on occasion (Baumeister & Butler, 1997; Hucker, 1997).

A small minority of men with sexual sadism, in contrast, enjoy inflicting sadistic acts that are nonconsensual, serious, and sometimes fatal (Chang & Heide, 2009; Dietz et al., 1990; Krueger, 2010). In some cases, sadistic activities lead up to or terminate in actual sexual relations; in others, full sexual gratification is obtained from the sadistic practice alone. A sadist,

for example, might slash a woman with a razor or stick her with a needle, experiencing an orgasm in the process. The pain inflicted by sadists may come from whipping, biting, cutting, or burning; the act may vary in intensity, from fantasy to severe mutilation and even murder. Paraphilic sadism and masochism, in which sadomasochistic activities are the preferred or exclusive means to sexual gratification, are much rarer; not uncommonly, they co-occur in the same individual (Kirsh & Becker, 2007). *DSM-5* requires that the diagnosis of sadism be reserved for cases either in which the victim is nonconsenting or in which the sadistic experience is marked by distress or interpersonal difficulties. Many cases of sexual sadism have comorbid disorders—especially the narcissistic, schizoid, or antisocial personality disorders (Kirsh & Becker, 2007). Perhaps sexual sadists with these personality disorders are especially non-empathic and thus likely to act on their sexual urges.

Extreme sexual sadists may mentally replay their torture scenes later while masturbating. Serial killers, who tend to be sexual sadists, sometimes record or videotape their sadistic acts. One study characterized 20 sexually sadistic serial killers who were responsible for 149 murders throughout the United States and Canada (Warren et al., 1996). Most were white males in their late 20s or early 30s. Their murders were remarkably consistent over time, reflecting sexual arousal to the pain, fear, and panic of their victims. Choreographed assaults allowed them to carefully control their victims' deaths. Some of the men reported that the God-like sense of being in control of the life and death of another human being was especially exhilarating. Eighty-five percent of the sample reported consistent violent sexual fantasies, and 75 percent collected materials with a violent theme including audiotapes, videotapes, pictures, or sketches of their sadistic acts or sexually sadistic pornography.

Notorious serial killers include Ted Bundy, who was executed in 1989. Bundy confessed to the murder of over 30 young women, nearly all of whom fit a targeted type: women with long hair parted in the middle. Bundy admitted that he used his victims to re-create the covers of detective magazines or scenes from "slasher movies." Jeffrey Dahmer was convicted in 1992 of having mutilated and murdered 15 boys and young men, generally having sex with them after death. (He was subsequently murdered in prison.) Dennis Rader, the BTK Killer (for Bind, Torture, Kill), was captured in 2005 after committing 10 murders over 30 years in Wichita, Kansas. Rader exemplifies several interesting phenomena associated with homicidal sexual sadism. As a child he tortured animals and fantasized about tying up and torturing attractive children he watched on television. When he began enacting his fantasies, he stalked his victims for weeks to learn their habits before he attacked them. He enjoyed tying them up and then strangled them. Only after they were dead would he gratify himself sexually through masturbation. He often retained clothing of his victims, which he would sometimes wear. Sometimes in private he would practice bondage on himself because he found this erotic.

Dennis Rader was married with two children, an active member in his church, and a respected member of the community; he was also a serial killer known as the BTK killer.

What causes some men to be sexually sadistic killers? Although many sadists have had chaotic childhoods, Bundy, Dahmer, and Rader all came from apparently stable and loving families. Unfortunately, we do not have a good understanding of the causal factors involved in these extreme cases of sadism.

Sexual sadism is understandably an important concern of criminologists, law enforcement officers, and forensic mental health professionals. Unfortunately, the diagnosis of sexual sadism is not very reliable (Marshall & Hucker, 2006) or valid (Kingston et al., 2010), perhaps due to the sadist's unwillingness to his sometimes appallingly violent sexual fantasies (Nietschke et al., 2012). This is concerning, given how important it is to detect dangerous sexual sadists and how stigmatizing a diagnosis of sexual sadism might be to someone whose sexual desires are harmless. One promising modification currently being considered is a dimensional approach that could distinguish sexual sadists who are dangerous from those who are not (Krueger, 2010; Marshall & Hucker, 2006). Another is to focus on behavioral indicators of sadism, which are sometimes more apparent (Nietschke et al., 2012).

**SEXUAL MASOCHISM DISORDER** The term **masochism** is derived from the name of the Austrian novelist Leopold V. Sacher-Masoch (1836–1895), whose fictional characters dwelt lovingly on the sexual pleasure of pain. In sexual

masochism, a person experiences sexual stimulation and gratification from the experience of pain and degradation in relating to a lover. According to *DSM-5* (see “*DSM-5 Criteria*” on p. 410), the person must have experienced recurrent, intense sexually arousing fantasies, urges, or behaviors involving the act of being humiliated, beaten, bound, or otherwise made to suffer.

Consensual sadomasochistic relationships, involving a dominant, sadistic “master” and a submissive, masochistic “slave” are not uncommon in either heterosexual or homosexual relationships. Such masochists do not usually want, or cooperate with, true sexual sadists and prefer individuals willing to hurt or humiliate them within preset limits. Masochism appears to be more common than sadism and occurs in both men and women (Baumeister & Butler, 1997; Sandnabba et al., 2002). Sadomasochistic activities, including bondage and discipline, are often performed communally within “dungeons” popular in major cities. Such activities might involve men being bound and whipped by women called “dominatrixes,” who wear tight leather or rubber outfits and are paid to inflict pain and humiliation in a sexually charged sense. Most mem-

bers of this sadomasochistic community are high functioning and do not appear to suffer because of their sexual interests (Krueger, 2010).  [Watch the Video Jocelyn: Exploring Sexual Sadism and Masochism on MyPsychLab.](#)

Some rare forms of masochism are more problematic, however. One particularly dangerous form of masochism, called *autoerotic asphyxia*, involves self-strangulation. Although some writers have speculated that loss of oxygen to the brain intensifies orgasm, there is little evidence that this motivates practitioners of autoerotic asphyxia. In contrast, studies of such practitioners have found that their sexual fantasies are strongly masochistic (Hucker, 2011). Coroners in most major U.S. cities are familiar with cases in which the deceased is found hanged next to masochistic pornographic literature or

Sadomasochistic activities, including bondage and discipline, are often performed communally within “dungeons” popular in major cities.

other sexual paraphernalia. Accidental deaths attributable to this practice have been estimated to range between 500 and 1,000 per year in the United States (LeVay & Baldwin, 2012). Although autoerotic asphyxia is much more common in men, it can occur in women too, and it has occurred across many cultures going back hundreds of years. In some cases it occurs in a consensual or nonconsensual sadomasochistic act between two or more people (McGrath & Turvey, 2008).

The following is a case of autoerotic asphyxia with a tragic ending.

 **“I Got Tangled in the Rope”** A woman heard a man shouting for help and went to his apartment door. . . .

The woman with her two sons . . . broke into the apartment. They found the man lying on the floor, his hands tied behind him, his legs bent back, and his ankles secured to his hands. A mop handle had been placed behind his knees. He was visibly distraught, sweating, and short of breath, and his hands were turning blue. He had defecated and urinated in his trousers. In his kitchen the woman found a knife and freed him.

When police officers arrived and questioned the man, he stated that he had returned home that afternoon, fallen asleep on his couch, and awakened an hour later only to find himself hopelessly bound. The officers noted that the apartment door had been locked when the neighbors broke in . . . [and] when the officers filed their report, they noted that “this could possibly be a sexual deviation act.” Interviewed the next day, the man confessed to binding himself in the position in which he was found.

A month later, the police were called back to the same man’s apartment. A building manager had discovered him face down on the floor in his apartment. A paper bag covered his head like a hood. When the police arrived, the man was breathing rapidly with a satin cloth stuffed in his mouth. Rope was stretched around his head and mouth and wrapped his chest and waist. Several lengths ran from his back to his crotch, and ropes at his ankles had left deep marks. A broom handle locked his elbows behind his back. Once freed, the man explained, “While doing isometric exercises, I got tangled up in the rope.” . . .

Two years passed and the man moved on to another job. He failed to appear for work one Monday morning. A fellow employee found him dead in his apartment. During their investigation, police were able to reconstruct the man’s final minutes. On the preceding Friday, he had bound himself in the following manner: sitting on his bed and crossing his ankles, left over right, he had bound them together with twine. Fastening a tie around his neck, he then secured the tie to an 86-inch pole behind his back. . . . [By a complicated set of maneuvers he applied] pressure to the pole, still secured to the tie around his neck, [and] strangled himself.

## Causal Factors and Treatments for Paraphilias

Many individuals with paraphilic interests have explanations for their unusual sexual preferences. For example, one amputee paraphilic (whose preference was a partner with a missing limb) recalled that his fascination with female amputees originated during adolescence. He was neglected emotionally by his cold family but heard a family member express sympathetic feelings for an amputee. He developed the wish that he would become an amputee and thus earn their sympathy (see First, 2005, for a discussion of this paraphilia, known as *apotemnophilia*). This story raises many questions. Emotionally cold families are not uncommon, and sympathy for amputees is nearly universal. Certainly not every male in a cold family who detects sympathy for amputees develops an amputee paraphilia. Such stories do not necessarily have any validity because we are often unaware of the forces that shape us (Nisbett & Wilson, 1977).

Several facts about paraphilia are likely to be important in their development. First, as we have already noted, nearly all persons with paraphilic interests are male; females with most paraphilic interests are so rare that they are found in the literature only as case reports or a series of case reports (e.g., Fedoroff et al., 1999). Second, paraphilic interests usually begin around the time of puberty

or early adolescence. Third, people with paraphilic interests often have a strong sex drive, with some men often masturbating many times a day. Fourth, people with paraphilic interests frequently have more than one. For example, the corpses of men who died accidentally in the course of autoerotic asphyxia were partially or fully cross-dressed in 25 to 33 percent of cases (Blanchard & Hucker, 1991). There is no obvious reason for the association between sexual masochism and transvestism. Why should it be so?

Money (1986) and others have suggested that male vulnerability to paraphilic interests is closely linked to their greater dependence on visual sexual imagery. Perhaps sexual arousal in men depends on physical stimulus features to a greater degree than in women, whose arousal may depend more on emotional context such as being in love with a partner. If so, men may be more vulnerable to forming sexual associations to nonsexual stimuli, which may be most likely to occur after puberty, when the sexual drive is high. Many believe that these associations arise as a result of classical and instrumental conditioning and/or social learning that occurs through observation and modeling. When observing paraphilic stimuli (e.g., photographs of models in their underwear), or when fantasies about paraphilic stimuli occur, boys may masturbate, and the reinforcement by orgasm-release may serve to condition an intense attraction to paraphilic stimuli (e.g., Kaplan & Krueger, 1997; LeVay & Baldwin, 2012). This hypothesis cannot explain, however, why only a small minority of males develop fetishes for panties and bras, despite the nearly universal experience of masturbating to pictures or videos of women wearing them.

Men's vulnerability to paraphilic interests such as fetishism may be a result of their greater dependence on visual stimuli. This in turn makes them more likely to form sexual associations to nonsexual stimuli such as women's legs or high-heeled shoes, quite possibly through a process of classical conditioning.

**TREATMENTS FOR PARAPHILIC INTERESTS** The vast majority of studies concerning the treatment of paraphilic interests have been conducted with sex offenders. The literature concerning treatment of men with paraphilic interests who have not committed any offense, or who have victimless paraphilic interests (e.g., masochism), consists primarily of case reports because most people with paraphilic interests do not seek treatment for these conditions. Thus we defer discussion of the treatment of paraphilic interests until we discuss the treatment of sex offenders, many of whom have paraphilic interests.

## Gender Dysphoria

In *DSM-5* Gender Dysphoria has replaced *Gender Identity Disorder*. "Gender dysphoria" is discomfort with one's sex-relevant physical characteristics or with one's assigned gender. The change in terminology is both usefully descriptive and theoretically neutral. That is, individuals who have been previously diagnosed with gender identity disorder certainly experience gender dysphoria, but whether or not this is always due to atypical gender identity development is less clear. Gender dysphoria also is consistent with a dimensional approach (the degree of dysphoria can vary) and may fluctuate over time within the same individual (Cohen-Kettenis & Pfafflin, 2010). Gender dysphoria can be

**Gender Dysphoria in Children**

- A. A marked incongruence between one's experienced/expressed gender and assigned gender, of at least 6 months' duration, as manifested by at least six of the following (one of which must be Criterion A1):
1. A strong desire to be of the other gender or an insistence that one is the other gender (or some alternative gender different from one's assigned gender).
  2. In boys (assigned gender), a strong preference for cross-dressing or simulating female attire; or in girls (assigned gender), a strong preference for wearing only typical masculine clothing and a strong resistance to the wearing of typical feminine clothing.
  3. A strong preference for cross-gender roles in make-believe play or fantasy play.
  4. A strong preference for the toys, games, or activities stereotypically used or engaged in by the other gender.

5. A strong preference for playmates of the other gender.
6. In boys (assigned gender), a strong rejection of typically masculine toys, games, and activities and a strong avoidance of rough-and-tumble play; or in girls (assigned gender), a strong rejection of typically feminine toys, games, and activities.
7. A strong dislike of one's sexual anatomy.
8. A strong desire for the primary and/or secondary sex characteristics that match one's experienced gender.

- B. The condition is associated with clinically significant distress or impairment in social, school, or other important areas of functioning.

diagnosed at two different life stages, either during adolescence or adulthood (i.e., gender dysphoria in adolescents and adults) or childhood (gender dysphoria in children).  [Watch the Video](#)  
*Travis: Gender Dysphoria* on [MyPsychLab](#).

**GENDER DYSPHORIA IN CHILDHOOD** Boys with gender dysphoria show a marked preoccupation with traditionally feminine activities (Zucker, 2010; Zucker & Bradley, 1995). They may prefer to dress in female clothing. They enjoy stereotypical girls' activities such as playing dolls and playing house. They usually avoid rough-and-tumble play and often express the desire to be a girl. Boys with gender dysphoria are often ostracized as "sissies" by their peers.

Girls with gender dysphoria typically balk at parents' attempts to dress them in traditional feminine clothes such as dresses, preferring boys' clothing and short hair. Fantasy heroes typically include powerful male figures like Batman and Superman. They show little interest in dolls and increased interest in sports. Although mere tomboys frequently have many or most of these traits, girls with gender identity disorder are distinguished by their desire to be a boy or to grow up as a man. Young girls with gender dysphoria are treated better by their peers than are boys with gender dysphoria because cross-gender behavior in girls is better tolerated (Cohen-Kettenis et al., 2003; Zucker et al., 1997). In clinic-referred gender dysphoria, boys outnumbered girls five to one in one study (Cohen-Kettenis et al., 2003) and by three to one in another study (Cohen-Kettenis et al., 2006). An appreciable percentage of that imbalance may reflect

greater parental concern about femininity in boys than about masculinity in girls.

The most common adult outcome of boys with gender dysphoria has been homosexuality rather than transsexualism (Zucker, 2005). In Richard Green's (1987) prospective study of 44 very feminine boys from the community, only one sought sex change surgery by age 18. About three-quarters became gay or bisexual men who were evidently satisfied with their biological sex. However, several later studies of clinic-referred children have found that 10 to 20 percent of boys with gender dysphoria later were diagnosed as transsexual by age 16 or 18, and about 40 to 60 percent identified themselves as homosexual or bisexual, a percentage that may have increased by the time they were older (Zucker, 2005). There are several smaller prospective studies of girls with gender dysphoria that have shown that 35 to 45 percent may show persistent gender dysphoria (leading to a desire for sex reassignment surgery in many), and approximately half had a homosexual orientation. However, the largest prospective study to date, which followed 25 girls with gender dysphoria (ages 3–12) into young adulthood (average age 23), found somewhat lower rates of persistent gender dysphoria and homosexuality. At follow-up, three were classified as being dissatisfied with their gender, and two of these three wanted to have sex reassignment surgery. However, 32 percent had homosexual or bisexual fantasies, and 24 percent engaged in homosexual or bisexual behavior. These rates are clearly much higher than expected from base rates of gender dysphoria in the population but not as high as in boys with gender dysphoria (Drummond et al., 2008).

- A. A marked incongruence between one's experienced/expressed gender and assigned gender, of at least 6 months' duration, as manifested by at least two of the following:
1. A marked incongruence between one's experienced/expressed gender and primary and/or secondary sex characteristics (or in young adolescents, the anticipated secondary sex characteristics).
  2. A strong desire to be rid of one's primary and/or secondary sex characteristics because of a marked incongruence with one's experienced/expressed gender (or in young adolescents, a desire to prevent the development of the anticipated secondary sex characteristics).
  3. A strong desire for the primary and/or secondary sex characteristics of the other gender.

4. A strong desire to be of the other gender (or some alternative gender different from one's assigned gender).
5. A strong desire to be treated as the other gender (or some alternative gender different from one's assigned gender).
6. A strong conviction that one has the typical feelings and reactions of the other gender (or some alternative gender different from one's assigned gender).

- B. The condition is associated with clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Given that many such children typically adjust well in adulthood, should they be considered to have a mental disorder as children? Some have argued that such children should not be considered "disordered" because the primary obstacle to their happiness may be a society that is intolerant of cross-gender behavior. However, many researchers who work with these children maintain that the distress and unhappiness these children and adolescents have about the discrepancy between their biological sex and their psychological gender are consistent with this being called a mental disorder (e.g., Zucker, 2005, 2010). Moreover, these children are frequently mistreated by their peers and have strained relations with their parents even though their cross-gender behavior harms no one.

Research from non-Western cultures shows that stigmatization of gender-nonconforming children is not universal (Vasey & Bartlett, 2007). In Samoa, very feminine males are often considered "Fa'afafine" (roughly meaning "in the manner of women"), a kind of third gender, neither male nor female. Fa'afafine are identified as young children by their behavior and usually are accepted by their families and culture. As adults these individuals are sexually attracted to other men and typically have sexual relations with heterosexual men. They generally do not recall that their childhood gender nonconformity was associated with distress. Because of this, some have argued that childhood gender dysphoria should not appear in *DSM-5* (Vasey & Bartlett, 2007). Despite these objections, the diagnosis has been retained as gender dysphoria in children (Zucker, 2010).

**Treatment** Children and adolescents with gender dysphoria are often brought in by their parents for psychotherapy (Zucker et al., 2008). Specialists attempt both to treat the child's unhappiness with his or her biological sex and to ease strained relations with parents and peers. Children with gender dysphoria often have other general psychological and behavioral problems

such as anxiety and mood disorders that also need therapeutic attention (Zucker et al., 2002). Therapists try to improve peer and parental relations by teaching such children how to reduce their cross-gender behavior, especially in situations where it might cause interpersonal problems. Gender dysphoria is typically treated psychodynamically—that is, by examining inner conflicts. Controlled studies evaluating such treatment remain to be conducted (Zucker, 2005). If a child will eventually transition into the other sex, it is beneficial to prevent full sexual maturity from occurring in the original, unwanted sex. Thus, in the progressive Netherlands, under some circumstances, gender dysphoric early adolescents are given hormonal treatment to delay puberty while they decide how to proceed (Cohen-Kettenis, 2010).

Two related facts about gender dysphoria in children are especially important clinically. First, as we have noted, most gender dysphoric children do not become gender dysphoric adults. The problem generally remits during childhood (Wallien & Cohen-Kettenis, 2008). Second, individuals who are still gender dysphoric into adolescence are likely to remain so into adulthood, and they are also likely to take medical steps to transform their bodies. The crucial age period at which many gender dysphoric children desist or persist appears to be 10 to 13 (Steensma et al., 2011). Increasing numbers of parents of gender dysphoric children cooperate with their children's wishes and allow them socially to assume an identity opposite their birth sex (Rosin, 2008). On the one hand, this surely decreases the anguish that such children feel. On the other hand, it is plausible that this strategy will ultimately lead to more transsexual adolescent or adult outcomes.

**TRANSSEXUALISM** **Transsexualism** occurs in adults with gender dysphoria who desire to change their sex, and surgical advances have made this goal, although expensive, partially feasible. Transsexualism represents the extreme on a continuum of transgenderism, or the degree to which one identifies as the other sex

(Cohen-Kettenis & Pfafflin, 2010). Transsexualism is apparently a very rare disorder. In the past, European studies suggested that approximately 1 in 30,000 adult males and 1 in 100,000 adult females seek sex reassignment surgery. However, more recent estimates suggest that about 1 in 12,000 men in Western countries has actually undergone the surgery (Lawrence, 2007). Until fairly recently, most researchers assumed that transsexualism was the adult version of childhood gender dysphoria, and indeed this is often the case. That is, many transsexuals had gender dysphoria as children (despite the fact that most children with gender dysphoria do not become transsexual), and their adult behavior is analogous. This appears to be the case for the large majority of female-to-male transsexuals (individuals born female who become male). Virtually all such individuals recall being extremely tomboyish, with masculinity persisting unabated into adulthood. Most, but not all, female-to-male transsexuals are sexually attracted to women.

In contrast to female-to-male transsexuals, there are at least two kinds of male-to-female transsexuals, with very different causes and developmental courses: *homosexual* and *autogynephilic transsexuals* (Bailey, 2003; Blanchard, 1989). Homosexual transsexual men are generally very feminine and have the same sexual orientation as gay men: They are sexually attracted to biological males (their preoperative biological sex). However, because these transsexual men experience their gender identity as female, they often define their sexual orientation as heterosexual and resent being labeled gay. Thus what is referred to in the research literature as a homosexual male-to-female transsexual is a genetic male seeking a sex change operation who describes himself as a woman trapped in a man's body and who is sexually attracted to heterosexual male partners (Bailey, 2003). In contrast, autogynephilic transsexuals are motivated by **autogynephilia**—a paraphilia in which their attraction is to thoughts, images, or fantasies of themselves as a woman (Blanchard, 1991, 1993). Although it may not be relevant for treatment purposes (both types of transsexuals are appropriate candidates for sex reassignment surgery), this distinction is fundamental to understanding the diverse psychology of male-to-female transsexualism. Moreover, estimates show an increased prevalence in Western countries of male-to-female transsexualism in recent years, and most of this increase is in autogynephilic transsexualism (Lawrence, 2007).

One important finding is that homosexual transsexuals generally have had gender dysphoria since childhood, paralleling what is found in female-to-male transsexuals, as discussed above. However, because most boys with gender dysphoria do not become transsexual adults (but instead become gay or bisexual men), there must be other important determinants of transsexualism. One hypothesis is that there are some prenatal hormonal influences affecting which children who develop gender identity disorder later become transsexuals (Meyer-Bahlburg, 2011). Another is that some families are more systematic in their support of boys' defeminization compared with other families.

Autogynephilic (sometimes called heterosexual) transsexualism almost always occurs in genetic males who usually report a

Mianne Bagger (a Danish-born Australian resident) is a male-to-female transsexual who has golfed professionally in women's tournaments since 2003. She is the first known female professional golfer who was born male. Before she could play women's tournaments, rule changes had to be implemented in Europe, Australia, and other countries so that it was no longer required that a competitor be female at birth.

history of transvestic fetishism. However, unlike other transvestites, autogynephilic transsexuals fantasize that they have female genitalia, which can lead to acute gender dysphoria, motivating their desire for sex reassignment surgery. Autogynephilic transsexuals may report sexual attraction to women, to both men and women, or to neither. Research has shown that these subtypes of autogynephilic transsexuals (varying in sexual orientation) are very similar to each other and differ from homosexual transsexuals in other important respects (Bailey, 2003; Blanchard, 1985, 1989, 1991). For example, relative to homosexual transsexuals, the autogynephilic transsexuals have more fetishistic and masochistic tendencies, a stronger preference for younger and more attractive partners, and a stronger interest in uncommitted sex (Veale et al., 2008). Unlike homosexual transsexuals, autogynephilic transsexuals do not appear to have been especially feminine in childhood or adulthood, and they typically seek sex reassignment surgery much later in life than do homosexual transsexuals (Blanchard, 1994). The causes of autogynephilic transsexualism thus probably overlap etiologically with the causes of other paraphilic (with which they often co-occur) but are not yet well understood (Veale et al., 2008).

Autogynephilia remains a controversial concept among some transgender individuals, who object that autogynephilia

is inconsistent with their experiences and that their motivation to change their sex is not sexual. Some supporters of the theory of autogynephilia attribute the denial of autogynephilia to factors including sexual shame and stigmatization (Bailey & Triea, 2007). In *DSM-IV-TR* adult gender identity disorder, the distinction between homosexual and autogynephilic transsexualism was recorded as a specifier: the patient's sexual orientation. This practice was intended to facilitate data collection regarding possible important clinical differences between the two types. However, for complex reasons a subgroup of transsexuals vehemently dislikes the idea that there are two different kinds of male-to-female transsexuals; they are especially hostile to the notion of autogynephilia (Dreger, 2008). For this reason, the specifier of sexual orientation has been removed from adult gender dysphoria in *DSM-5*. Sexual orientation (i.e., the distinction between homosexual and autogynephilic) appears to be a highly valid predictor of other differences between the two types of male-to-female transsexuals (Lawrence, 2010). However, this appears to be a case in which a trade-off was made between scientific rigor and social acceptability.

**Treatment** Psychotherapy is usually not effective in helping adolescents or adults to resolve their gender dysphoria (Cohen-Kettenis et al., 2000; Zucker & Bradley, 1995). The only treatment that has been shown to be effective is surgical sex reassignment. Initially, transsexuals who want and are awaiting surgery are given hormone treatment. Biological men are given estrogens to facilitate breast growth, skin softening, and shrinking of muscles. Biological women are given testosterone, which suppresses menstruation, increases facial and body hair, and deepens the voice. Before they are eligible for surgery, transsexuals typically must live for many months with hormonal therapy, and they generally must live at least a year as the gender they wish to become. If they successfully complete the trial period, they undergo surgery and continue to take hormones indefinitely. In male-to-female transsexuals, this entails removal of the penis and testes and the creation of an artificial vagina. One fascinating study of 11 male-to-female transsexuals found that the artificial vaginal tissue created from penile tissue showed signs of sexual arousal to male erotic stimuli if the person was a homosexual male-to-female transsexual, and to female erotic stimuli if the person was an autogynephilic transsexual (Lawrence et al., 2005). In general, the transsexual neovagina is sexually functional. Male-to-female transsexuals usually also undergo extensive electrolysis to remove their beards and body hair. They also learn to raise the pitch of their voice.

Female-to-male transsexuals typically are given mastectomies and hysterectomies and often have other plastic surgery to alter various facial features (such as the Adam's apple). Only a subset of female-to-male transsexuals seeks an artificial penis because relevant surgical techniques are still somewhat primitive and very expensive. Moreover, the artificial penis is not capable of normal erection, so those who have this surgery must rely on artificial supports to have intercourse anyway. The others function sexually without any penis.

Does sex reassignment surgery help transsexuals lead satisfying lives? In 1990 a review of the outcome literature found that 87 percent of 220 male-to-female transsexuals had satisfactory outcomes (meaning that they did not regret their decisions) and that 97 percent of 130 female-to-male transsexuals had successful outcomes (Green & Fleming, 1990). More recent studies have reported similar findings. Thus the majority of transsexuals are satisfied with the outcome of sex reassignment surgery, although there is variability in the degree of satisfaction (Cohen-Kettenis & Gooren, 1999; Lawrence, 2006). The Lawrence study (2006) of 232 male-to-female transsexuals all operated on by the same surgeon found the participants to be least satisfied with vaginal lubrication and vaginal touch sensations, although overall level of satisfaction was still high. Regarding psychological adjustment, a recent follow-up showed that transsexuals who had sex reassignment surgery were less well-adjusted compared with normal controls (Dhejne et al., 2011). The optimal comparison, however, is not with normal controls but with transsexuals desiring but not given sex reassignment surgery. In spite of the reasonably good success record for transsexual patients who are carefully chosen, such surgery remains controversial because some professionals continue to maintain that it is inappropriate to treat psychological disorders through drastic anatomical changes.

### in review

- Define *paraphilia*, and cite six paraphilic disorders recognized in the *DSM*, along with their associated features.
- What two components characterize gender dysphoria?
- Identify the two types of male-to-female transsexuals, and describe their developmental course as well as that of female-to-male transsexuals.
- What are the most effective treatments for childhood gender dysphoria and adult transsexualism?

## Sexual Abuse

**Sexual abuse** is sexual contact that involves physical or psychological coercion or at least one individual who cannot reasonably consent to the contact (e.g., a child). Such abuse includes pedophilia, incest, and rape, and it concerns society much more than any other sexual problem. It is somewhat ironic, then, that of these three forms of abuse, only pedophilia is included in *DSM-5*. This partly reflects the seriousness with which the society views these offenses and its preference for treating coercive sex offenders as criminals rather than as having a mental disorder (although obviously many criminals also have mental disorders).

### Childhood Sexual Abuse

The past few decades have seen intense concern about childhood sexual abuse, with an accompanying increase in relevant research. There are at least three reasons for including some

discussion of this here. First, as noted in previous chapters, there are possible links between childhood sexual abuse and some mental disorders, so such abuse may be important in the etiology of some disorders (see especially Chapters 3, 5, 8, and 10). Second, much evidence suggests that, broadly defined, childhood sexual abuse is more common than was once assumed, and it is important to understand some of its causes. Third, some dramatic and well-publicized cases involving allegations of childhood sexual abuse have raised very controversial issues such as the validity of children's testimony and the accuracy of recovered memories of sexual abuse. We shall consider all three of these issues in turn.

**PREVALENCE OF CHILDHOOD SEXUAL ABUSE** The prevalence of childhood sexual abuse depends on its definition, which has varied substantially across studies. For example, different studies use different definitions of "childhood," with the upper age limit ranging from 12 to as high as 19 years. Some studies have counted any kind of sexual interaction, even that which does not include physical contact (e.g., exhibitionism); others have counted only physical contact; others have counted only genital contact; and still others have counted consensual sexual contact with a minor. A recent review of data from 22 countries estimated that 7.9 percent of men and 19.7 percent of women had suffered sexual abuse prior to age 18. The highest rates were from African countries, and the lowest rates were from Europe; U.S. figures were intermediate. Obviously "prior to age 18" comprises a wide range of ages, and, for example, age 17 is not always viewed as part of childhood.

**CONSEQUENCES OF CHILDHOOD SEXUAL ABUSE** Childhood sexual abuse may have both short-term and long-term consequences. The most common short-term consequences are fears, posttraumatic stress disorder (PTSD), sexual inappropriateness (e.g., touching others' genitals or talking about sexual acts), and poor self-esteem, but approximately one-third of sexually abused children show no symptoms (e.g., Kendall-Tackett et al., 1993; McConaghy, 1998).

Associations between reports of childhood sexual abuse and adult psychopathology have been commonly reported (Maniglio, 2009). Specific examples include borderline personality disorder (Bandelow et al., 2005; Battle et al., 2004), somatization disorder with dissociative symptoms (Sar et al., 2004), and dissociative identity disorder (Maldonado & Spiegel, 2007; Ross, 1999). A wide variety of sexual symptoms have also been alleged to result from early sexual abuse (e.g., Leonard & Follette, 2002; Loeb et al., 2002; see review in Maniglio, 2009), ranging, for example, from sexual aversion to sexual promiscuity. A similar range of negative consequences has also been reported in a sample of about 3,000 male and female adults in China, although the rate of childhood sexual abuse in China is lower than in Western countries (Luo et al., 2008). Unfortunately, as discussed in Chapters 8 and 10, knowledge about these hypothesized

associations is very limited because of difficulties in establishing causal links between early experiences and adult behavior (see also "Unresolved Issues").

## CONTROVERSIES CONCERNING CHILDHOOD SEXUAL ABUSE

Several types of high-profile criminal trials have highlighted the limitations of our knowledge concerning questions of great scientific and practical importance. In one type of case, children have accused adults working in day care settings of extensive, often bizarre sexual abuse, and controversial issues have been raised about the degree to which children's accusations can be trusted. In a second type of case, adults claim to have repressed and completely forgotten memories of early sexual abuse and then to have "recovered" the memories during adulthood, typically while seeing a therapist who believes that repressed memories of childhood sexual abuse are a very common cause of adult psychopathology. Many controversial issues have been raised about the validity of these "recovered" memories.

**Children's Testimony** Several cases of alleged sexual abuse in day care settings shocked the country starting in the 1980s and continuing into the early 1990s. The most notorious was the McMartin Preschool case in California (Eberle & Eberle, 1993). In 1983, Judy Johnson complained to police that her son had been molested by Raymond Buckey, who helped run the McMartin Preschool, which her son attended. Johnson's complaints grew increasingly bizarre. For example, she accused Buckey of sodomizing her son while he stuck the boy's head in a toilet and of making him ride naked on a horse. Johnson was later diagnosed with acute paranoid schizophrenia, and she died of alcohol-related liver disease in 1986. By the time she died, prosecutors no longer needed her. Children at the preschool who were interviewed began to tell fantastically lurid stories—for example, that they were forced to dig up dead bodies at cemeteries, jump out of airplanes, and kill animals with bats. Nevertheless, prosecutors and many McMartin parents believed the children. Buckey and his mother (who owned the day care facility) were tried in a trial that took two and a half years and cost \$15 million. The jury acquitted Ms. Buckey on all counts and failed to convict Raymond Buckey on any; however, he was freed only after retrial, after having spent 5 years in jail. The jurors' principal reason for not finding the defendants guilty was their concern that interviewers had used leading questions or coercive methods of questioning. Moreover, subsequent research on children who reported satanic abuse found no evidence (including physical evidence) that such abuse had occurred, and so any such reports of satanic abuse are scientifically very doubtful (London et al., 2005). Despite these concerns, some day care workers accused of satanic sexual abuse have served years in prison.

Obviously, investigations of possible child sexual abuse will often depend on the reports and testimony of children. We have noted the tendency in recent times of people to believe children's reports, no matter how unlikely they seem. Is the confidence in

Evidence has suggested that the use of anatomically correct dolls to question young children about where they may have been touched in alleged incidents of sexual abuse does not improve the accuracy of their testimony relative to verbal interviews alone.

children's reports of sexual abuse well-founded? In a very important series of studies, the psychologists Stephen Ceci and Maggie Bruck have shown that children can easily be led to concoct stories of events that never occurred (Bruck et al., 2002; Ceci et al., 2000, 2007; London et al., 2005). The likelihood of concocting stories increases when interviewers have asked leading questions, repeated questioning, and reinforcing some kinds of answers more than others. This research shows that failure to proceed with care in interrogating children can easily lead to false accusations and injustice. In the legal case *U.S. v. Desmond Rouse* (2004), a federal appeals court (i.e., a court just below the U.S. Supreme Court) established new rules for evaluating the admissibility of children's testimony based almost exclusively on the work of Ceci and Bruck.

**Recovered Memories of Sexual Abuse** In 1990, a young woman named Eileen Franklin testified in court that she had seen her father rape and murder an 8-year-old playmate 20 years earlier. Remarkably, despite her claim to have witnessed the murder, she had had no memory of the event until she "recovered" the memory by accident in adulthood (MacLean, 1992). Franklin's father was convicted and given a life sentence, although in 1995 the conviction was overturned because of two serious constitutional errors made during the original trial that might have affected the jury's verdict. In a different kind of case, Patricia Burgus sued her two psychiatrists in Chicago for false-memory implantation, claiming the doctors had persuaded her through hypnosis and other therapeutic techniques "to believe that she was a member of a satanic cult, that she was sexually abused by multiple men, and that she engaged in cannibalism and abused her own children" (Brown et al., 2000, p. 3). In 1997 she was awarded \$10.6 million.

As discussed in some detail in Chapter 8, whether traumatic experiences can be utterly forgotten and then somehow recovered intact years later has been heatedly debated over the past several

decades. Some have argued that repressed memories are common (e.g., Herman, 1993) and are responsible for a great deal of psychopathology. In the controversial but very popular book *The Courage to Heal*, journalists Ellen Bass and Laura Davis assert, "If you are unable to remember any specific instances [of sexual abuse] . . . but still have the feeling that something abusive happened to you, it probably did" (1988, p. 21). Yet as researchers have pointed out, there is absolutely no evidence that this statement is true. Some therapists still routinely give this book to their clients, and those clients often do report "recovering" such memories. Those skeptical about recovery of repressed memories point out that even normal, unrepressed memories can be highly inaccurate and that false memories can be induced experimentally (Davis & Loftus, 2009; Loftus et al., 1995) (see Chapter 8). The debate about the validity of memories of childhood sexual abuse that arise during therapy remains extremely heated. Some researchers (the nonbelievers) maintain that the concept of repressed memory is wholly or largely invalid. In their view, virtually all "recovered memories" are false (Crews, 1995; Davis & Loftus, 2009; Thomas & Loftus, 2002). Others (the believers) maintain that false memories rarely occur and that recovered memories are typically valid. Still others believe that valid recovered memories are simply the remembering of events forgotten because, at the time, they were not traumatic (McNally & Geraerts, 2009). Psychologists equally familiar with the evidence have argued bitterly about this issue, and, as discussed in more detail in Chapter 8, a task force assembled by the American Psychological Association to study the issue in the mid-1990s failed to reach a consensus, although an online guide urges caution ("Questions and answers about childhood sexual abuse," 2013). Indeed, the debate concerning recovered memories of sexual abuse is one of the most important and interesting contemporary controversies in the domains of psychopathology and mental health, as discussed in the Unresolved Issues section in Chapter 8. Despite the continuing controversy among scientists, cases of recovered memories of sexual abuse appear to have become much rarer. A survey conducted of the False Memory Syndrome Foundation—largely parents who say they have been accused by their children of sexual abuse based on recovered memories—showed that accusations peaked in 1991 and 1992, with 579 made during that time. In 1999 and 2000 only 36 accusations were made (McHugh & Kreek, 2004).

## Pedophilic Disorder

According to *DSM-5*, **pedophilic disorder**—a paraphilic disorder not discussed earlier—is diagnosed when an adult has recurrent, intense sexual urges or fantasies about sexual activity with a prepubertal child; acting on these desires is not necessary for the diagnosis if they cause the pedophile distress (see "*DSM-5 Criteria*" on p. 410). *DSM-5* retains the wording of *DSM-IV-TR*, that a child is understood to be "generally age 13 or younger." In doing so, the *DSM-5* rejected two potentially important suggestions from the *DSM-5* subcommittee on paraphilic disorders:

that pedophilia be diagnosed according to the degree of physical maturity of the child (as rated by Tanner scores, which index degree of pubertal maturation), and second, that diagnostic criteria for pedophilia (attraction to prepubescent children) be changed to include men with hebephilia (attraction to pubescent children—children in the early stages of puberty). The debate over these proposals was heated, and the issues are interesting. We believe that *DSM-5* should have made the changes. Read the Thinking Critically About *DSM-5* to see if you agree.

Pedophiles' sexual interaction with children frequently involves manual or oral contact with a child's genitals; penetrative anal or vaginal sex is much rarer. Although penetration and associated force are often injurious to the child, injuries are usually a byproduct rather than the goal they would be with a sadist (although a minority of men diagnosed with pedophilic disorder are also sexual sadists; Cohen & Galynker, 2002).

Nearly all individuals with pedophilia are male, and about two-thirds of pedophilic offenders' victims are girls,

typically between the ages of 8 and 11 (Cohen & Galynker, 2002). Most pedophiles prefer girls, but perhaps one in four prefers boys. The rate of homosexuality among pedophiles is much higher than the analogous rate among normal adult-attracted men (Seto, 2008). Although some social conservatives have argued that this shows that gay men tend to commit pedophilic acts, this is an incorrect inference. Gay men are no more interested in male children than heterosexual men are in female children. Homosexual pedophilia is an entirely different erotic preference from normal male homosexuality (Herek, 2009). Homosexual pedophilic sex offenders tend to have more victims than heterosexual pedophilic sex offenders (Blanchard et al., 2000; Cohen & Galynker, 2002). One survey of pedophiles found that a majority have used childhood pornography (Seto, 2004).

Studies investigating the sexual responses of men with pedophilia have revealed several patterns of results (Barbaree & Seto, 1997; Seto et al., 2006). Such studies typically use a *penile*

## THINKING CRITICALLY about *DSM-5*

### Pedophilia and Hebephilia

**DSM-5**

Pedophilia has been understood and defined as attraction to prepubertal children, that is, children without any signs of puberty (e.g., no pubic hair, breast growth, or penis growth). However, studies of sex offenders, both of victim characteristics and of offender sexual arousal patterns, have unequivocably demonstrated the existence of a subgroup who are most aroused not to prepubescent children, but to pubescent children (children in the early stages of puberty). Scientists have called such men *hebephiles*. Pubescent children are not fully sexually mature, despite showing some signs of pubertal development. Pedophilia and hebephilia appear to be closely related, because it is not uncommon for pedophiles also to be attracted to pubescent children and hebephiles to prepubescent children. The *DSM-5* paraphilic subcommittee proposed that the definition of pedophilia be expanded to include attraction to pubescent children. (That is, the proposal was that *DSM-5* pedophilia would now include hebephilia as well as *DSM-IV-TR* pedophilia.) Furthermore, instead of diagnosing pedophilia based on the age of children to whom a man is sexually attracted (i.e., 13 years old and younger), the committee proposed that diagnosis be made based on the physical maturity of the children. They proposed that this be done on the basis of well-known developmental markers. (These markers, called Tanner scores, represent the degree of pubertal maturation and range from "none" to "completed.") This would be more diagnostically accurate than relying on children's ages because children mature at variable rates. A 12-year-old girl might be prepubescent, but in this day and age she is more likely to be pubescent because most girls in the United States have begun puberty by that age (Razzak, 2012).

In *DSM-IV-TR*, which relied on child victims' ages, a diagnosis of pedophilia would be likely regardless of the girl's level of physical maturity. But the *DSM-IV-TR* diagnostic criteria for pedophilia defined it as sexual attraction to prepubescent children. Thus, *DSM-IV-TR* diagnostic criteria for pedophilia often led to technically inaccurate diagnoses. Using physical maturity rather than age of desired children to diagnose pedophilia would require that clinicians think correctly about the meaning of pedophilia.

The proposed changes proved highly controversial because of the proposed expansion of pedophilia to include attraction to pubescent children. Opponents of its inclusion asserted that attraction to pubescent girls is characteristic of normal men (e.g., Rind & Yuill, 2012; Wakefield, 2012). The idea that normal men are attracted to pubescent children is largely mistaken, and represents a failure to appreciate the physical immaturity of children in the early stages of puberty, compared with children or adolescents who have completed puberty. In the end, the *DSM-5* rejected both the expansion of the definition of pedophilia to include attraction to pubescent children and diagnosing pedophilia on the basis of desired children's degree of sexual maturity (focusing on developmental markers of prepubescence and pubescence). Instead, *DSM-5* retains the internally contradictory criteria of *DSM-IV-TR*, namely that pedophilia is attraction to prepubescent children, and that prepubescence is understood as "younger than age 13" even though many of such children are not prepubescent. Many people working in the area are not pleased that *DSM-5* did not make the proposed changes. What do you think?

*plethysmograph* to measure erectile responses to sexual stimuli directly rather than relying on self-report. (A plethysmograph consists of an expandable band placed around the penis that is connected to a recording device.) Men with pedophilia typically show greater sexual arousal than matched nonoffenders in response to pictures of nude or partially clad girls—and greater arousal to such pictures than to pictures of adult women. But some men with pedophilia respond to children as well as to adolescents and/or adults (Seto, 2004; Seto et al., 1999).

Child molesters are more likely than nonoffenders to engage in self-justifying cognitive distortions, including the beliefs that children will benefit from sexual contact with adults and that children often initiate such contact (Marziano et al., 2006). Motivationally, many pedophilic child molesters appear to be shy and introverted yet still desire mastery or dominance over another individual. Some also idealize aspects of childhood such as innocence, unconditional love, or simplicity (Cohen & Galynker, 2002).

Pedophilia usually is first recognized in adolescence and persists over a person's life. Many pedophiles engage in work with children or youth so that they have extensive access to children. Some pedophiles never act on their preferences, but many do. It is currently impossible to estimate the proportion of men with pedophilia who remain child-celebate. Several studies show that adolescent and adult men with pedophilia are much more likely to have been sexually or physically abused as children than are rapists of adults (Daversa & Knight, 2007; Lee & Katzman, 2002). The meaning of this association remains unclear.

Recent research findings also support the importance of several neurobiological influences on pedophilia. Compared with non-pedophilic sex offenders, men with pedophilia have lower IQs (Cantor, Blanchard et al., 2005; Seto, 2004), threefold higher rates of non-right-handedness (Cantor, Klassen et al., 2005; Seto, 2004), higher rates of head injuries resulting in loss of consciousness, and differences in brain structure detected by brain-imaging techniques, at least some of which are critical for normal sexual development (Cantor et al., 2008; Schiltz et al., 2007). All these findings point to pedophilia involving certain perturbations of early neurodevelopment that may create a vulnerability to the disorder.

For several decades we have seen an increasing number of cases of child molestation among a group long considered to be highly trustworthy: the Catholic clergy. Although the majority of priests are innocent of sexual wrongdoing, the Catholic Church has been repeatedly forced to admit that a significant minority have sexually abused children. In a large study of the problem, 81 percent of complainants against Catholic clergy were male, and more than 40 percent of cases involved children aged 12 or younger when the alleged abuse began (John Jay College of Criminal Justice, 2004). At least 400 priests were charged with sexual abuse during the 1980s, and \$400 million was paid in damages between 1985 and the early 1990s (Samborn, 1994). One very serious scandal involved James R. Porter, a 57-year-old father of four who was alleged to have sexually abused as many as 100 children when he was a priest

in Massachusetts during the 1960s. (Complicating the case, some but not all of the accusations against him were based upon recovered memories.) Porter later admitted to some of his offenses and was convicted. The Church settled a multimillion-dollar suit with 25 men whom Porter was convicted of abusing.

Scandal in the Catholic Church erupted anew in 2002, with heightened publicity regarding revelations that not only had a substantial number of priests in many cities been sexually involved with children and adolescents, but a significant number had also been protected by their superiors. Indeed, this scandal led, after a prolonged public outcry, to the resignation of Cardinal Bernard Law of the Archdiocese of Boston. Over many years, Law had protected numerous priests who were guilty of sexual misconduct, allowing them to move from one parish to another after their sexual misconduct was discovered. Thus he allowed their sexual molestation to continue with more and more girls and boys. The Conference of Bishops subsequently adopted a policy of mandatory removal of any priest from his ministerial duties if he is known to have had sexual contact with a minor. This new policy seems to be working at least to some extent. In September 2005, for example, Cardinal Francis George of the Archdiocese of Chicago permanently removed 11 priests from public ministerial duties for reasons of sexual misconduct (*Chicago Tribune*, September 27, 2005). New cases continue to emerge, and there is no particular reason to expect they will stop anytime soon. Similar problems of priests engaging in abuse have also occurred in Ireland (LeVay & Baldwin, 2012).

Former priest John Geoghan was found guilty of sexually molesting two boys and accused of sexually molesting dozens more in several parishes in the Boston area.

Not all men with pedophilia molest children. In a confidential study of German men who sought mental health services because of their pedophilic feelings, 30 percent reported that they had never had sexual contact with a child. Most of those, however, had viewed child pornography (Neutze et al., 2011). The organization B4UAct (Before You Act) is intended to support law-abiding men with pedophilic feelings and to raise awareness that such men exist and suffer due to societal prejudice (Clarke-Flory, 2012). Another organization called Virtuous Pedophiles is intended to reduce stigma toward law-abiding pedophiles by raising consciousness about their existence (Clarke-Flory, 2012).

## Incest

Culturally prohibited sexual relations (up to and including coitus) between family members such as a brother and sister or a parent and child are known as **incest**. Although a few societies have sanctioned certain incestuous relationships—at one time it was the established practice for Egyptian pharaohs to marry their sisters to prevent the royal blood from being “contaminated”—the incest taboo is virtually universal among human societies. Incest often produces children with mental and physical problems because close genetic relatives are much more likely than nonrelatives to share the same recessive genes (which often have negative biological effects) and hence to produce children with two sets of recessive genes. Presumably for this reason, many nonhuman animal species, and all known primates, have an evolved tendency to avoid matings between close relatives. The mechanism for human incest avoidance appears to be lack of sexual interest in people to whom one is continuously exposed from an early age. For example, biologically unrelated children who are raised together in Israeli kibbutzim rarely marry or have affairs with others from their rearing group when they become adults (Kenrick & Luce, 2004). Evolutionarily, this makes sense. In most cultures, children reared together are biologically related.

In our own society, the actual incidence of incest is difficult to estimate because it usually comes to light only when reported to law enforcement or other agencies. It is almost certainly more common than is generally believed, in part because many victims are reluctant to report the incest or do not consider themselves victimized. Brother–sister incest is the most common form of incest even though it is rarely reported (LeVay & Baldwin, 2012). The second most common pattern is father–daughter incest. It seems that girls living with stepfathers are at especially high risk for incest, perhaps because there is less of an incest taboo among nonblood relatives (Finkelhor, 1984; Masters et al., 1992). Mother–son incest is thought to be relatively rare. Frequently, incest offenders do not stop with one child in a family (Wilson, 2004), and some incestuous fathers involve all of their daughters serially as they become pubescent.

Some incestuous child molesters have pedophilic arousal patterns (Barsetti et al., 1998; Seto et al., 1999), suggesting that

they are at least partly motivated by sexual attraction to children, although they also show arousal to adult women. However, they differ from extrafamilial child molesters in at least two respects (Quinsey et al., 1995). First, the large majority of incest offenses are against girls, whereas extrafamilial offenses show a more equal distribution between boys and girls. Second, incest offenders are more likely to offend with only one or a few children in the family, whereas pedophilic child molesters are likely to have more victims (LeVay & Baldwin, 2012).

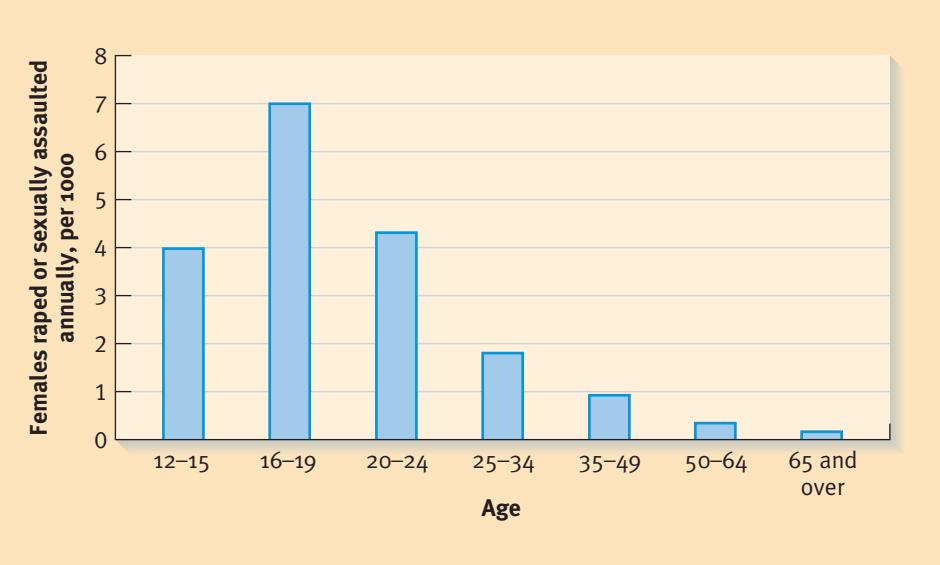

In 2007 the world was shocked at revelations concerning the case of an Austrian incest perpetrator named Josef Fritzl. Years earlier Fritzl had kidnapped his own daughter Elisabeth when she was 18 and incarcerated her in a soundproof compartment he had built in his own basement. He forced her to write a note saying that she had joined a cult and that she wanted no further contact with the family. She lived there for 24 years without the knowledge of her mother and other family members who lived upstairs. During her long incarceration, her father repeatedly forced her to have sex. During those years she bore seven children (one of whom died in infancy). Three of the children were reared by the family upstairs, ostensibly having been left for the family by Elisabeth. The other three lived in the basement with her. It was due to a medical problem in one of the latter children that the ordeal finally ended. She begged Josef to let her take the child to the hospital, and he agreed. Hospital staff thought the Fritzls’ cover story to be suspicious and alerted police, who successfully investigated (Dahlkamp et al., 2008).

## Rape

The term **rape** describes sexual activity that occurs under actual or threatened forcible coercion of one person by another (see Figure 12.1). In most states, legal definitions restrict forcible rape to forced intercourse or penetration of a bodily orifice by a penis or other object. *Statutory rape* is sexual activity with a person who is legally defined (by statute or law) to be under the age of consent (18 in most states) even if the underage person consents. In the vast majority of cases, rape is a crime of men against women, although in prison settings it is often committed by men against men.

It is important to note that forced sex is not unique to humans but rather occurs in many species in the animal kingdom, where it has often evolved as a reproductive strategy by males to produce more offspring. It has also existed in most human societies (including preliterate ones) at some time in history (Lalumière et al., 2005a). Across history, rape is traditionally most frequent during and following wars, when it sometimes reaches epidemic proportions. This may be because during war, men perceive few costs for the offense and it is perceived as a good way to express antagonism and contempt toward the enemy (Lalumière et al., 2005a).

**PREVALENCE** The results of different studies estimating the prevalence of rape have varied widely. This is, at least in part, because of differences across studies in the precise definition of rape

**FIGURE 12.1**

**Age of Rape and Sexual Assault Victims.** Young women are most at risk.

Source: Data from U.S. Department of Justice, 2002.

and the way information is gathered (direct or indirect questions, for example). For instance, the U.S. Department of Justice figures from 1998 estimated that one in three women would experience rape or attempted rape at some point in their lives, with many of these being attempted but not completed rapes; but other estimates have been substantially lower. Marital rape is now illegal in all 50 states in the United States and is estimated to occur in 10 to 14 percent of married women and 40 to 50 percent of battered women (Martin et al., 2007). Since the late 1970s, the prevalence of rape has diminished dramatically, from nearly 3 to fewer than 0.5 per 1,000 individuals per year (Bureau of Justice, 2011).

**IS RAPE MOTIVATED BY SEX OR AGGRESSION?** Traditionally, rape has been classified as a sex crime, and society has assumed that a rapist is motivated by lust. However, in the 1970s some feminist scholars began to challenge this view, arguing that rape is motivated by the need to dominate, to assert power, and to humiliate a victim rather than by sexual desire for her (e.g., Brownmiller, 1975). Certainly from the perspective of the victim, rape—which is among women’s greatest fears—is always an act of violence and is certainly not a sexually pleasurable experience, whatever the rapist’s motivation.

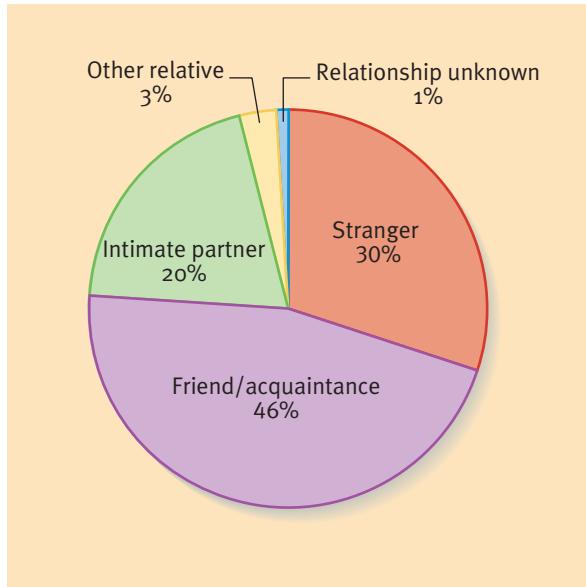

In spite of the fact that feminist writers have argued that rape is primarily a violent act, there are many compelling reasons why sexual motivation is often, if not always, a very important factor too (e.g., Bryden & Grier, 2011; Ellis, 1989; Thornhill & Palmer, 2000). For example, although rape victims include females of all degrees of physical attractiveness, the age distribution of rape victims is not at all random but includes a very high proportion of women in their teens and early 20s, who are generally considered the most sexually attractive. This age distribution is quite different from the distribution of other violent crimes, in which the elderly are overrepresented because of their vulnerability. Furthermore, rapists usually cite sexual motivation

as a very important cause of their actions. Finally, as we shall see, at least some rapists exhibit features associated with paraphilic and have multiple paraphilic (Abel & Rouleau, 1990; LeVay & Baldwin, 2012). Men with paraphilic are typically highly sexually motivated.

In the past few decades, several prominent researchers studying sex offenders have shown that all rapists actually have both aggressive and sexual motives but to varying degrees. For example, Knight and Prentky (1990) identified four subtypes of rapists, with two subtypes motivated primarily by aggression and two subtypes motivated primarily by distorted sexual motives (see also Knight et al., 1994). More recently, McCabe and Wauchope (2005) provided empirical support for a somewhat different classification system that also has four subtypes of rapists with differing amounts of sexual and aggressive motives. At present it is not clear which scheme of classification is best, and some rapists cannot readily be characterized (LeVay & Baldwin, 2012).

**RAPE AND ITS AFTERMATH** Stranger rape tends to be a repetitive activity rather than an isolated act, and most rapes are planned events. About 80 percent of rapists commit the act in the neighborhoods in which they reside; most rapes occur in an urban setting at night, in places ranging from dark, lonely streets to elevators and hallways, and apartments or homes. About a third or more of all rapes involve more than one offender. The remainder are single-offender rapes in which the victim and the offender are acquainted with each other (in about two-thirds of rapes); this includes wives (Bennice & Resick, 2003) (see Figure 12.2).

In addition to the physical trauma inflicted on a victim, the psychological trauma may be severe, leading in a substantial number of female victims to PTSD (see Chapter 5), which, when caused by rape, is often also associated with severe sexual problems. A rape may also have a negative impact on a victim’s

**FIGURE 12.2**

**Most Rapes Are Not Committed by Strangers.** The graph shows the relationships of perpetrators of rape and sexual assault to their victims.  
Source: Data from U.S. Department of Justice, 2002.

marriage or other intimate relationships. Although there has been little systematic study of men who have been raped, one study of 40 male rape victims revealed that nearly all experienced some long-term psychological distress following rape, including anxiety, depression, increased feelings of anger, and loss of self-image (Walker et al., 2005).

Rape, even at its least violent, is a bullying, intrusive violation of another person's integrity, selfhood, and personal boundaries that deserves to be viewed with more gravity—and its victims with more compassion and sensitivity—than has often been the case. Nevertheless, the myth of "victim-precipitated" rape, once a favorite of defense attorneys and of some police and court jurisdictions, still remains in certain circles. According to this view, a victim (especially a repeat victim), though often bruised both psychologically and physically, is regarded as the cause of the crime, often on such grounds as the alleged provocativeness of her clothing, her past sexual behavior, or her presence in a location considered risky (LeVay & Baldwin, 2012; Stermac et al., 1990). The attacker, on the other hand, is regarded as unable to quell his lust in the face of such irresistible provocation—and therefore is not treated as legally responsible for the act. Fortunately, *rape shield laws* began to be introduced in the 1970s. These laws protect rape victims by, for example, preventing the prosecutor from using evidence of a victim's prior sex history; however, many problems in these laws still remain (LeVay & Baldwin, 2012).

A recent example of the complexity inherent in the legal situation of rape prosecution is that of Dominique Strauss-Kahn (DSK), who was managing director of the International Monetary Fund and an aspiring French politician. In May 2011, he was accused by a New York City hotel worker of sexually assaulting her when she entered his hotel room to clean it. A police

investigation confirmed that sexual contact had occurred, but DSK insisted that it was consensual. Subsequently another woman came forward accusing him of raping her years earlier in France. However, the 2011 case unraveled when prosecutors learned that DSK's accuser had lied about other matters, including the claim that she had been raped in her country of origin. The charges were dropped. It is possible that DSK got away with rape. It is also possible that he was falsely accused. Cases such as the accusations against DSK highlight both barriers to prosecuting rape cases and the need for adequate protections for the accused.

**RAPISTS AND CAUSAL CONSIDERATIONS** Information gathered by the FBI about arrested and convicted rapists suggests that rape is usually a young man's crime. According to FBI Uniform Crime Reports, about 60 percent of all rapists arrested are under 25 years old. Of the rapists who get into police records, about 30 to 50 percent are married and living with their wives at the time of the crime. As a group, they come from the low end of the socioeconomic ladder and commonly have a prior criminal record (Ward et al., 1997). They are also quite likely to have experienced sexual abuse, a violent home environment, and inconsistent caregiving in childhood (Hudson & Ward, 1997).

One subset of rapists, date rapists (a date rapist is an acquaintance who rapes a woman in the context of a date or other social interaction), have a somewhat different demographic profile in that they are often middle- to upper-class young men who rarely have criminal records. However, these men, like incarcerated rapists, are characterized by promiscuity, hostile masculinity, and an emotionally detached, predatory personality (e.g., Knight, 1997; LeVay & Baldwin, 2012). Their victims are often highly intoxicated (Mohler-Kuo et al., 2004; Testa et al., 2003). What distinguishes them, primarily, is that incarcerated rapists show much higher levels of impulsive, antisocial behavior than date rapists.

As suggested earlier, there is evidence that some rapists are afflicted by a paraphilia (Abel & Rouleau, 1990; Freund & Seto, 1998). For example, rapists often report having recurrent, repetitive, and compulsive urges to rape. Although they typically try to control these urges, the urges sometimes become so strong that they act on them. Many rapists also have other paraphilic behaviors such as exhibitionism and voyeurism. They also frequently have a characteristic pattern of sexual arousal (Abel & Rouleau, 1990; Clegg & Fremouw, 2009; Lohr et al., 1997). Most rapists are similar to normal, nonoffending men in being sexually aroused by depictions of mutually satisfying, consensual intercourse, but many rapists are also sexually aroused by depictions of sexual assaults involving an unwilling victim (Clegg & Fremouw, 2009; Lalumière et al., 2005b). A small minority of rapists are sexual sadists, characterized by very violent assaults and aroused more by assault than by sexual stimuli.

In terms of personality, rapists are very often characterized by impulsivity, quick loss of temper, lack of personally intimate relationships, and insensitivity to social cues or pressures

Which scenario do you think is more likely to lead to rape? It is difficult to guess because date rape is increasingly common, and rapes by casual acquaintances usually occur in dark, lonely places.

(Giotakos et al., 2004), and a subset qualify for a diagnosis of psychopathy (e.g., Knight & Guay, 2006). Many rapists also show some deficits in social and communication skills (Emmers-Sommer et al., 2004), as well as in their cognitive appraisals of women's feelings and intentions (Ward et al., 1997). For example, they are particularly deficient in skills involved in successful conversation, which is necessary for developing consenting relationships with women. In addition, they have difficulty decoding women's negative cues during social interactions and often interpret friendly behavior as flirtatious or sexually provocative (Emmers-Sommer et al., 2004). This can lead to inappropriate behaviors that women would experience as sexually intrusive.

Estimates are that only 20 to 28 percent of rapes are ever reported, compared to 60 percent of robberies, but the proportion of rapes being reported has increased over the past several decades (Magid et al., 2004). Among men who are arrested, only about half are convicted; of these, only about two-thirds serve a jail term (LeVay & Baldwin, 2012). Convictions often bring light sentences, and a jail term does not dissuade a substantial number of offenders from repeating their crimes. Consequently, the large majority of rapists are not in prison but out among us.

### Treatment and Recidivism of Sex Offenders

For several decades in the United States there has been extreme concern about, and intolerance of, sex offenders who repeat their crimes. Soon after his release from prison, convicted sex offender Earl Shriner forced a 7-year-old boy off his bike in the woods near Tacoma, Washington, and then raped and stabbed him before cutting off the boy's penis. Just before his release from prison, Shriner had confided to a cellmate that he still had fantasies of molesting and murdering children (Popkin, 1994). In a similar case, 7-year-old Megan Kanka was sexually molested and murdered by a convicted child molester living in her neighborhood. Cases such as these have inspired a number of measures to

protect society from sexual predators (see "The World Around Us" box).

But are such stories representative? Are sex offenders typically incurable? Should they receive life sentences on the presumption that they are bound to offend again? Or have they been unfairly singled out by media sensationalism even though they really are responsive to treatment? The efficacy of treatment for sex offenders is controversial, and this is the topic to which we now turn (e.g., Fedoroff, 2009).

In general, sex offender recidivism is actually markedly lower than for many other kinds of crimes. Recidivism rates for some types of offenders are higher than they are for others, however (Mann et al., 2010). Specifically, sex offenders with deviant sexual preferences (e.g., exhibitionists, severe sadists, and those who are most attracted to children) have particularly high rates of sexual recidivism (Dickey et al., 2002; Langevin et al., 2004). One follow-up study of more than 300 sex offenders over 25 years found that over half were charged with at least one additional sexual offense (Langevin et al., 2004). A recent review found that sexualized violence—a preference for sadistic or coercive sex—was the strongest predictor of recidivism. Other predictors included negative social influences, poor cognitive problem-solving, and loneliness (Mann et al., 2010). The recidivism rate for rapists steadily decreases with age, as does performance of sexually deviant behavior more generally (Barbaree & Blanchard, 2008).

**PSYCHOTHERAPIES AND THEIR EFFECTIVENESS** Therapies for sex offenders typically have at least one of the following four goals: to modify patterns of sexual arousal and attraction, to modify cognitions and social skills in order to allow more appropriate sexual interactions with adult partners, to change habits or behavior that increases the chance of reoffending, or to reduce sexual drive. Attempts to modify sexual arousal patterns usually involve *aversion therapy*, in which a paraphilic stimulus such as a slide of

## Megan's Law

**O**n July 29, 1994, 7-year-old Megan Kanka, from Hamilton Township, New Jersey, was walking home from her friend's house when a neighbor invited her to his house to see his new puppy. The neighbor, Jesse Timmendequas, 33, was a landscaper who had lived across the street for about a year. Unknown to Megan, to Megan's parents, or to anyone else in the neighborhood, he was also a twice-convicted child molester (who lived with two other convicted sex offenders). When Megan followed him inside, he led her to an upstairs bedroom, strangled her unconscious with his belt, raped her, and asphyxiated her with a plastic bag. Timmendequas then placed Megan's body in a toolbox, drove to a soccer field, and dumped it near a portable toilet. Timmendequas was subsequently apprehended, convicted, and sentenced to death; however, because New Jersey abolished the death penalty in 2007, he will serve a life term in prison.

Megan's murder sparked outrage at the fact that dangerous sex offenders could move into a neighborhood without notifying the community of their presence. In response, the New Jersey state legislature passed Megan's Law, which mandates that upon release, convicted sex offenders register with police and that authorities notify neighbors that convicted sex offenders have moved in by distributing fliers, alerting local organizations, and canvassing door-to-door. Similar laws have been passed in many

other states, and it is now possible in several states to visit a website containing pictures and addresses of convicted sex offenders, subject to that state's Megan's Law. Although Megan's Laws have been enormously popular with state legislators and citizens, they have not been uncontroversial. Civil libertarians have objected to community notification requirements, which, they argue, endanger released offenders (who have arguably paid their debts to society) and also prevent them from integrating successfully back into society. Although the various Megan's Laws are intended to protect potential victims rather than to encourage harassment of sex offenders, the latter has occurred, with up to one-third to one-half of registered offenders in some states experiencing one or more of the following: loss of a job or home, threats, harassment, property damage, and/or harm to family members (Levenson et al., 2007). In addition, the limited amount of relevant data has brought the effectiveness of Megan's Laws into question. For example, since 1995 a number of studies have compared recidivism rates from the period before which registration as a sex offender was required to rates after these laws were passed. Unfortunately, the results have not really provided any reassuring evidence that notifying communities has enhanced community safety (Levenson et al., 2007). A recent analysis in New Jersey, where Megan Kanka lived and died, found that Megan's Law had made no difference (Zgoba & Levenson, 2008).

a nude prepubescent girl for a man with pedophilia is paired with an aversive event such as forced inhalation of noxious odors or a shock to the arm. An alternative to electric aversion therapy is *covert sensitization*, in which the patient imagines a highly aversive event while viewing or imagining a paraphilic stimulus, or *assisted covert sensitization*, in which a foul odor is introduced to induce nausea at the point of peak arousal (Beech & Harkins, 2012).

Deviant arousal patterns also need to be replaced by arousal to acceptable stimuli (Maletzky, 2002; Quinsey & Earls, 1990). Most often, investigators have attempted to pair the pleasurable stimuli of orgasm with sexual fantasies involving sex between consenting adults. For example, sex offenders are asked to masturbate while thinking of deviant fantasies. At the moment of ejaculatory inevitability, the patient switches his fantasy to a more appropriate theme. Although aversion therapy has been shown to be somewhat effective in the laboratory (Maletzky, 1998; Quinsey & Earls, 1990), how well this therapeutic change generalizes to the patient's outside world is uncertain if his motivation wanes. Further, although aversion therapy is still widely used for sex offenders, it is no longer used as a sole form of treatment (Marshall, 1998).

The remaining psychological treatments are aimed at reducing the chances of sexual reoffending. *Cognitive*

*restructuring* attempts to eliminate sex offenders' cognitive distortions because these may play a role in sexual abuse (Maletzky, 2002). For example, an incest offender who maintained that "If my ten-year-old daughter had said no, I would have stopped" might be challenged about a number of implied distortions: that a child has the capacity to consent to have sex with an adult; that if a child does not say no, she has consented; and that it is the child's responsibility to stop sexual contact. In addition, *social-skills training* aims to help sex offenders (especially rapists) learn to process social information from women more effectively and to interact with them more appropriately (Beech & Harkins, 2012; Maletzky, 2002; McFall, 1990). For example, some men read positive sexual connotations into women's neutral or negative messages or believe that women's refusals of sexual advances reflect "playing hard to get." Training typically involves interaction of perpetrators with female partners, who can give the offenders feedback on their response to the interactions.

Although some studies in the treatment literature have reached positive conclusions (see Maletzky, 2002, for a review), other studies have found essentially no differences between treated and untreated offenders (Emmelkamp, 1994; Rice et al.,

1991). A recent meta-analysis of 23 recidivism outcome studies revealed an advantage for treatment: 10.9 percent of treated sex offenders versus 19.2 percent of untreated offenders committed another sex crime (Hanson et al., 2009). The most effective treatment programs followed the Canadian “Risk-Need-Responsiveness” model, in which an offender’s risk is first assessed to determine who should get the most intensive treatment. Second, there is a focus on factors that directly increase chance of reoffending such as paraphilic desire or impulsivity. Third, correctional programs should be matched to offender characteristics such as learning style, level of motivation, and the offender’s individual characteristics. Such multifaceted cognitive-behavioral techniques appear to be more effective than older techniques such as aversion therapy. There are also indications in the literature that certain paraphilics respond better to treatment than others (Laws & O’Donohue, 2008). For example, one very long-term follow-up (5 to 15 years) of over 2,000 sex offenders who had entered a cognitive-behavioral treatment program found that non-pedophilic child molesters and exhibitionists achieved better overall success rates than pedophilic offenders and rapists (Maletzky & Steinhauer, 2002).

**BIOLOGICAL AND SURGICAL TREATMENTS** In recent years antidepressants from the SSRI (selective serotonin reuptake inhibitor) category have been found to be useful in treating a variety of paraphilics by reducing paraphilic desire and behavior; they are not, however, useful in the treatment of sexual offenders. The most controversial treatment for sex offenders involves castration—either surgical removal of the testes or the hormonal treatment sometimes called “chemical castration” (e.g., Berlin, 2003; Bradford & Greenberg, 1996; Weinberger et al., 2005). Both surgical and chemical castration lower the testosterone level, which in turn lowers the sex drive, allowing the offender to resist any inappropriate impulses. Chemical castration has most often involved the administration of antiandrogen steroid hormones such as Depo-Provera and Lupron, which can both have serious side effects. One uncontrolled study of the drug Lupron yielded dramatic results: Thirty men with paraphilics reported an average of 48 deviant fantasies per week prior to therapy, and no such fantasies during treatment (Rosler & Witztum, 1998; see also Maletzky & Field, 2003). However, relapse rates upon discontinuation of the drug were very high (Maletzky, 2002).

Studies of surgical castration of repeat sex offenders with violent tendencies conducted in Europe and more recently in the United States had similar results (but without high rates of relapse; Weinberger et al., 2005). These studies have typically included diverse categories of offenders, from child molesters to rapists of adult women. Follow-up has sometimes exceeded 10 years. Recidivism rates for castrated offenders are typically less than 3 percent, compared with greater than 50 percent for uncastrated offenders (e.g., Berlin, 1994; Green, 1992; Prentky, 1997). Despite the apparently high success rates, many feel that the treatment is brutal, unethical, and dehumanizing (Farkas &

Stichman, 2002; Gunn, 1993), although this assumption has been challenged (Bailey & Greenberg, 1998).

Interestingly, some recent cases have involved a request by the sex offender himself to be castrated in exchange for a lighter sentence (LeVay & Baldwin, 2012). In some states such as California, a repeat offender’s eligibility for probation or parole following childhood molestation is linked to his acceptance of mandated hormonal therapy (Scott & Holmberg, 2003). Oregon evaluated the success of requiring such treatment and found that those receiving chemical castration fared better in terms of committing fewer new offenses and fewer parole violations, and were less likely to return to prison (Maletzky et al., 2006). Nevertheless, civil libertarians, exemplified by the American Civil Liberties Union (ACLU), have argued that because of potentially severe side effects, such requirements violate the Constitution’s ban on cruel and unusual punishment. More research is desirable to determine whether, and under what conditions, such biological treatments should be used with some sex offenders (Rice & Harris, 2011). Such research should be a priority.

### COMBINING PSYCHOLOGICAL AND BIOLOGICAL TREATMENTS

**Not surprisingly, many treatment programs now use a combination of hormone therapy and cognitive-behavioral treatments, the hope being that the hormone treatment can be tapered off after the offender has learned techniques for impulse control (Maletzky, 2002).** However, the single most important defect of nearly all available studies is the lack of randomly assigned controls who are equally motivated for treatment. Some have argued that denying treatment to sex offenders is unethical (e.g., Marshall et al., 1991). However, this would be true only if the treatment were effective, and it is not clear at this point whether it is. Thus others have argued that randomized controlled trials are crucial for making progress in this area (e.g., Seto et al., 2008). Research in this area is further complicated by the fact that the outcome variable in most studies is whether the man is convicted for another sex offense during the follow-up period. The fact that most sex offenses go unpunished (the offender is often never even caught, let alone convicted) might exaggerate the apparent effectiveness of treatment and underestimate the dangerousness of sex offenders. Given the social importance of determining whether sex offenders can be helped and how likely they are to reoffend, it is crucial that society devote the resources necessary to answering these questions.

**SUMMARY** It is possible both to acknowledge that sex offenders cause immense human suffering and to feel sympathy for the plight of the many offenders who have been burdened with a deviant sexual arousal pattern that has caused them great personal and legal trouble. Society cannot allow these people to act on their sexual preference, nor can their past crimes be forgotten. Nevertheless, in deciding how to treat these people, it is important and humane to remember that many of them have a tormented inner life.

## in review

- What are the short-term consequences of childhood sexual abuse, and why are we less certain about its long-term consequences?
- What are the major issues surrounding children's testimony about sexual abuse and adults' recovered memories of sexual abuse?
- Define pedophilia, incest, and rape, and summarize the major clinical features of the perpetrators of these crimes.
- Identify the main goals of treatment of sex offenders, and describe the different treatment approaches.

## Sexual Dysfunctions

The term **sexual dysfunction** refers to impairment either in the desire for sexual gratification or in the ability to achieve it. The impairment varies markedly in degree, but regardless of which partner is alleged to be dysfunctional, the enjoyment of sex by both parties in a relationship is typically adversely affected. Sexual dysfunctions occur in both heterosexual and homosexual couples. In some cases, sexual dysfunctions are caused primarily by psychological or interpersonal factors. In others, physical factors are most important, including many cases of sexual dysfunction that are secondary consequences of medications people may be taking for other, unrelated medical conditions (Baron-Kuhn & Segraves, 2007). In recent years, both explanations and treatments of sexual dysfunction have become more biological, although some psychological treatments have been **empirically validated**, and psychosocial factors clearly play a causal role as well (Heiman, 2002; Meston & Rellini, 2008; Segraves & Althof, 2002).

Today researchers and clinicians typically identify four different phases of the human sexual response as originally proposed by Masters and Johnson (1966, 1970, 1975) and Kaplan (1979). According to *DSM-5*, disorders can occur in any of the first three phases:

- The first phase is the **desire phase**, which consists of fantasies about sexual activity or a sense of desire to have sexual activity.
- The second phase is the **excitement (or arousal) phase**, characterized both by a subjective sense of sexual pleasure and by physiological changes that accompany this subjective pleasure, including penile erection in the male and vaginal lubrication and clitoral enlargement in the female.
- The third phase is **orgasm**, during which there is a release of sexual tension and a peaking of sexual pleasure.
- The final phase is **resolution**, during which the person has a sense of relaxation and well-being.

Although these four phases are described as if they were distinct, it is important to remember that they are experienced by an individual as a continuous set of feelings and biological and behavioral reactions. There are other conceivable ways to discuss

## research CLOSE-UP

### Empirically Validated

Empirically validated treatments are treatments that have been determined to be helpful based on well-designed, scientific research by more than just one group of researchers.

and organize the sequence that occurs. Indeed, in *DSM-5*, female sexual interest/arousal disorder replaces two separate disorders in *DSM-IV-TR*, because research has not adequately demonstrated that sexual interest and arousal are distinguishable in women (Brotto, 2010; Graham, 2010).

How common are sexual dysfunctions? It is obviously difficult to do large-scale research on such a sensitive topic. Nevertheless, the National Health and Social Life Survey (Laumann et al., 1999) assessed sexual problems in 3,159 randomly selected Americans by asking them if they had experienced the symptoms of any of the different sexual dysfunctions in the past 12 months. Sexual problems were very common, with 43 percent of women and 31 percent of men reporting having experienced at least one of these problems in the previous 12 months. For women, the reported rate of sexual problems decreased with age; for men it increased. Married men and women, and those with higher educational attainment, had lower rates of problems. For women, the most common complaints were lack of sexual desire (22 percent) and sexual arousal problems (14 percent). For men, climaxing too early (21 percent), erectile dysfunction (5 percent), and lack of sexual interest (5 percent) were reported most frequently. However, this study was criticized by Bancroft et al. (2003), who believe that these numbers overestimate how many people have true sexual dysfunctions. Although the

Sexual dysfunctions can occur in the desire, excitement, or orgasm phases of the sexual response cycle. Many people, if not most, will experience some sexual dysfunction sometime during their lives. If it becomes chronic or disturbing to one or both partners, it warrants treatment.

**Men**

**Delayed Ejaculation**

- A. Either of the following symptoms must be experienced on almost all or all occasions (approximately 75%–100%) of partnered sexual activity (in identified situational contexts or, if generalized, in all contexts), and without the individual desiring delay:
1. Marked delay in ejaculation.
  2. Marked infrequency or absence of ejaculation
- B. The symptoms in Criterion A have persisted for a minimum duration of approximately 6 months.
- C. The symptoms in Criterion A cause clinically significant distress in the individual.
- D. The sexual dysfunction is not better explained by a nonsexual mental disorder or as a consequence of severe relationship distress or other significant stressors and is not attributable to the effects of a substance/medication or another medical condition.

**Erectile Disorder**

- A. At least one of the three following symptoms must be experienced on almost all or all (approximately 75%–100%) occasions of sexual activity (in identified situational contexts or, if generalized, in all contexts):
1. Marked difficulty in obtaining an erection during sexual activity.
  2. Marked difficulty in maintaining an erection until the completion of sexual activity.
  3. Marked decrease in erectile rigidity.
- B. The symptoms in Criterion A have persisted for a minimum duration of approximately 6 months.
- C. The symptoms in Criterion A cause clinically significant distress in the individual.
- D. The sexual dysfunction is not better explained by a nonsexual mental disorder or as a consequence of severe relationship distress or other significant stressors and is not attributable to the effects of a substance/medication or another medical condition.

**Premature (Early) Ejaculation**

- A. A persistent or recurrent pattern of ejaculation occurring during partnered sexual activity within approximately 1 minute following vaginal penetration and before the individual wishes it.
- Note:** Although the diagnosis of premature (early) ejaculation may be applied to individuals engaged in nonvaginal sexual activities, specific duration criteria have not been established for these activities.
- B. The symptom in Criterion A must have been present for at least 6 months and must be experienced on almost all or all (approximately 75%–100%) occasions of sexual activity (in identified situational contexts or, if generalized, in all contexts).
- C. The symptom in Criterion A causes clinically significant distress in the individual.

- D. The sexual dysfunction is not better explained by a nonsexual mental disorder or as a consequence of severe relationship distress or other significant stressors and is not attributable to the effects of a substance/medication or another medical condition.

**Male Hypoactive Sexual Desire Disorder**

- A. Persistently or recurrently deficient (or absent) sexual/erotic thoughts or fantasies and desire for sexual activity. The judgment of deficiency is made by the clinician, taking into account factors that affect sexual functioning, such as age and general and sociocultural contexts of the individual's life.
- B. The symptoms in Criterion A have persisted for a minimum duration of approximately 6 months.
- C. The symptoms in Criterion A cause clinically significant distress in the individual.
- D. The sexual dysfunction is not better explained by a nonsexual mental disorder or as a consequence of severe relationship distress or other significant stressors and is not attributable to the effects of a substance/medication or another medical condition.

**Women**

**Female Orgasmic Disorder**

- A. Presence of either of the following symptoms and experienced on almost all or all (approximately 75%–100%) occasions of sexual activity (in identified situational contexts or, if generalized, in all contexts):
1. Marked delay in, marked infrequency of, or absence of orgasm.
  2. Markedly reduced intensity of orgasmic sensations.
- B. The symptoms in Criterion A have persisted for a minimum duration of approximately 6 months.
- C. The symptoms in Criterion A cause clinically significant distress in the individual.
- D. The sexual dysfunction is not better explained by a nonsexual mental disorder or as a consequence of severe relationship distress (e.g., partner violence) or other significant stressors and is not attributable to the effects of a substance/medication or another medical condition.

**Female Sexual Interest/Arousal Disorder**

- A. Lack of, or significantly reduced, sexual interest/arousal, as manifested by at least three of the following:
1. Absent/reduced interest in sexual activity.
  2. Absent/reduced sexual/erotic thoughts or fantasies.
  3. No/reduced initiation of sexual activity, and typically unresponsive to a partner's attempts to initiate.
  4. Absent/reduced sexual excitement/pleasure during sexual activity in almost all or all (approximately 75%–100%) sexual encounters (in identified situational contexts or, if generalized, in all contexts).

- 5. Absent/reduced sexual interest/arousal in response to any internal or external sexual/erotic cues (e.g., written, verbal, visual).
- 6. Absent/reduced genital or nongenital sensations during sexual activity in almost all or all (approximately 75%–100%) sexual encounters (in identified situational contexts or, if generalized, in all contexts).
- B. The symptoms in Criterion A have persisted for a minimum duration of approximately 6 months.
- C. The symptoms in Criterion A cause clinically significant distress in the individual.
- D. The sexual dysfunction is not better explained by a nonsexual mental disorder or as a consequence of severe relationship distress (e.g., partner violence) or other significant stressors and is not attributable to the effects of a substance/medication or another medical condition.

#### **Genito-Pelvic Pain/Penetration Disorder**

- A. Persistent or recurrent difficulties with one (or more) of the following:
  - 1. Vaginal penetration during intercourse.
  - 2. Marked vulvovaginal or pelvic pain during vaginal intercourse or penetration attempts.
  - 3. Marked fear or anxiety about vulvovaginal or pelvic pain in anticipation of, during, or as a result of vaginal penetration.
  - 4. Marked tensing or tightening of the pelvic floor muscles during attempted vaginal penetration.
- B. The symptoms in Criterion A have persisted for a minimum duration of approximately 6 months.
- C. The symptoms in Criterion A cause clinically significant distress in the individual.
- D. The sexual dysfunction is not better explained by a nonsexual mental disorder or as a consequence of a severe relationship distress (e.g., partner violence) or other significant stressors

and is not attributable to the effects of a substance/medication or another medical condition.

#### **Men/Women**

##### **Substance/Medication-Induced Sexual Dysfunction**

- A. A clinically significant disturbance in sexual function is predominant in the clinical picture.
- B. There is evidence from the history, physical examination, or laboratory findings of both (1) and (2):
  - 1. The symptoms in Criterion A developed during or soon after substance intoxication or withdrawal or after exposure to a medication.
  - 2. The involved substance/medication is capable of producing the symptoms in Criterion A.
- C. The disturbance is not better explained by a sexual dysfunction that is not substance/medication-induced. Such evidence of an independent sexual dysfunction could include the following:

The symptoms precede the onset of the substance/medication use; the symptoms persist for a substantial period of time (e.g., about 1 month) after the cessation of acute withdrawal or severe intoxication; or there is other evidence suggesting the existence of an independent non-substance/medication-induced sexual dysfunction (e.g., a history of recurrent non-substance/medication-related episodes).

- D. The disturbance does not occur exclusively during the course of a delirium.
- E. The disturbance causes clinically significant distress in the individual.

**Note:** This diagnosis should be made instead of a diagnosis of substance intoxication or substance withdrawal only when the symptoms in Criterion A predominate in the clinical picture and are sufficiently severe to warrant clinical attention.

Laumann and colleagues' results are often referred to as being about sexual *dysfunction*, in fact, the investigators never asked people about whether the problems caused them distress or impairment in any way; yet these are necessary criteria for making a diagnosis in *DSM-5*. When Bancroft et al. (2003) did a related survey (although just in women), they found very similar percentages to those found by Laumann and colleagues. However, Bancroft and colleagues found that only about half as many reported that the problem caused them "severe distress." Nevertheless, this is still a relatively high percentage of people experiencing sexual dysfunction at some point in their lives.

Interestingly, a later study of 27,500 people across 29 countries all over the world revealed fairly similar results (Laumann et al., 2005). There were some differences, of course, in prevalence across countries, but the results were more similar than different.

East Asian and Southeast Asian countries reported slightly higher rates of sexual problems than most other countries.

The "DSM-5 Criteria" box above summarizes each of the dysfunctions covered here.

#### **Sexual Dysfunctions in Men**

For cultural reasons, and possibly also for biological reasons, sex is thought to be especially important to men. Certainly the pharmaceutical industry has capitalized on men's distress about sexual dysfunction, earning billions of dollars from sales of treatments for male sexual dysfunction, primarily **erectile disorder**. Whether men are actually more upset than women by sexual dysfunction or this is simply one more domain where women's feelings have been ignored until recently, there is no dispute that we know far more about men's sexual dysfunctions than women's.

## Male Hypoactive Sexual Desire Disorder

Hypoactive sexual desire disorder is diagnosed in men who have for at least 6 months been distressed or impaired due to low levels of sexual thoughts, desires, or fantasies. Men given this diagnosis are also assessed for the course of the dysfunction (i.e., lifelong or acquired) and possible causal factors, including problems emanating from partners, relationships, cultural beliefs or attitudes, personal vulnerabilities (e.g., poor body image), or medical conditions. Despite the historically higher level of attention to male than to female sexual dysfunctions, this is one disorder in men that has received relatively little attention—and substantially less than its parallel disorder in women (Brotto, 2010). In the large American survey conducted by Laumann et al. (1999), men in the oldest cohort (50–59 years old) were three times more likely to suffer from low desire compared with men in the youngest cohort (18–29 years old). Predictors of low desire included daily alcohol use, stress, unmarried status, and poorer health. In a large British survey, complaints of low interest in sex was the most common problem reported by men (17.1 percent; Mercer et al., 2003). However, only a small minority (1.8 percent) of the male sample had low desire for the required 6 month period to qualify for diagnosis. Most experts believe that **male hypoactive sexual desire disorder** is acquired or situational rather than lifelong. Typical situational risk factors include depression and relationship stress.

**Treatment** The treatment literature on low sexual desire in men is scant. In men whose testosterone levels are markedly low (including hypogonadal men whose testes make insufficient testosterone and men with HIV that diminishes their testosterone production), testosterone injections have helped (Brotto, 2010). Because psychological factors are more closely linked to low male sexual desire compared with hormonal factors, psychological treatments may be more effective for other men.

**ERECTILE DISORDER** Inability to achieve or maintain an erection sufficient for successful sexual intercourse was formerly called *impotence*. It is now known as **male erectile disorder** and can be diagnosed only when the difficulties are considered to originate from either psychogenic or a combination of psychogenic and medical factors (see “*DSM-5 Criteria*” on p. 432). In lifelong erectile disorder, a man with adequate sexual desire has never been able to sustain an erection long enough to accomplish a satisfactory duration of penetration. In acquired or situational erectile disorder, a man with adequate sexual desire has had at least one successful experience of sexual activity requiring an erection but is presently unable to produce or maintain the required level of penile rigidity. Lifelong erectile disorder is relatively rare, but most men of all ages occasionally have difficulty obtaining or maintaining an erection. Laumann et al. (1999) landmark study on the prevalence of sexual dysfunction

estimates that 7 percent of 18- to 19-year-old men and 18 percent of 50- to 59-year-old men reported having erectile disorder.

Masters and Johnson (1975; Masters et al., 1992) and Kaplan (1987) hypothesized that erectile dysfunction is primarily a function of anxiety about sexual performance. In other reviews of the accumulated evidence, however, Barlow and colleagues (Beck & Barlow, 1984a; Sbrocco & Barlow, 1996) have played down the role of anxiety per se—because under some circumstances, anxiety can actually enhance sexual performance in normally functioning men and women (Barlow et al., 1983; Palace & Gorzalka, 1990; see Sbrocco & Barlow, 1996, for a review). Barlow (2002) emphasizes that it is the cognitive distractions frequently associated with anxiety in dysfunctional people that seem to interfere with their sexual arousal. For example, one study found that nondysfunctional men who were distracted by material they were listening to on earphones while watching an erotic film showed less sexual arousal than men who were not distracted (Abrahamson et al., 1985). Barlow and colleagues hypothesize that sexually dysfunctional men and women get distracted by negative thoughts about their performance during a sexual encounter (“I’ll never get aroused” or “She’ll think I’m inadequate”). Their research suggests that this preoccupation with negative thoughts, rather than anxiety per se, is responsible for inhibiting sexual arousal (see also Weiner & Rosen, 1999; Wincze et al., 2008). Moreover, such self-defeating thoughts not only decrease pleasure but also can increase anxiety if the erection does not happen, and this in turn can fuel further negative, self-defeating thoughts (Sbrocco & Barlow, 1996). A related finding is that men with erectile dysfunction make more internal and stable causal attributions for hypothetical negative sexual events than do men without sexual dysfunction, much as depressed people do for more general hypothetical negative events (Nobre, 2010; Scepkowski et al., 2004). Combined with Bancroft and colleagues’ (2005) findings that fear of performance failure is a strong predictor of erectile dysfunction in both gay and heterosexual men, one can see how a vicious cycle develops in which fears of failure are sometimes followed by erectile dysfunction, which is then attributed to internal and stable causes, thereby perpetuating the problem.

Erectile problems occur in as many as 90 percent of men on certain antidepressant medications (especially the SSRIs) and are one of the primary reasons men cite for discontinuing these medications (Rosen & Marin, 2003). These problems are also a common consequence of aging. One large study of over 1,400 men found that 37 percent between ages 57 and 85 reported significant erectile difficulties, with the problems gradually increasing with age (Lindau et al., 2007). However, complete and permanent erectile disorder before the age of 60 is relatively rare. Moreover, studies have indicated that men and women in their 80s and 90s are often quite capable of enjoying intercourse (Masters et al., 1992; Meston & Rellini, 2008). For example, in one study of 202 healthy men and women between the ages of 80 and 102, it was found that nearly two-thirds of the men

and one-third of the women were still having sexual intercourse, although this was generally not their most common form of sexual activity (Bretschneider & McCoy, 1988).

The most frequent cause of erectile disorder in older men is vascular disease, which results in decreased blood flow to the penis or in diminished ability of the penis to hold blood to maintain an erection. Thus hardening of the arteries, high blood pressure, and other diseases such as diabetes that cause vascular problems often account for erectile disorder. Smoking, obesity, and alcohol abuse are associated lifestyle factors, and lifestyle changes can improve erectile function (Gupta et al., 2011). Diseases that affect the nervous system, such as multiple sclerosis, can also cause erectile problems. For young men, one cause of erectile problems is having had priapism—that is, an erection that will not diminish even after a couple of hours, typically unaccompanied by sexual excitement. Priapism can occur as a result of prolonged sexual activity, as a consequence of disease, or as a side effect of certain medications. Untreated cases of priapism are likely to result in erectile dysfunction and thus should be regarded as a medical emergency (Morrison & Burnett, 2011).

**Treatment** A variety of treatments—primarily medical—have been employed in recent years, often when cognitive-behavioral treatments have failed. These include: (1) medications that promote erections like Viagra, Levitra, and Cialis; (2) injections of smooth-muscle-relaxing drugs into the penile erection chambers (*corpora cavernosa*); and (3) even a vacuum pump (Duterte et al., 2007; Rosen, 1996). In extreme cases, for example when erections are impossible due to nerve damage that can be a consequence of surgery for prostate cancer, penile implants may still be used. These devices can be inflated to provide erection on demand. They are made of silicone rubber or polyurethane rubber. Such treatments have generally shown success in clinical trials, although they are rather extreme interventions that often evoke bothersome side effects such as decreased penis size (Duterte et al., 2007). They were used in thousands of cases in the 1960s and 1970s before current medications were available.

In 1998 the revolutionary drug Viagra (sildenafil) was introduced on the U.S. market and was received with a great deal of attention. Viagra works by making nitric oxide, the primary neurotransmitter involved in penile erection, more available. Viagra is taken orally at least 30 to 60 minutes before sexual activity. Unlike some other biological treatments for erectile dysfunction, Viagra promotes erection only if some sexual excitation is present. Thus, contrary to some myths, Viagra does not improve libido or promote spontaneous erections (Duterte et al., 2007; Segraves & Althof, 2002). Two other related medications introduced in 2003 to treat erectile dysfunction are Levitra (vardenafil; Stark et al., 2001) and Cialis (tadalafil; Padma-Nathan et al., 2001), with the effects of Cialis being longer lasting (up to 36 hours). Clinical trials of these medications

have been impressive. In one early double-blind study, over 70 percent of men receiving at least 50 mg of Viagra reported that their erections had improved, compared with fewer than 30 percent of men receiving a placebo (Carlson, 1997; see also Goldstein et al., 1998). Results with Cialis and Levitra are similar. Overall efficacy rates in terms of ability to obtain an erection are 40 to 80 percent, but levels of satisfaction are often much lower, perhaps because these medications do not increase sexual desire or satisfaction and perhaps because sexual desire and satisfaction are more closely intertwined with psychological and relationship factors. Side effects are relatively uncommon and not serious (e.g., the most common side effects are headache and facial flushing, seen in 10 to 20 percent of men), provided that the person had no serious preexisting heart problems (Duterte et al., 2007). When heart problems do exist, these medications should be prescribed with caution because they can interact in dangerous ways with heart medications. These medications have been highly successful commercially—for example, in 2008 almost \$2 billion worth of Viagra was sold. Interestingly, however, many men who fill one prescription never refill it, according to the drug companies' own statistics. The commercial success of drugs like Viagra and Cialis is an indication of both the high prevalence of sexual dysfunction in men and the importance that people attach to sexual performance. There are also a few studies showing that the usefulness of these medications may be further enhanced when used in conjunction with cognitive-behavioral treatment (e.g., Bach et al., 2004; Meston & Rellini, 2008).

**EARLY EJACULATION** In *DSM-5* “premature ejaculation,” is called early ejaculation disorder, the persistent and recurrent onset of orgasm and ejaculation with minimal sexual stimulation. It may occur before, on, or shortly after penetration and before the man wants it to (see “*DSM-5 Criteria*” on p. 432). The average duration of time to ejaculate in men with this problem is 15 seconds or 15 thrusts of intercourse. The consequences often include failure of the partner to achieve satisfaction and, often, acute embarrassment for the early ejaculating man, with disruptive anxiety about recurrence on future occasions. Men who have had this problem from their first sexual encounter often try to diminish sexual excitement by avoiding stimulation, by self-distracting, and by “spectatoring,” or psychologically taking the role of an observer rather than a participant (Metz et al., 1997). Early ejaculation decreases sexual and relationship satisfaction both in men who have it and their partners (Graziottin & Althof, 2011).

An exact definition of prematurity is necessarily somewhat arbitrary. For example, the age of a client must be considered—the alleged “quick trigger” of the younger man being more than a mere myth (McCarthy, 1989). Indeed, perhaps half of young men complain of early ejaculation. Not surprisingly, early ejaculation is most likely after a lengthy abstinence. *DSM-5* acknowledges these many factors that may affect time to ejaculation

by noting that the diagnosis is made only if ejaculation occurs before, on, or shortly after penetration and before the man wants it to. Early ejaculation is the most common male sexual dysfunction at least up to age 59 (Meston & Rellini, 2008; Segraves & Althof, 2002).

In sexually normal men, the ejaculatory reflex is, to a considerable extent, under voluntary control. They monitor their sensations during sexual stimulation and are somehow able, perhaps by judicious use of distraction, to forestall the point of ejaculatory inevitability until they decide to “let go,” with the average latency to ejaculation from penetration being 10 minutes for men with no sexual problems. Men with early ejaculation are for some reason unable to use this technique effectively. Explanations have ranged from psychological factors such as increased anxiety, to physiological factors such as increased penile sensitivity and higher levels of arousal to sexual stimuli. Presently, however, no explanation has received much empirical support, and it is clear that none of these possible explanations alone can account for all men with the problem (Meston & Rellini, 2008).

**Treatment** For many years, most sex therapists considered early ejaculation to be psychogenically caused and highly treatable via behavioral therapy such as the pause-and-squeeze technique developed by Masters and Johnson (1970). This technique requires the man to monitor his sexual arousal during sexual activity. When arousal is intense enough that the man feels that ejaculation might occur soon, he pauses, and he or his partner squeezes the head of the penis for a few moments until the feeling of pending ejaculation passes, repeating the stopping of intercourse as many times as needed to delay ejaculation. Initial reports suggested that this technique was approximately 60 to 90 percent effective; however, more recent studies have reported a much lower overall success rate (Duterte et al., 2007; Segraves & Althof, 2002). In recent years, for men for whom behavioral treatments have not worked, there has been increasing interest in the possible use of pharmacological interventions. Antidepressants such as paroxetine (Paxil), sertraline (Zoloft), fluoxetine (Prozac), and dapoxetine (Priligy), which block serotonin reuptake, have been found to significantly prolong ejaculatory latency in men with early ejaculation (Porst, 2011). Evidence suggests, however, that the medications work only as long as they are being taken.

**DELAYED EJACULATION DISORDER** Sometimes called *retarded ejaculation*, **delayed ejaculation disorder** refers to the persistent inability to ejaculate during intercourse (see “*DSM-5 Criteria*” on p. 432). It occurs in only about 3 to 10 percent of men. Men who are completely unable to ejaculate are rare. About 85 percent of men who have difficulty ejaculating

during intercourse can nevertheless achieve orgasm by other means of stimulation, notably through solitary masturbation (Wincze et al., 2008). In milder cases a man can ejaculate in the presence of a partner but only by means of manual or oral stimulation.

In other cases, delayed ejaculation can be related to specific physical problems such as multiple sclerosis or to the use of certain medications. For example, we noted that antidepressants that block serotonin reuptake appear to be an effective treatment for early ejaculation. However, in other men, these same medications—especially the SSRIs—sometimes delay or prevent orgasm to an unpleasant extent (Ashton et al., 1997; Meston & Rellini, 2008). These side effects are common but can sometimes be treated pharmacologically with medications like Viagra (Ashton et al., 1997).

**Treatment** Psychological treatments include couples therapy in which a man tries to get used to having orgasms through intercourse with a partner rather than via masturbation. Treatment may also emphasize the reduction of performance anxiety about the importance of having an orgasm versus sexual pleasure and intimacy in addition to increasing genital stimulation (Meston & Rellini, 2008; Segraves & Althof, 2002).

## Female Sexual Interest/Arousal Disorder

Research suggests that women with low desire tend to have low levels of sexual arousal during sexual activity and vice versa. There are no common syndromes in which women with low sexual desire have normal levels of sexual arousal, or vice versa. Thus for women, *DSM-5* has combined dysfunctional low desire with dysfunctionally low sexual arousal in the disorder **Female Sexual Interest/Arousal Disorder**. Another interesting change from *DSM-IV-TR* to *DSM-5* is the elimination of **sexual aversion disorder**, in which a person shows extreme aversion to, and avoidance of, all genital sexual contact with a partner. A leading researcher on sexual dysfunction has recently argued that sexual aversion disorder should be considered as an anxiety disorder akin to simple phobias rather than as a sexual dysfunction (Brotto, 2010). Perhaps this is one reason why it was eliminated from the Sexual Dysfunctions section of *DSM-5*.

Research on the degree to which the diminished sex drive has a biological basis remains controversial, but in many (and perhaps most) cases (and especially in women), psychological factors appear to be more important than biological factors (Meston & Bradford, 2007; Segraves & Woodard, 2006). In the past, these people usually came to the attention of clinicians primarily at the request of their partners (who typically complained of insufficient sexual interaction), but as public knowledge about the frequency of this disorder has increased, more people are

presenting for treatment on their own. This fact exposes one problem with the diagnosis, because it is known that preferences for frequency of sexual contact vary widely among otherwise normal individuals. Who is to decide what is “not enough”? *DSM-5* explicitly indicates that this judgment is left to the clinician, taking into account the person’s age and the context of his or her life.

Prior or current depression or anxiety disorders may contribute to many cases of sexual desire disorders (Meston & Bradford, 2007). Although sexual desire disorders typically occur in the absence of obvious physical pathology, there is evidence that physical factors sometimes play a role. For example, in both men and women, sexual desire depends in part on testosterone (Alexander & Sherwin, 1993; Meston & Rellini, 2008). That sexual desire problems increase with age may be in part attributable to declining levels of testosterone, but testosterone replacement therapy is usually not beneficial, except in men and women who have very low testosterone levels (Meston & Rellini, 2008). In addition, medications from the SSRI category of antidepressants (see Chapters 7 and 16) not uncommonly reduce sexual desire. Different antidepressants vary considerably in their negative effect on sexual function, and psychiatrists have not always paid close enough attention to the impact that these effects have on patients’ general functioning (Serretti & Chiesa, 2009). Psychological factors thought to contribute to sexual desire disorders include low relationship satisfaction, daily hassles and worries, increased disagreements and conflicts, low levels of feelings, and reduced cues of emotional bonding (Meston & Rellini, 2008). In some cases a history of unwanted sexual experiences such as rape may also contribute.

Among the *DSM-IV-TR* diagnoses hypoactive sexual desire disorder was the most common female sexual dysfunction in the United States and most other countries across the world (Laumann et al., 1994, 1999, 2005), and there is no reason to doubt that female sexual interest/arousal disorder is the most common *DSM-5* female sexual dysfunction. Despite this fact, disorders of female sexual desire have inspired far less research into its origins and treatment than have most male dysfunctions, especially erectile disorder and early ejaculation. One main reason for this disparity is doubtless the great importance that many men place on their ability to perform sexually. Until recently, there has also been a more general neglect of female sexuality and an implicit (though largely mistaken) societal attitude that women simply do not care much about sex.

Fortunately, this has been changing gradually in recent years (e.g., Althof et al., 2005; Basson, 2005; Meston & Bradford, 2007). One emerging finding is that it is uncommon for women to cite sexual desire as a reason or incentive for sexual activity. For many women, sexual desire is experienced only after sexual stimuli have led to subjective sexual arousal (Basson, 2003a; Meston & Bradford, 2007), and for others, motivation for sexual

activity may involve a desire for increasing emotional intimacy or increasing one’s sense of well-being and one’s self-image as an attractive female (Basson, 2003, 2005). Thus, some research suggests that the supposedly linear sequence of desire leading to arousal, leading to orgasm that was originally posited for women as well as men by Masters and Johnson (1970) and the *DSM* is not very accurate for women (e.g., Basson, 2005; Meston & Bradford, 2007).

Until recently studied separately from low sexual desire, dysfunctionally low sexual arousal in women was formerly and somewhat pejoratively known as *frigidity*. In *DSM-IV-TR* female sexual arousal disorder—the absence of feelings of sexual arousal and an unresponsiveness to most or all forms of erotic stimulation—was in many ways the female counterpart of erectile disorder (see “*DSM-5 Criteria*” on p. 433). Its chief physical manifestation was a failure to produce the characteristic swelling and lubrication of the vulva and vaginal tissues during sexual stimulation—a condition that may make intercourse quite uncomfortable and orgasm impossible.

Although the causes of low sexual arousal are not well understood, possible reasons range from early sexual traumatization; to excessive and distorted socialization about the “evils” of sex; to dislike of, or disgust with, a current partner’s sexuality; to her partner’s restricted repertoire of sexual activity. One interesting study also found that women with sexual arousal disorder show lower tactile sensitivity than is seen in other women; the lower their level of tactile sensitivity, the more severe their arousal dysfunction (Frolich & Meston, 2005). Biological causal factors include the use of SSRIs for anxiety and depression, the occurrence of certain medical illnesses (e.g., spinal cord injury, cancer treatment, diabetes, etc.), and the decreases in estrogen levels that occur during and following menopause. Some difficulties with physiological arousal and lubrication have been noted in 20 to 30 percent of sexually active women and in as many as 44 percent of postmenopausal women. Moreover, arousal problems in women very frequently co-occur with low levels of sexual desire; thus the new *DSM-5* combined diagnosis. Indeed, having problems with sexual arousal may often lead to lack of desire (Meston & Bradford, 2007).

**Treatment** Although there has been interest since antiquity in the possibility that a drug to increase sexual desire might be found, no effective aphrodisiacs yet exist. As noted earlier, testosterone appears to be effective only in men and women who have very low levels of testosterone; that is, raising levels of this important sex hormone above normal levels has no beneficial effects (e.g., Meston & Rellini, 2008). Consistent with an effect of hormones, a German study showed that women using oral contraceptives, which sometimes work by raising estrogen levels, which in turn reduce testosterone levels, had somewhat lower

levels of sexual desire and arousal compared with those who did not (Wallwiener et al., 2010).

Several studies have found that sustained use of buproprion (an atypical antidepressant), relative to placebo, improved sexual arousability and orgasm frequency in women who were in a committed relationship and had hypoactive sexual desire disorder (e.g., Segraves et al., 2004). Another drug, flibanserin, has been developed to increase sexual desire in women, but the Food and Drug Administration denied approval for this use in 2010, saying that there is not yet sufficient research (Wilson, 2010). Pharmaceutical companies are eager to find a treatment for low sexual desire in women, but some women have argued that the companies are more concerned about making money than about curing a legitimate illness (Segal, 2008).

There are no well-established psychotherapies for hypoactive sexual desire. Typically therapists focus on education, communication training, cognitive restructuring of dysfunctional beliefs about sexuality, sexual fantasy training, and sensate focus training (Meston & Rellini, 2008). Sensate focus exercises are also used in the treatment of several other forms of sexual dysfunctions, as we will see. They involve teaching couples to focus on the pleasurable sensations brought about by touching without the goal of actually having intercourse or orgasm. Relationship problems often contribute importantly to low sexual desire, as do concerns related to body-image (Basson, 2010). Addressing these problems thus may be helpful.

Few controlled treatment studies of low sexual arousal in women have been conducted (Meston & Bradford, 2007), although clinical experience suggests that psychotherapy and sex therapy may play important roles in helping women with this disorder. Typically the techniques that are used are similar to those used to increase sexual desire. The widespread use of vaginal lubricants may effectively mask and treat the symptoms of this disorder in many women, but lubricants do not enhance genital blood flow or genital sensations.

In addition, because female genital response depends in part on the same neurotransmitter systems as male genital response, there has been great interest in the possibility that Viagra, Levitra, or Cialis would have positive effects for women analogous to their positive effects for men (Meston & Rellini, 2008). Unfortunately, enough research has now been performed to make it clear that such drugs are not as useful for women as they are for men (Basson et al., 2002; Meston & Rellini, 2008). Although these medications may enhance genital arousal and perceptions of physical sensations in women, they do not affect women's psychological experiences of arousal. It is likely that women's sexual desire and arousal are more dependent on relationship satisfaction and mood than they are in men.

**GENITO-PELVIC PAIN/PENETRATION DISORDER** This disorder represents an important change in *DSM-5*. In past versions of *DSM-IV-TR* were distinguished two "sexual pain disorders": vaginismus and dyspareunia. The disorders have been combined in *DSM-5* because scientific research did not support their distinction (Binik, 2010a, 2010b). In particular, vaginismus has been believed to be an involuntary spasm of the muscles near the entrance of the vagina, preventing penetration and sexual intercourse. However, no scientific evidence exists that women with vaginismus have vaginal spasms or that vaginismus could be reliably diagnosed. In contrast, women diagnosed with vaginismus commonly complained of pain during penetration and anxiety before and during sexual encounters (Reissing et al., 2003). The latter symptoms made the distinction between vaginismus and dyspareunia (which is genital pain associated with sexual intercourse) unclear. That is, women with a past diagnosis of vaginismus were not clearly distinct from those with a past diagnosis of dyspareunia. Furthermore, as noted, the hallmark "symptom" of vaginismus, does not clearly occur, while the hallmark symptom of dyspareunia, genital pain during penetration, occurs commonly in women with vaginismus as well. Thus, in *DSM-5* there is only one **genito-pelvic pain/penetration disorder**, which combines the genital pain of dyspareunia with muscle tension (not muscle spasms) and fear and anxiety related to genital pain or penetrative sexual activity.

Based on past studies of women with "sexual pain disorders" it appears that genito-pelvic pain/penetration disorder is more likely to have organic than psychological causes. Some examples of physical causes include acute or chronic infections or inflammations of the vagina or internal reproductive organs, vaginal atrophy that occurs with aging, scars from vaginal tearing, or insufficiency of sexual arousal. Understandably, dyspareunia is often associated with vaginismus, and some have questioned whether they are indeed distinct disorders.

Recently, some prominent sex researchers have argued against classifying sexual pain disorders as "sexual disorders" rather than as "pain disorders" (e.g., Binik, 2005; Binik et al., 2007). For example, Binik and colleagues argue that the pain in "sexual pain disorders" is qualitatively similar to the pain in other, nonsexual areas of the body and that the causes of "sexual pain disorder" are more similar to the causes of other pain disorders (e.g., lower back pain) than to the causes of other sexual dysfunctions. This concern is represented in the new name for the diagnosis (i.e., genito-pelvic pain/penetration disorder). It is also interesting to note in this regard that the disorder sometimes precedes any sexual experiences—for example, in some adolescent girls trying to use a tampon.

**Treatment** In past treatment studies of vaginismus and dyspareunia, cognitive-behavioral interventions have been effective in some cases. Cognitive-behavioral treatment techniques tend to include education about sexuality, identifying and correcting maladaptive cognitions, graduated vaginal dilation exercises to facilitate vaginal penetration, and progressive muscle relaxation (e.g., Bergeron, Binik et al., 2001). Medical treatments, such as surgical removal of the vulvar vestibule, a small area of the vulva between the labia minora, can be very successful (Binik, 2010a). It is likely that genito-pelvic pain/penetration disorder comprises several distinct syndromes with different etiologies and potentially different treatments. If so, the more we learn, the better our treatment options will be.

**FEMALE ORGASMIC DISORDER** The diagnosis of orgasmic dysfunction in women is complicated by the fact that the subjective quality of orgasm varies widely among women, within the same woman from time to time, and in regard to mode of stimulation (Graham, 2010). Nevertheless, according to *DSM-5*, **female orgasmic disorder** can be diagnosed in women who are readily sexually excitable and who otherwise enjoy sexual activity but who show persistent or recurrent delay in or absence of orgasm following a normal sexual excitement phase and who are distressed by this (see “*DSM-5 Criteria*” on p. 433). Of these women, many do not routinely experience orgasm during sexual intercourse without direct supplemental stimulation of the clitoris; indeed, this pattern is so common that it is generally not considered dysfunctional (Meston & Bradford, 2007). A small percentage of women are able to achieve orgasm only through direct mechanical stimulation of the clitoris, as in vigorous digital manipulation, oral stimulation, or the use of an electric vibrator. Even fewer are unable to have the experience under any known conditions of stimulation; this condition, which is called lifelong orgasmic dysfunction, is analogous to lifelong erectile disorder in males. More commonly, women experience difficulty having an orgasm only in certain situations or were able to achieve orgasm in the past but currently can rarely do so (Meston & Bradford, 2007). Laumann et al. (1999) found that rates of this disorder are highest in the 21- to 24-year-old age category and decline thereafter, and other studies have estimated that about one in three or four women report having had significant orgasmic difficulties in the past year (Meston & Bradford, 2007).

What causes female orgasmic disorder is not well understood, but a multitude of contributory factors have been hypothesized. For example, some women feel fearful and inadequate in sexual relations. A woman may be uncertain whether her partner finds her sexually attractive, and this may lead to anxiety and tension, which then interfere with her sexual enjoyment. Or she may feel inadequate or experience sexual guilt (especially common in

religious women) because she is unable to have an orgasm or does so infrequently. Sometimes a nonorgasmic woman will pretend to have orgasms to make her sexual partner feel fully adequate. The longer a woman maintains such a pretense, however, the more likely she is to become confused and frustrated; in addition, she is likely to resent her partner for being insensitive to her real feelings and needs. This in turn only adds to her sexual difficulties.

Possible biological causal factors sometimes contributing to orgasmic difficulties in women (as they do in men) include intake of the SSRIs as antidepressant medications. Many medical conditions already mentioned with other sexual disorders are also sometimes associated with orgasmic difficulties (Meston & Rellini, 2008). Recent evidence suggests that differences between women in their genital anatomy may allow some women to have orgasms during intercourse more easily than other women can (Wallen & Lloyd, 2011).

**Treatment** One important issue regarding treatment is whether women should seek it or not. Most clinicians agree that a woman with lifelong orgasmic disorder needs treatment if she is to become orgasmic. However, in the middle range of orgasmic responsiveness, our own view is that this question is best left to a woman herself to answer. If she is dissatisfied about her responsiveness, then she should seek treatment.

For those who do seek treatment, it is important to distinguish between lifelong and situational female orgasmic dysfunction. Cognitive-behavioral treatment of orgasmic dysfunction usually involves education about female sexuality and female sexual anatomy, as well as directed masturbation exercises. Later the partner may be included to explore these activities with the client. For those with lifelong orgasmic dysfunction, such programs can have nearly a 100 percent success rate in terms of the woman’s ability to have an orgasm at least through masturbation, but transition to having an orgasm with a partner can be slow and difficult in some cases (Meston & Rellini, 2008). “Situational” anorgasmia (where a woman may experience orgasm in some situations, with certain kinds of stimulation, or with certain partners, but not under the precise conditions she desires) often proves more difficult to treat, perhaps in part because it is often associated with relationship problems that may also be hard to treat (Althof & Schreiner-Engel, 2000).

### in review

- Compare and contrast the symptoms of the dysfunctions of sexual desire, arousal, and orgasm in men and women.
- Why have common female sexual dysfunctions been studied less than male sexual dysfunctions?
- What are the most effective treatments for male erectile disorder and premature ejaculation and for female orgasmic disorder?

## How Harmful Is Childhood Sexual Abuse?

**M**ost contemporary Americans believe that childhood sexual abuse (CSA) is very harmful. This is reflected both in their concern for the victims of CSA and in their outrage at its perpetrators. The assumption of harmfulness is so deeply ingrained that many people find it shocking even to consider the alternative possibility that, at least sometimes, CSA is not very harmful. Surely, though, the issue of harm is answerable by empirical means. What do the results show?

In 1998 psychologist Bruce Rind of Temple University and two colleagues published, in the prestigious journal *Psychological Bulletin*, an article reviewing 49 previous studies that had asked college students about their sexual experiences during childhood (Rind et al., 1998). Furthermore, the studies assessed the students' current adjustment, enabling Rind and colleagues to examine the association between early sexual experiences and mental health in young adulthood. Here are some conclusions of this study:

- Correlations between childhood sexual abuse and later problems were of surprisingly small magnitude, suggesting that such experiences are not typically very harmful.
- After general family problems had been statistically controlled for, the small association between CSA and adult problems was reduced to essentially zero, suggesting that the negative family environment in which child sexual abuse often occurs, rather than the sexual abuse per se, might explain much of the link between CSA and later problems. Indeed, poor family environment predicted adjustment problems an average of nine times more strongly than CSA did (Rind & Tromovitch, 2007).
- Incest (sex with relatives) and forced sex were both associated with more problems than sex between nominally consenting, nonrelated individuals.
- Age at which CSA was experienced was unrelated to adult outcome.

At first, the study's provocative conclusions attracted little attention. However, after the conservative radio personality Dr. Laura Schlessinger learned of the study, she incited a firestorm of controversy. Both Dr. Laura and other critics accused Rind and his coauthors of giving comfort to child molesters and being insensitive to victims of CSA. The controversy culminated in 1999 with a resolution by the U.S. House of Representatives that condemned the study (Lilienfeld, 2002; Rind et al., 2000).

Rind's study was attacked on two general grounds: First, some argued that it is socially dangerous to make the kinds of claims that the authors make in their article (Ondersma et al., 2001).

Second, some argued that the study was not strong enough, scientifically, to justify such risky conclusions. Let us examine both criticisms.

Clearly, it would be wrong to underestimate the harm of CSA. Victims of CSA would suffer from having their pain unappreciated,

and we may well invest too little in solving problems related to CSA. But overstating the harm of CSA may also entail significant costs. For example, people who are led to believe that they have been gravely and permanently harmed by CSA may suffer unnecessarily if CSA actually does not invariably have grave and permanent consequences. If CSA is often not very harmful, we need to know that.

Assessing the validity of Rind's study is a scientific matter. *Psychological Bulletin* published a lengthy scientific critique of Rind's study (Dallam et al., 2001) along with a reply by Rind and his coauthors (2001). One criticism of the original study was that it relied on college students, who may be unrepresentative. Perhaps they were able to attend college despite CSA because they were especially resilient. However, in another study, Rind analyzed data from community samples (samples not selected on the basis of educational attainment) and got virtually identical results (Rind & Tromovitch, 1997). Some of Rind's statistical decisions and analyses have also been criticized, but he has shown that his results do not change much when he analyzes the data the way his critics would.

A later meta-analysis of a large representative group of nearly 1,800 adult Australians (ages 18 to 59) reported that CSA in women is associated with their having more symptoms of sexual dysfunction in adulthood (Najman et al., 2005). However, a later reanalysis of these data by Rind and Tromovitch (2007) showed that the magnitude of this relationship was quite small (similar to that in Rind et al.'s 1998 study). Moreover, Najman and colleagues did not statistically control for other important factors, such as poor family environment, that were shown to be even more important in Rind et al.'s 1998 study. Rind (2003, 2004) also extended his discussion to the issue of how harmful adult-adolescent sexual relationships are. The current American view, which has spread throughout the Western world, is that such relations are by definition also "childhood sexual abuse" even though marriages involving young teenagers were common in previous centuries. He reviewed evidence showing that current views on this topic are driven by ideology and moral panic rather than by any empirical research showing these experiences to be harmful—especially those between adolescent boys and adult females, where considerable evidence suggests that many teenage boys see perceived benefits from such relationships regarding their sexual confidence and self-acceptance. These are obviously controversial issues that deserve additional careful research in the future.

Clearly these studies do not yet definitively answer the question of "How harmful is CSA?" but future research must contend with their findings and pay close attention to the relative importance of other negative family factors that are usually highly correlated with CSA.

# 12 summary

## 12.1 Why is it difficult to define boundaries between normality and psychopathology in the area of variant sexuality?

- Defining boundaries between normality and psychopathology in the area of variant sexuality is very difficult, in part because sociocultural influences on what have been viewed as normal or aberrant sexual practices abound.
- Degeneracy theory and abstinence theory both maintained that sexual activity should only occur for purposes of procreation because wasting semen was harmful; both were very influential for long periods of time in the United States and many other Western cultures and led to very conservative views on heterosexual sexuality.
- In contrast to Western cultures, in the Sambia tribe in Melanesia, homosexuality is practiced by all adolescent males in the context of male sexual initiation rites; these males transition to heterosexuality in young adulthood.
- Until rather recently in many Western cultures, homosexuality was viewed either as criminal behavior or as a form of mental illness. However, since 1974 homosexuality has been considered by mental health professionals to be a normal sexual variant.

## 12.2 What do we mean by sexual and gender variants?

- Sexual deviations in the form of paraphilic disorders involve persistent and recurrent patterns of sexual behavior and arousal, lasting at least 6 months, in which unusual objects, rituals, or situations are required for full sexual satisfaction. They occur almost exclusively in males, who often have more than one of them. The paraphilic disorders include fetishes, transvestic fetishism, voyeurism, exhibitionism, sadism, masochism, pedophilia, and frotteurism.
- Gender dysphoria occurs in children and adults. Childhood gender dysphoria occurs in children who have unbonded and dysphoria/distress about their biological sex. Most boys who have this disorder grow up to have a homosexual orientation; a much smaller number become transsexuals. Prospective studies of girls who have this disorder have reported similar results.
- Transsexualism is a very rare disorder in which the person believes that he or she is trapped in the body of the wrong sex and goes through elaborate steps necessary to change his or her sex. It is now recognized that there are two distinct types of male-to-female transsexuals: homosexual transsexuals and auto-gynephilic transsexuals, each with different characteristics and developmental antecedents. The only known effective treatment

for transsexuals is a sex change operation. Although its use remains highly controversial, it does appear to have fairly high success rates when the people are carefully diagnosed before the surgery as being true transsexuals.

## 12.3 What are the three primary types of sexual abuse?

- There are three overlapping categories of sexual abuse: pedophilia, incest, and rape. All three kinds of abuse occur at alarming rates today.
- Pedophilia is defined as sexual interest in prepubertal children.
- Incest involves sexual activity between blood relatives.
- Rape describes sexual activity that occurs under actual or threatened forcible coercion by one person on another.
- Treatment of sex offenders has not as yet proved highly effective in most cases, although promising research in this area is being conducted.

## 12.4 What is a sexual dysfunction?

- Sexual dysfunction involves impairment either in the desire for sexual gratification or in the ability to achieve it. Dysfunction can occur in the first three of the four phases of the human sexual response: the desire phase, the excitement phase, and orgasm.
- Male hypoactive sexual desire disorder is diagnosed in men when they have little or no interest in sex. In extreme cases they may actually have an aversion to sexual activity.
- Erectile disorder occurs in men who are unable to attain or to maintain an adequate erection until the completion of sexual activity.
- Formerly called premature ejaculation, early ejaculation occurs in men who persistently and recurrently have the onset of orgasm and ejaculation occurs after only minimal sexual stimulation.
- Delayed ejaculation refers to the persistent inability to ejaculate during intercourse.
- Female sexual interest/arousal disorder is diagnosed in women who persistently show a lack of interest in sexual activity and/or great difficulty getting adequately aroused enough to have an orgasm.
- Genito-pelvic pain/penetration disorder is diagnosed in women who have persistent or recurrent difficulties in at least one of the following four areas:
  - Marked difficulty having vaginal intercourse/penetration
  - Marked vulvovaginal or pelvic pain during vaginal intercourse/penetration attempts
  - Marked fear or anxiety either about vulvovaginal or pelvic pain or vaginal penetration
  - Marked tensing or tightening of the pelvic floor muscles during attempted vaginal penetration

he leaves, so he quickly becomes disorganized again. He lives with his elderly mother, but he sometimes disappears for several months at a time and is eventually picked up by the police as he wanders the streets. (Modified from Spitzer et al., 2002, pp. 189–90.)

.....

The disorder that Emilio has is called schizophrenia. Schizophrenia is a severe disorder that is often associated with considerable impairments in functioning. This chapter describes the pieces of the schizophrenia puzzle as we currently know them. Keep in mind from the outset that not all of the pieces or their presumed interconnections have been found, so our puzzle is far from being solved. As you read through this chapter you will learn just how complex and challenging this disorder is—not only for patients who suffer from it and for their families who try to care for them, but also for the clinicians who attempt to treat it and the researchers who are determined to understand it.

## Schizophrenia

**Schizophrenia** occurs in people from all cultures and from all walks of life. The disorder is characterized by an array of diverse symptoms, including extreme oddities in perception, thinking, action, sense of self, and manner of relating to others. However, the hallmark of schizophrenia is a significant loss of contact with reality, referred to as **psychosis**. Although the clinical presentation of schizophrenia differs from one patient to another, the case of Emilio is quite typical.

### → Emilio: "Eating Wires and Lighting Fires"

Emilio is a 40-year-old man who looks 10 years younger. He is brought to the hospital, his 12th hospitalization, by his mother because she is afraid of him. He is dressed in a ragged overcoat, bedroom slippers, and a baseball cap, and he wears several medals around his neck. His affect ranges from anger at his mother ("She feeds me shit . . . what comes out of other people's rectums") to a giggling, obsequious seductiveness toward the interviewer. His speech and manner have a childlike quality, and he walks with a mincing step and exaggerated hip movements. His mother reports that he stopped taking his medication about a month ago and has since begun to hear voices and to look and act more bizarrely. When asked what he has been doing, he says "eating wires and lighting fires." His spontaneous speech is often incoherent and marked by frequent rhyming and clang associations (where sounds, rather than meaningful relationships, govern word choice).

Emilio's first hospitalization occurred after he dropped out of school at age 16, and since that time he has never been able to attend school or hold a job. He has been treated with neuroleptics (medications used to treat schizophrenia) during his hospitalizations, but he doesn't continue to take his medications when

The internal suffering of the person with schizophrenia is often readily apparent, as are bizarre behavior and unusual appearance.

## Origins of the Schizophrenia Construct

The first detailed clinical description of what we now recognize to be schizophrenia was offered in 1810 by John Haslam, the apothecary at the Bethlem Hospital in London, England. Haslam described the case of a patient who appears to have suffered from a variety of symptoms—including delusions—that are typical of schizophrenia (see Carpenter, 1989). Fifty years later, the Belgian psychiatrist Benedict Morel described the case of a 13-year-old boy who had formerly been the most brilliant pupil in his school but who gradually lost interest in his studies; became increasingly withdrawn, lethargic, seclusive, and quiet; and appeared to have forgotten everything he had learned. Morel thought the boy's intellectual, moral, and physical functions had deteriorated as a result of brain degeneration of hereditary origin. He used the term *démence précoce* (mental deterioration at an early age) to describe the condition and to distinguish it from the dementing disorders associated with old age.

It is the German psychiatrist Emil Kraepelin (1856–1926) who is best known for his careful description of what we now regard as schizophrenia. Kraepelin used the Latin version of Morel's term (*dementia praecox*) to refer to a group of conditions that all seemed to feature mental deterioration beginning early in life. Kraepelin, an astute observer of clinical phenomena, described the patient with dementia praecox as someone who “becomes suspicious of those around him, sees poison in his food, is pursued by the police, feels his body is being influenced, or thinks that he is going to be shot or that the neighbours are jeering at him” (Kraepelin, 1896). Kraepelin also noted that the disorder was characterized by hallucinations, apathy and indifference, withdrawn behavior, and an incapacity for regular work.

It was a Swiss psychiatrist named Eugen Bleuler (1857–1939) who gave us the diagnostic term we still use today. In 1911, Bleuler used *schizophrenia* (from the Greek roots of *sxizo*, pronounced “schizo” and meaning “to split or crack,” and *phren*, meaning “mind”) because he believed the condition was characterized primarily by disorganization of thought processes, a lack of coherence between thought and emotion, and an inward orientation away (split off) from reality. Although the term is often thought to reflect a “Jekyll and Hyde” split personality, this is a major misconception. The splitting does not refer to multiple personalities (an entirely different form of disorder, now called dissociative identity disorder). Instead, in schizophrenia there is a split within the intellect, between the intellect and emotion, and between the intellect and external reality. Interestingly, the subtitle of Bleuler's monograph (Bleuler, 1911/1950) was “The Group of Schizophrenias,” indicating that he believed this disorder was not a single diagnostic entity.

## Epidemiology

The risk of developing schizophrenia over the course of one's lifetime is a little under 1 percent—actually around 0.7 percent (Saha et al., 2005). What this means is that approximately 1 out

of every 140 people alive today who survive until at least age 55 will develop the disorder. Of course, a statistic like this does not mean that everyone has exactly the same risk. This is an average lifetime risk estimate. As we shall see later, some people (e.g., those who have a parent with schizophrenia) have a statistically higher risk of developing the disorder than do others (e.g., people who come from families where there has never been a case of schizophrenia).

There are also other groups of people who seem to have an especially high risk of developing schizophrenia. For example, people whose fathers were older (aged 45 to 50 years or more) at the time of their birth have two to three times the normal risk of developing schizophrenia when they grow up (Byrne et al., 2003; Malaspina et al., 2001). Having a parent who works as a dry cleaner is also a risk factor (Perrin, Opler et al., 2007). Moreover, people of Afro-Caribbean origin living in the United Kingdom have higher-than-expected rates of schizophrenia (Harrison et al., 1997). Although the reasons for these differences are not well understood, they are of great interest to researchers.

The vast majority of cases of schizophrenia begin in late adolescence and early adulthood, with 18 to 30 years of age being the peak time for the onset of the illness (Tandon et al., 2009). Although schizophrenia is sometimes found in children, such cases are rare (Green et al., 1992; McKenna et al., 1994). Schizophrenia can also have its initial onset in middle age or later, but again, this is not typical.

The characteristic age of onset of schizophrenia differs in men and women. In men, there is a peak in new cases of

Children whose fathers are older at the time of their birth have two to three times the normal risk of developing schizophrenia.

**FIGURE 13.1**

**Onset of Schizophrenia.** Age distribution of onset of schizophrenia (first sign of mental disorder) for men and women.

Source: From Haffner, H., et al. (1998). Causes and consequences of the gender difference in age at onset of schizophrenia. *Schizophrenia Bulletin*, 24(1), 99-114.

schizophrenia between ages 20 and 24. The incidence of schizophrenia in women peaks during the same age period, but the peak is less marked than it is for men (see Figure 13.1). After about age 35, the number of men developing schizophrenia falls markedly, whereas the number of women developing schizophrenia does not. Instead, there is a second rise in new cases that begins around age 40, as well as a third spike in onset that occurs when women are in their early sixties (Abel et al., 2010).

In addition to being more likely to have an early age of onset, males also tend to have a more severe form of schizophrenia (Leung & Chue, 2000). Brain-imaging studies show that schizophrenia-related anomalies of brain structure (discussed later) are more severe in male patients than they are in female patients (Nopoulos et al., 1997). Gender-related differences in illness severity may also explain why schizophrenia is more common in males than it is in females. The male-to-female sex ratio is 1.4:1. So for every three men who develop the disorder, only two women do so (Aleman et al., 2003; Kirkbridge et al., 2006). If women have a less severe form of schizophrenia, and if they also have more symptoms of depression (see Leung & Chue, 2000), they may either not be diagnosed at all or else be diagnosed with other disorders, thus giving rise to the sex ratio imbalance.

What might explain the better clinical outcome of women with schizophrenia? One possibility is that female sex hormones play some protective role. When estrogen levels are low (as is true premenstrually) or are falling, psychotic symptoms in women with schizophrenia often get worse (Bergemann et al., 2007). The protective effect of estrogen may therefore help explain both the delayed onset of schizophrenia and the more favorable clinical course of the disorder in females. Declining levels of estrogen around menopause might also explain why late-onset schizophrenia is much more likely to strike women than men. There is some evidence that this late-onset pattern in women is associated with a more severe clinical presentation (Haffner et al., 1998).

### in review

- What did Kraepelin mean by the term *dementia praecox*? How accurate is this description?
- What was Bleuler's use of the term *schizophrenia* meant to convey?
- Is schizophrenia the same thing as split personality?
- What is the prevalence of schizophrenia? What groups of people show lower or higher rates of schizophrenia than expected?
- How does the age of onset of schizophrenia vary by gender?
- How does gender influence the severity of schizophrenia? Why might this be?

### Clinical Picture

As we have mentioned earlier, the *DSM* is a work in progress. Diagnostic criteria are not fixed and immutable but instead change subtly over time as new research findings become available. We show the current *DSM-5* criteria for the diagnosis of schizophrenia in the *DSM-5* table on page 447. These are broadly similar to those used in *DSM-IV* and to the diagnostic criteria in the ICD (WHO, 2003), which is the diagnostic system used in Europe and other parts of the world. One change that has occurred in *DSM-5* is the elimination of the requirement that only one other symptom is necessary if delusions are bizarre or if the auditory hallucinations are of a certain type.

In isolation, however, lists of symptoms convey little about the clinical essence of schizophrenia. In the sections that follow, we elaborate on the hallmark symptoms of this major form of psychotic disorder.

### Delusions

A **delusion** is essentially an erroneous belief that is fixed and firmly held despite clear contradictory evidence. The word *delusion* comes from the Latin verb *ludere*, which means "to play." In essence, tricks are played on the mind. People with delusions

- A. Two (or more) of the following, each present for a significant portion of time during a 1-month period (or less if successfully treated). At least one of these must be (1), (2), or (3):
  - 1. Delusions.
  - 2. Hallucinations.
  - 3. Disorganized speech (e.g., frequent derailment or incoherence).
  - 4. Grossly disorganized or catatonic behavior.
  - 5. Negative symptoms (i.e., diminished emotional expression or avolition).
- B. For a significant portion of the time since the onset of the disturbance, level of functioning in one or more major areas, such as work, interpersonal relations, or self-care, is markedly below the level achieved prior to the onset (or when the onset is in childhood or adolescence, there is failure to achieve expected level of interpersonal, academic, or occupational functioning).
- C. Continuous signs of the disturbance persist for at least 6 months. This 6-month period must include at least 1 month of symptoms (or less if successfully treated) that meet Criterion A (i.e., active-phase symptoms) and may include periods of prodromal or residual symptoms. During these prodromal or residual periods, the signs of the disturbance may be manifested by
- only negative symptoms or by two or more symptoms listed in Criterion A present in an attenuated form (e.g., odd beliefs, unusual perceptual experiences).
- D. Schizoaffective disorder and depressive or bipolar disorder with psychotic features have been ruled out because either 1) no major depressive or manic episodes have occurred concurrently with the active-phase symptoms, or 2) if mood episodes have occurred during active-phase symptoms, they have been present for a minority of the total duration of the active and residual periods of the illness.
- E. The disturbance is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or another medical condition.
- F. If there is a history of autism spectrum disorder or a communication disorder of childhood onset, the additional diagnosis of schizophrenia is made only if prominent delusions or hallucinations, in addition to the other required symptoms of schizophrenia, are also present for at least 1 month (or less if successfully treated).

believe things that others who share their social, religious, and cultural backgrounds do not believe. A delusion therefore involves a disturbance in the *content* of thought. Not all people who have delusions suffer from schizophrenia. However, delusions are common in schizophrenia, occurring in more than 90 percent of patients at some time during their illness (Cutting, 1995). In schizophrenia, certain types of delusions or false beliefs are quite characteristic. Prominent among these are beliefs that one's thoughts, feelings, or actions are being controlled by external agents (made feelings or impulses), that one's private thoughts are being broadcast indiscriminately to others (thought broadcasting), that thoughts are being inserted into one's brain by some external agency (thought insertion), or that some external agency has robbed one of one's thoughts (thought withdrawal). Also common are delusions of reference, where some neutral environmental event (such as a television program or a song on the radio) is believed to have special and personal meaning intended only for the person. Other strange propositions, including delusions of bodily changes (e.g., bowels do not work) or removal of organs, are also not uncommon.

Sometimes delusions are not just isolated beliefs. Instead they become elaborated into a complex delusional system. The

The inner world of people with schizophrenia is often confused, punctuated by alien voices, paranoia, and illogical thoughts.

next case study provides an example of this. This material was printed on a flier and handed to one of the authors by a man who appeared to be in his 30s. Any errors of grammar are errors in the original flier.

→ **Are You Being Mind Controlled?** Are you being or were you mind controlled to do something very stupid? Twenty-five percent of our population have what is called electronic hearing. This 25 percent can hear a silent radio and do not hear it. You might be one. In hearing pitch the average person hears from zero to sixteen thousand cycles. Twenty-five percent can hear up to thirty thousand cycles. The silent radio can be heard by these high hearing frequency persons. The silent radio sounds the same as thoughts in their minds.

This silent radio tricks these persons into every crime imaginable. It tricks them into bad decisions, to quit jobs, to divorce, to run away, to be sheriff saled and any stupidity possible. The broadcasters over this silent radio are government, medical, psychiatrists, religious and educational. This is an enormous budget used to destroy the innocent and helpless. The media is scared to cover this up.

This minority, which can be in any ethnic or race, has lost all rights under law because the Russians do it everywhere. It is shocking to discover very large corporations and all colleges have mind control departments. If you and your family constantly make bad decisions and have ruinous problems, you probably are mind controlled. Every year these mind controlled people are going down the economic ladder as they cannot be trusted. No company knows when one will be selected as a guinea pig. Who could risk a sizeable work force of persons with electronic hearing for your competitor could easily wipe you out?

## Hallucinations

A **hallucination** is a sensory experience that seems real to the person having it, but occurs in the absence of any external perceptual stimulus. This is quite different from an illusion, which is a misperception of a stimulus that actually exists. The word comes from the Latin verb *hallucinare* or *allucinare*, meaning to “wander in mind” or “idle talk.” Hallucinations can occur in any sensory modality (auditory, visual, olfactory, tactile, or gustatory). However, auditory hallucinations (e.g., hearing voices) are by far the most common. In a sample recruited from 7 different countries, auditory hallucinations were found in 75 percent of patients with schizophrenia (Bauer et al., 2011). In contrast, visual hallucinations were reported less frequently (39 percent of patients), and olfactory, tactile, and gustatory hallucinations were even more rare (1–7 percent). Even deaf people who are diagnosed with schizophrenia sometimes report auditory hallucinations (Aleman & Larøi, 2008). As “The World Around Us” box on the next page illustrates, hallucinations can even be induced in healthy people if they are under a lot of stress and drink a lot of caffeine.

Watch the Video *Larry: Schizophrenia* on **MyPsychLab**.

Hallucinations often have relevance for the patient at some affective, conceptual, or behavioral level. Patients can become emotionally involved in their hallucinations, often incorporating them into their delusions. In some cases, patients may even act

on their hallucinations and do what the voices tell them to do. People who consider themselves to be socially inferior tend to perceive the voices they hear as being more powerful than they are and to behave accordingly (Paulik, 2011).

In an interesting study of the phenomenology of auditory hallucinations, Nayani and David (1996) interviewed 100 hallucinating patients and asked them a series of questions about their hallucinatory voices. The majority of patients (73 percent) reported that their voices usually spoke at a normal conversational volume. Hallucinated voices were often those of people known to the patient in real life, although sometimes unfamiliar voices or the voices of God or the Devil were heard. Most patients reported that they heard more than one voice and that their hallucinations were worse when they were alone. Most commonly, the hallucinated voices uttered rude and vulgar expletives or else were critical (“You are stupid”), bossy (“Get the milk”), or abusive (“Ugly bitch”), although some voices were pleasant and supportive (“My darling”).

Are patients who are hallucinating really hearing voices? Neuroimaging studies of hallucinating patients are providing answers to this interesting question. Several research groups have used PET and fMRI to look at activity in the brains of patients when they are actually experiencing auditory hallucinations (Cleghorn et al., 1992; McGuire et al., 1996). Although it might be expected that patients hearing voices would show an increase of activity in areas of the brain involved in speech comprehension (e.g., Wernicke’s area in the temporal lobe), imaging studies reveal that hallucinating patients show increased activity in Broca’s area—an area of the temporal lobe that is involved in speech production. In some cases, the pattern of brain activation that occurs when patients experience auditory hallucinations is very similar to that seen when healthy volunteers are asked to imagine that there is another person talking to them (Shergill et al., 2000). Overall, the research findings suggest that auditory hallucinations occur when patients misinterpret their own self-generated and verbally mediated thoughts (inner speech or self-talk) as coming from another source. Indeed, if transcranial magnetic stimulation (in which a magnetic field passing through the skull temporarily disrupts activity in underlying brain areas) is used to reduce activity in speech production areas, hallucinating patients actually show a reduction in their auditory hallucinations (Hoffman et al., 2005)! Modern research approaches are thus supporting a very old idea: Auditory hallucinations are really a form of misperceived subvocal speech (Gould, 1949).

## Disorganized Speech and Behavior

Delusions reflect a disorder of thought *content*. Disorganized speech, on the other hand, is the external manifestation of a disorder in thought *form*. Basically, an affected person fails to make sense, despite seeming to conform to the semantic and syntactic rules governing verbal communication. The failure is not attributable to low intelligence, poor education, or cultural deprivation. Years ago, Meehl (1962) aptly referred to the process as one of “cognitive

## Stress, Caffeine, and Hallucinations

**D**o you feel that you are under a lot of stress? Do you drink a lot of caffeinated beverages each day? If so, you may be interested in the findings from a recent study that was conducted using healthy volunteers who had no history of psychiatric disorders (Crowe et al., 2011). Ninety-two participants were recruited into what they believed was a study of auditory perception. As participants entered the testing room to begin the experiment, the song "White Christmas" by Bing Crosby was playing. After the song ended, participants were given headphones and asked to listen to white noise. They were told that the White Christmas song they had just heard might be embedded in the white noise at a subthreshold level. Every time they thought they heard a fragment of the song during the 3 minutes of white noise, participants were told to note this using a hand counter.

In reality, no sound fragments of White Christmas were embedded in the sound at all. Participants only heard white noise. However, those participants who reported that they had been under a high level of stress in the past year and who were high caffeine users (five or more drinks per day) reported hearing significantly more embedded song fragments than participants in the low-stress and low-caffeine group did. Moreover, it was the combination of high stress and high caffeine intake that was important. In participants who reported high stress but low caffeine intake or in participants who reported low stress but high caffeine intake, the number of false alarms or "hallucinations" (hearing a song fragment that was not there) was not elevated. The associations also remained when variables such as age, creativity, social desirability, mental imagery ability, and hallucination-proneness were taken into account.

Overall the results of this study demonstrate that, under certain conditions, the combination of high caffeine consumption and high stress can render normal people vulnerable to auditory hallucinations. Caffeine is known to increase how much cortisol is produced in response to a stressor. Caffeine consumption has also been found to correlate with hallucination proneness in other studies of healthy people (Jones & Fernyhough, 2009). It is also important to note that patients with schizophrenia typically drink a great deal of coffee. During times of high stress, this might perhaps increase their risk of having an exacerbation in hallucinatory symptoms.

The combination of high stress levels and high caffeine intake is associated with hallucinations in psychiatrically healthy people.

slippage"; others have referred to it as "derailment" or "loosening" of associations or, in its most extreme form, as "incoherence."

In disorganized speech, the words and word combinations sound communicative, but the listener is left with little or no understanding of the point the speaker is trying to make. In some cases, completely new, made-up words known as neologisms (literally, "new words") appear in the patient's speech. An example might be the word *detone*, which looks and sounds like a meaningful word but is a neologism. *Formal thought disorder* (a term clinicians use to refer to problems in the way that disorganized thought is expressed in disorganized speech) is well illustrated in the following example. It is taken from a letter written by a man with schizophrenia and addressed to Queen Beatrix of the Netherlands.

### → Disorganized Speech: A Letter to Queen Beatrix

I have also "killed" my ex-wife, [name], in a 2.5 to 3.0 hours sex bout in Devon Pennsylvania in 1976, while two Pitcairns were resid-

ing in my next room closet, hearing the event. Enclosed, please find my urology report, indicating that my male genitals, specifically my penis, are within normal size and that I'm capable of normal intercourse with any woman, signed by Dr. [name], a urologist and surgeon who performed a circumcision on me in 1982. Conclusion: I cannot be a nincompoop in a physical sense (unless Society would feed me chemicals for my picture in the nincompoop book).

Disorganized behavior can show itself in a variety of ways. Goal-directed activity is almost universally disrupted in schizophrenia. The impairment occurs in areas of routine daily functioning, such as work, social relations, and self-care, to the extent that observers note that the person is not himself or herself anymore. For example, the person may no longer maintain minimal standards of personal hygiene or may exhibit a profound disregard of personal safety and health. In other cases, grossly disorganized behavior appears as silliness or unusual dress (e.g., wearing

A person with catatonia may maintain an odd position for minutes or even hours.

Positive, negative, and disorganized symptoms can co-occur in the same patient. This woman appears to exhibit marked social withdrawal (a negative symptom) in addition to showing bizarre behavior (a disorganized symptom).

an overcoat, scarf, and gloves on a hot summer day). Many researchers attribute these disruptions of “executive” behavior to impairment in the functioning of the prefrontal region of the cerebral cortex (Lenzenweger & Dworkin, 1998).

*Catatonia* is an even more striking behavioral disturbance. The patient with catatonia may show a virtual absence of all movement and speech and be in what is called a *catatonic stupor*. At other times, the patient may hold an unusual posture for an extended period of time without any seeming discomfort.

### Positive and Negative Symptoms

Since the days of Bleuler, two general symptom patterns, or syndromes, of schizophrenia have been differentiated. These are referred to as positive- and negative-syndrome schizophrenia (e.g., Andreasen, 1985; Andreasen et al., 1995). Statistical procedures have further indicated that some symptoms like disordered speech and disorganized behavior that were previously thought to reflect positive symptoms might be better separated from “true” positive symptoms like hallucinations and delusions. A **disorganized symptom** pattern is now also recognized (Lenzenweger et al., 1991). These symptom types are illustrated in Table 13.1.

**Positive symptoms** are those that reflect an excess or distortion in a normal repertoire of behavior and experience, such as delusions and hallucinations. **Negative symptoms**, by contrast, reflect an

absence or deficit of behaviors that are normally present. Important negative symptoms in schizophrenia include **flat affect**, or blunted emotional expressiveness, and **alogia**, which means very little speech. Another negative symptoms is **avolition**, or the inability to initiate or persist in goal-directed activities. For example, the patient may sit for long periods of time staring into space or watching TV with little interest in any outside work or social activities.

Although most patients exhibit both positive and negative symptoms during the course of their disorders (Breier et al., 1994; Guelfi et al., 1989), a preponderance of negative symptoms in the clinical picture is not a good sign for the patient’s future outcome (e.g., Fenton & McGlashan, 1994; Miley et al., 2005).

Not all negative symptoms are exactly what they seem, however. Kring and Neale (1996) studied unmedicated male patients with schizophrenia while they were watching film clips. Three different types of film clips were used, the scenes in them being very positive, very negative, or neutral in terms of the emotions they were designed to elicit in the viewers. Videotapes of how the patients looked while they were watching the films were then coded by trained raters. As might be expected, the patients with schizophrenia showed less facial expressiveness than a group of healthy controls.

What was surprising was that when the patients were asked about their emotional experiences during the films, they reported as many emotional feelings as the controls—and sometimes slightly more. Measures of autonomic arousal also showed that when they were watching the films, the patients exhibited more physiological reactivity than the controls did. What these findings suggest, therefore, is that even though patients with schizophrenia may sometimes not look very emotionally expressive, they are nonetheless experiencing plenty of emotion.

**TABLE 13.1**  
**Positive, Negative, and Disorganized Symptoms of Schizophrenia**

Positive Symptoms	Negative Symptoms	Disorganized Symptoms
Hallucinations	Emotional flattening	Bizarre behavior
Delusions	Poverty of speech Asociality Apathy Anhedonia	Disorganized speech

### Subtypes of Schizophrenia

There is a great deal of heterogeneity in the presentation of schizophrenia, and patients with this disorder often look quite different clinically. In consideration of this, the *DSM-IV-TR*

recognized several subtypes of schizophrenia. The most clinically meaningful of these were **paranoid schizophrenia** (where the clinical picture is dominated by absurd and illogical beliefs that are often highly elaborated and organized into a coherent, though delusional, framework), **disorganized schizophrenia** (which is characterized by disorganized speech, disorganized behavior, and flat or inappropriate affect) and **catatonic schizophrenia** (which involves pronounced motor signs that reflect great excitement or stupor). Unfortunately, research using the subtyping approach did not yield major insights into the etiology or treatment of the disorder. Reflecting this, subtypes of schizophrenia are no longer included in *DSM-5*.

## Other Psychotic Disorders

**SCHIZOAFFECTIVE DISORDER** The *DSM-5* recognizes a diagnostic category called **schizoaffective disorder** (see the *DSM-5* table for diagnostic criteria). This diagnosis is conceptually something of a hybrid, in that it is used to describe people who have features of schizophrenia and severe mood disorder. In other words, the person not only has psychotic symptoms that meet criteria for schizophrenia but also has marked changes in mood for a substantial amount of time. Because mood disorders can be unipolar or bipolar in type, these are recognized as subtypes of schizoaffective disorder.

The reliability of schizoaffective disorder tends to be quite poor, and clinicians often do not agree about who meets the criteria for the diagnosis (Maj et al., 2000; Vollmer-Larsen et al., 2006). In an effort to improve this, in *DSM-5* it is specified that mood symptoms

### criteria for Schizoaffective Disorder

### DSM-5

- A. An uninterrupted period of illness during which there is a major mood episode (major depressive or manic) concurrent with Criterion A of schizophrenia.  
**Note:** The major depressive episode must include Criterion A1: Depressed mood.
- B. Delusions or hallucinations for 2 or more weeks in the absence of a major mood episode (depressive or manic) during the lifetime duration of the illness.
- C. Symptoms that meet criteria for a major mood episode are present for the majority of the total duration of the active and residual portions of the illness.
- D. The disturbance is not attributable to the effects of a substance (e.g., a drug of abuse, a medication) or another medical condition.

Source: Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, (Copyright 2013). American Psychiatric Association.

have to meet criteria for a full major mood episode and also have to be present for more than 50% of the total duration of the illness. This clarification should help improve the reliability of this diagnosis and possibly also decrease the number of people who receive it.

In general, the prognosis for patients diagnosed with schizoaffective disorder is somewhere between that of patients with schizophrenia and that of patients with mood disorders (Walker et al., 2004). Research suggests that the long-term (10-year) outcome is much better for patients with schizoaffective disorder than it is for patients with schizophrenia (Harrow et al., 2000).

**SCHIZOPHENIFORM DISORDER** **Schizophreniform disorder** is a category reserved for schizophrenia-like psychoses that last at least a month but do not last for 6 months and so do not warrant a diagnosis of schizophrenia (see the *DSM-5* table for diagnostic criteria). It may include any of the symptoms described in the preceding sections. Because of the possibility of an early and lasting remission after a first psychotic breakdown, the prognosis for schizophreniform disorder is better than that for established forms of schizophrenia.

### criteria for Schizophreniform Disorder

### DSM-5

- A. Two (or more) of the following, each present for a significant portion of time during a 1-month period (or less if successfully treated). At least one of these must be (1), (2), or (3):
  1. Delusions.
  2. Hallucinations.
  3. Disorganized speech (e.g., frequent derailment or incoherence).
  4. Grossly disorganized or catatonic behavior.
  5. Negative symptoms (i.e., diminished emotional expression or avolition).
- B. An episode of the disorder lasts at least 1 month but less than 6 months. When the diagnosis must be made without waiting for recovery, it should be qualified as "provisional."
- C. Schizoaffective disorder and depressive or bipolar disorder with psychotic features have been ruled out because either 1) no major depressive or manic episodes have occurred concurrently with the active-phase symptoms, or 2) if mood episodes have occurred during active-phase symptoms, they have been present for a minority of the total duration of the active and residual periods of the illness.
- D. The disturbance is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or another medical condition.

Source: Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, (Copyright 2013). American Psychiatric Association.

## criteria for Delusional Disorder

## DSM-5

- A. The presence of one (or more) delusions with a duration of 1 month or longer.
- B. Criterion A for schizophrenia has never been met.  
**Note:** Hallucinations, if present, are not prominent and are related to the delusional theme (e.g., the sensation of being infested with insects associated with delusions of infestation).
- C. Apart from the impact of the delusion(s) or its ramifications, functioning is not markedly impaired, and behavior is not obviously bizarre or odd.
- D. If manic or major depressive episodes have occurred, these have been brief relative to the duration of the delusional periods.
- E. The disturbance is not attributable to the physiological effects of a substance or another medical condition and is not better explained by another mental disorder, such as body dysmorphic disorder or obsessive-compulsive disorder.

Source: Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, (Copyright 2013). American Psychiatric Association.

## criteria for Brief Psychotic Disorder

## DSM-5

- A. Presence of one (or more) of the following symptoms. At least one of these must be (1), (2), or (3):
  1. Delusions.
  2. Hallucinations.
  3. Disorganized speech (e.g., frequent derailment or incoherence).
  4. Grossly disorganized or catatonic behavior.  
**Note:** Do not include a symptom if it is a culturally sanctioned response.
- B. Duration of an episode of the disturbance is at least 1 day but less than 1 month, with eventual full return to premorbid level of functioning.
- C. The disturbance is not better explained by major depressive or bipolar disorder with psychotic features or another psychotic disorder such as schizophrenia or catatonia, and is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or another medical condition.

Source: Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, (Copyright 2013). American Psychiatric Association.

**DELUSIONAL DISORDER** Patients with **delusional disorder**, like many people with schizophrenia, hold beliefs that are considered false and absurd by those around them. Unlike individuals with schizophrenia, however, people given the diagnosis of delusional disorder may otherwise behave quite normally. Their behavior does not show the gross disorganization and performance deficiencies characteristic of schizophrenia, and general behavioral deterioration is rarely observed in this disorder, even when it proves chronic (see the *DSM-5* table for criteria for delusional disorder). One interesting subtype of delusional disorder is *erotomania*. Here, the theme of the delusion involves great love for a person, usually of higher status. One study suggests that a significant proportion of women who stalk are diagnosed with erotomania (Purcell et al., 2001).

**BRIEF PSYCHOTIC DISORDER** **Brief psychotic disorder** is exactly what its name suggests. It involves the sudden onset of psychotic symptoms or disorganized speech or catatonic behavior. Even though there is often great emotional turmoil, the episode usually lasts only a matter of days (too short to warrant a diagnosis of schizopreniform disorder). After this, the person returns to his or her former level of functioning and may never have another episode again (see the *DSM-5* table for criteria for brief psychotic disorder). Cases of brief psychotic disorder are infrequently seen in clinical settings, perhaps because they remit so quickly. Brief psychotic disorder is often triggered by stress, as illustrated in the following case.

### → Four Days of Symptoms and Rapid Recovery

Ronald was 32 years old and had worked successfully as a lawyer for 6 years. He was married with two young children and he had many close friends. One day he returned home early from work and was shocked to find his wife in bed with his best friend. His initial reaction was anger, followed by depression. However, within 2 days he began to hear voices that called his name and that said, "Love, love, love." Ronald began to express odd ideas, speaking of fusing with God and dispensing peace on Earth. He also talked about needing to fight what he called the "giant conspiracy." During this time his affect was flat and he spoke in a slow and distinct manner. Ronald was admitted to hospital and was given medication. He and his wife also began marital therapy. Ronald showed rapid improvement of his symptoms and within 5 days of the onset of his initial symptoms he was back at work again. (Based on Janowsky et al., 1987)

### in review

- What are the major symptoms of schizophrenia?
- How is a hallucination different from a delusion?
- Explain the differences among positive, negative, and disorganized symptoms.
- Why were the subtypes of schizophrenia not included in *DSM-5*?
- In what ways are schizophrenia and schizoaffective disorder different?

- How will the change to the criteria for schizoaffective disorder in DSM-5 improve the reliability of this diagnosis?
- What are the major differences between schizophreniform disorder and brief psychotic disorder?

## Risk and Causal Factors

What causes schizophrenia? Despite enormous efforts by researchers, this question still defies a simple answer. In the sections that follow, we discuss what is currently known about the etiology of schizophrenia. What is clear is that no one factor can fully explain why schizophrenia develops. The old dichotomy of nature versus nurture is as misleading as it is simplistic. Psychiatric disorders are not the result of a single genetic switch being flipped. Rather, a complex interplay between genetic and environmental factors is responsible.

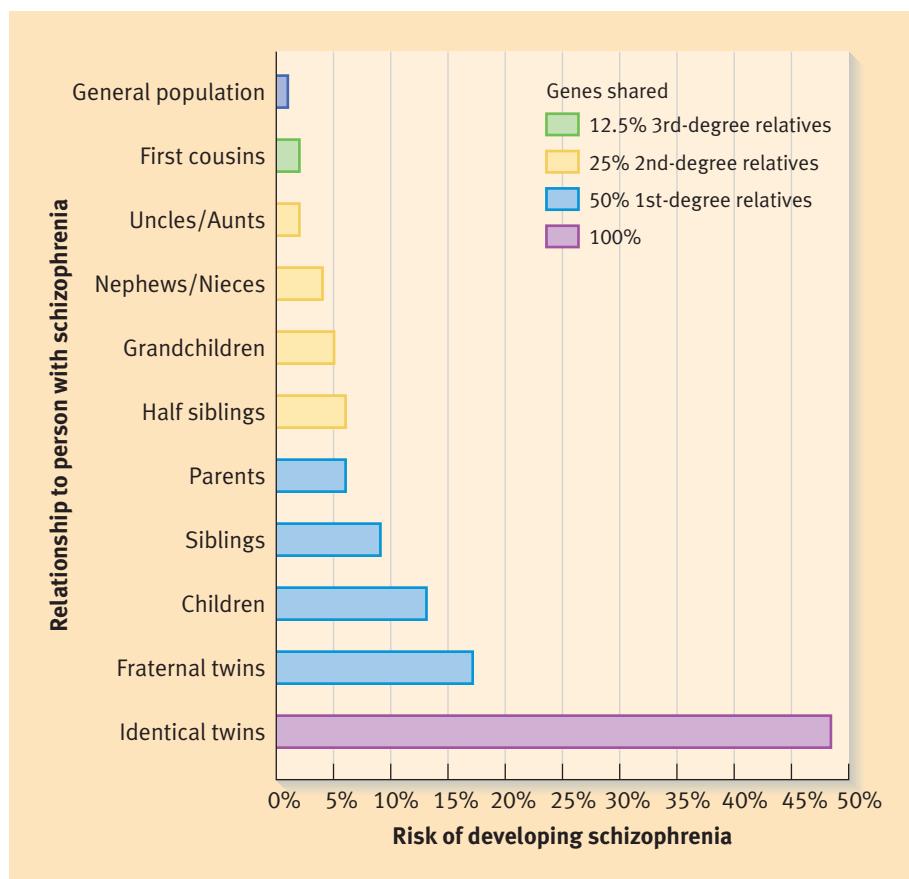

### Genetic Factors

It has long been known that disorders of the schizophrenia type are “familial” and tend to “run in families.” There is overwhelming evidence for higher-than-expected rates of schizophrenia among biological relatives of *index cases*; that is, the diagnosed group of people who provide the starting point for inquiry (also called *probands*). Figure 13.2 shows the percentage risk of developing schizophrenia given a specific genetic relationship with someone who has the disorder. As you can see, there is a strong association between

the closeness of the blood relationship (i.e., level of gene sharing or consanguinity) and the risk for developing the disorder. For example, the prevalence of schizophrenia in the first-degree relatives (parents, siblings, and offspring) of a proband with schizophrenia is about 10 percent. For second-degree relatives who share only 25 percent of their genes with the proband (e.g., half-siblings, aunts, uncles, nieces, nephews, and grandchildren), the lifetime prevalence of schizophrenia is closer to 3 percent.

Of course, just because something runs in families does not automatically implicate genetic factors. The terms *familial* and *genetic* are not synonymous, and a disorder can run in a family for nongenetic reasons (if I am obese and my dog is also obese, the reasons for this are clearly not genetic!). As we have repeatedly emphasized, the interpretation of familial concordance patterns is never completely straightforward, in part because of the strong relationship between the sharing of genes and the sharing of the environments in which those genes express themselves. Although they are indispensable in providing a starting point for researchers, family studies cannot, by themselves, tell us why a disorder runs in families. To disentangle the contributions of genes and environment, we need twin and adoption studies.

**TWIN STUDIES** We discussed twin studies in general in Chapter 3 and again more specifically in relation to anxiety and mood disorders. As with the mood disorders, schizophrenia

**FIGURE 13.2**

**Risk of Developing Schizophrenia by Genetic Relationship.** Lifetime age-adjusted, averaged risks for the development of schizophrenia-related psychoses in classes of relatives differing in their degree of genetic relatedness.

## The Genain Quadruplets

The Genain quadruplets, born sometime in the early 1930s, were rare MZ quadruplets who each developed schizophrenia, an outcome that would be expected to occur by chance only once in approximately 1.5 billion births. The genetically identical girls, given the pseudonym *Genain* (from the Greek for “dreadful gene”), were hospitalized at the National Institute of Mental Health in the mid-1950s and studied intensively by lead researcher David Rosenthal (see Rosenthal, 1963; see also Mirsky & Quinn, 1988). Rosenthal also selected first names for the girls using the initials of the institution, NIMH. Accordingly, the women are known to us as Nora (the firstborn), Iris, Myra, and Hester. They are all concordant for schizophrenia. However, they are discordant with regard to the severity of their illnesses.

The most severely ill Genain is Hester, who was born last and had the lowest birth weight. Hester was always the slowest to develop, and she was removed from school after 11th grade. She has never held a job outside the home and has suffered from chronic and unremitting severe symptoms since age 18. Neurocognitive testing at NIMH revealed that, along with Nora, Hester showed a great deal of evidence of brain disturbance.

Nora was always considered by the family to be the best of the four girls. She had the highest IQ and was the first to get a job. Nonetheless, after she was hospitalized at the age of 22 with hallucinations, delusions, and withdrawal, she had a long history of hospitalizations and has never been able to live independently or hold a job for an extended period of time.

In contrast, third-born Myra, despite having some problems in her 20s (when she was questionably diagnosed as having schizophrenia), does not appear to have experienced delusions and paranoia until her mid-40s. The only one of the Genains to marry and have children, she has a clinical picture that suggests schizoaffective disorder (a blend of psychotic symptoms and mood symptoms). Although she is not psychiatrically well by any

means, she was able to go off medications and eventually went into remission.

Finally, there is Iris. Like Nora, Iris had her first psychiatric hospitalization at age 22. She spent 12 years in a state hospital and suffered from hallucinations, delusions, and motor abnormalities. Although neurocognitive testing did not reveal any obvious brain disturbance, it is clear that she has suffered from a severe form of schizophrenia.

Why do these identical quadruplets not have identical illnesses? We do not know. Did Nora and Hester, being born first and last, experience more traumatic birth complications? Has Iris done less well than might have been expected from her neurocognitive test results because her parents insisted on treating the quads as though they were two sets of twins—a superior and talented set consisting of Nora and Myra, and an inferior, problematic set consisting of Iris and Hester? Did being paired with Hester somehow compromise Iris’s development? Has Myra done so well (relatively) because she was the most favored and because she did not sustain any brain damage?

And why did the quadruplets develop schizophrenia at all? In all probability, there was a family history of the disorder. Mr. Genain’s mother (the girls’ grandmother) had a nervous breakdown in her teens and appears to have had some symptoms of paranoid schizophrenia. It is also clear that the family environment was far from healthy and may have provided the stress that acted on the quadruplets’ genetic predispositions to induce full-blown illness. Mr. Genain was very disturbed and spent most of his time drinking and expressing his various fears and obsessions to his family. He imposed extreme restrictions and surveillance on the girls until the time of their breakdowns. He was sexually promiscuous and was reported to have sexually molested at least two of his daughters. Mrs. Genain seems to have ignored the sexual exploitation occurring in the home. In short, nothing about the family environment can be considered to have been normal.

concordance rates for identical twins are routinely and consistently found to be significantly higher than those for fraternal twins or ordinary siblings. The most famous case of concordance for schizophrenia is summarized in “The World Around Us” box, and describes the Genain Quadruplets.

Although being a twin does not increase one’s risk for developing schizophrenia (the incidence of schizophrenia among twins is no greater than it is for the general population), study after study has shown a higher concordance for schizophrenia among identical, or monozygotic (MZ), twins than among people related in any other way, including fraternal, or dizygotic (DZ), twins.

E. Fuller Torrey is a noted schizophrenia researcher who has a sister with the disorder. He and his colleagues (1994) have

published a review of the major literature worldwide on twin studies of schizophrenia. The overall pairwise concordance rate is 28 percent in MZ twins and 6 percent in DZ twins. This suggests that a reduction in shared genes from 100 percent to 50 percent reduces the risk of schizophrenia by nearly 80 percent. Also note that sharing 50 percent of one’s genes with a co-twin with schizophrenia is associated with a lifetime risk for schizophrenia of 6 percent. Although this is low in absolute terms, it is markedly higher than the baseline risk of less than 1 percent found in the general population.

If schizophrenia were exclusively a genetic disorder, the concordance rate for identical twins would, of course, be 100 percent. Although MZ concordance rates vary from one twin study to another, and although some researchers report higher

rates than the 28 percent reported by Torrey and colleagues (1994), they are never even close to 100 percent. Two conclusions can therefore be drawn: First, genes undoubtedly play a role in causing schizophrenia. Second, genes themselves are not the whole story. Twin studies provide some of the most solid evidence that the environment plays an important role in the development of schizophrenia. But why one MZ twin should develop schizophrenia when his or her co-twin does not is a fascinating question.

A great deal of research attention is now being directed at studying people with a known genetic liability for schizophrenia. Historically, the most important subjects to study in this regard have been MZ twins who are discordant for schizophrenia. This investigative strategy was pioneered many years ago by Fischer (1971, 1973) in an ingenious study. Fischer reasoned that genetic influences, if present, would be just as likely to show up in the offspring of the twins without schizophrenia in discordant pairs (see Figure 13.3) as they would be to show up in the offspring of the twins with schizophrenia (because they share all their genes in common). And, in a search of official records in Denmark, Fischer found exactly that. Subsequent to this, in a follow-up of Fischer's subjects, Gottesman and Bertelson (1989) reported an **age-corrected incidence rate** for schizophrenia of 17.4 percent for the offspring of the MZ twins without schizophrenia (i.e., the well MZ twins). This rate, which far exceeds normal expectancy, was not significantly different from that for offspring of the twins with schizophrenia in discordant pairs or from that for offspring of DZ twins with schizophrenia. Assuming that exposure to an aunt or uncle with schizophrenia would have, at most, limited etiologic significance, these results lend impressive support to the genetic hypothesis. They also, as the authors note, indicate that a predisposition to schizophrenia may remain "unexpressed" (as in the twins without

## research CLOSE-UP

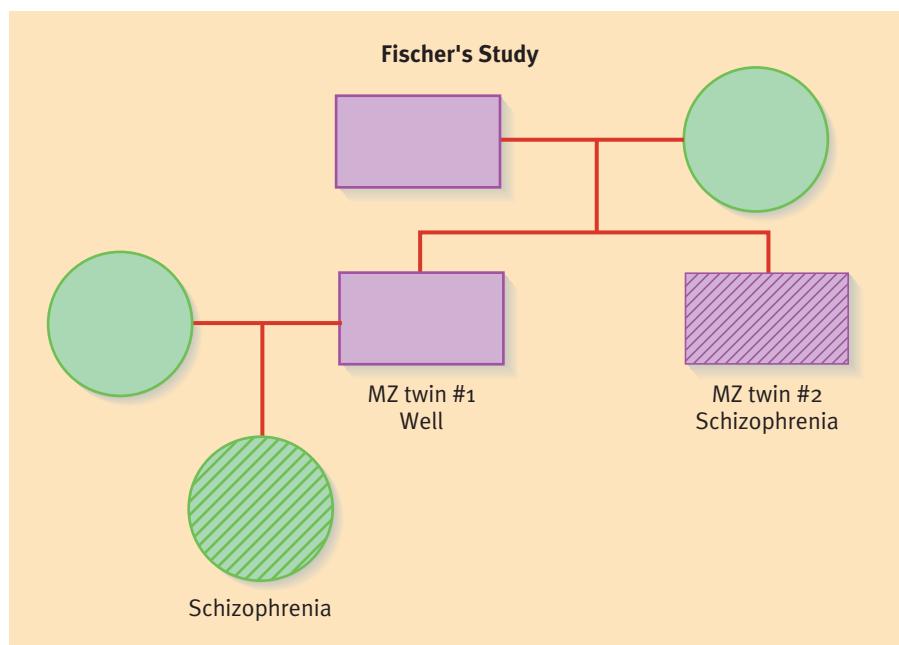

### Age-Corrected Incidence Rate

Incidence is the number of new cases that develop. An age-corrected incidence rate takes into account predicted breakdowns for subjects who are not yet beyond the age of risk for developing the disorder.

schizophrenia in discordant pairs) unless "released" by unknown environmental factors.

**ADOPTION STUDIES** One major assumption that twin studies make is that any differences found between MZ and DZ twins are attributable to genes. At the heart of this assumption is the idea that the environments of MZ twins are no more similar than the environments of DZ twins. But it is very reasonable to expect that, because MZ twins are identical (and always of the same gender), their environments will actually be more similar than the environments of DZ twins. To the extent that this is true, twin studies will overestimate the importance of genetic factors (because some similarities between MZ twins that actually occur for nongenetic reasons will be attributed to genetic factors). In some cases, of course, MZ twins go to a great deal of effort to try to be different from one another. The bottom line, however, is that the assumption that MZ and DZ twins have equally similar environments can create some problems when we try to interpret the findings of twin studies.

Several studies have attempted to overcome the shortcomings of the twin method in achieving a true separation of hereditary from environmental influences by using what is called the

**FIGURE 13.3**

**Fischer's Study.** Because MZ twins have identical genes, the children of the well twin will have an elevated risk of schizophrenia even if their parent did not suffer from the disorder.

adoption strategy. Here, concordance rates for schizophrenia are compared for the biological and the adoptive relatives of people who have been adopted out of their biological families at an early age (preferably at birth) and have subsequently developed schizophrenia. If concordance is greater among the patients' biological than adoptive relatives, a hereditary influence is strongly suggested; the reverse pattern would argue for environmental causation.

The first study of this kind was conducted by Heston in 1966. Heston followed up 47 children who had been born to mothers who were in a state mental hospital suffering from schizophrenia. The children had been placed with relatives or into foster homes within 72 hours of their birth. In his follow-up study, Heston found that 16.6 percent of these children were later diagnosed with schizophrenia. In contrast, none of the 50 control children (selected from among residents of the same foster homes whose biological mothers did not have schizophrenia) developed schizophrenia. In addition to the greater probability of being diagnosed with schizophrenia, the offspring whose mothers had schizophrenia were also more likely to be diagnosed as mentally retarded, neurotic, or psychopathic (i.e., antisocial). They also had been involved more frequently in criminal activities and had spent more time in penal institutions. These findings are often taken to suggest that any genetic liability conveyed by the mothers is not specific to schizophrenia but also includes a liability for other forms of psychopathology. But we must be careful about drawing such a conclusion. Heston's study provided no information about psychopathology in the fathers of the children. We therefore cannot know to what extent some of the problems the children had were due to genetic liability conveyed by their fathers.

Heston's study began by identifying mothers with schizophrenia and then traced what had happened to their adopted-away offspring. An alternative approach involves locating adult patients with schizophrenia who were adopted early in life and then looking at rates of schizophrenia in their biological and adoptive relatives. A large-scale and multifaceted adoption study of this type was undertaken in Denmark, with Danish and American investigators working in collaboration (Kendler & Gruenberg, 1984; Kendler et al., 1994; Kety et al., 1978, 1994). As would be expected on the basis of a genetic model, the data showed a preponderance of schizophrenia and "schizophrenia-spectrum" problems (e.g., schizotypal and paranoid personality disorder) in the biological relatives of adoptees with schizophrenia. More specifically, 13.3 percent of the 105 biological relatives had schizophrenia or schizophrenia-spectrum disorders themselves. In contrast, only 1.3 percent of the 224 adoptive parents showed such problems.

**THE QUALITY OF THE ADOPTIVE FAMILY** The Danish adoption studies did not include independent assessments of the child-rearing adequacy of the adoptive families into which the index children (those who developed schizophrenia) and the control children (those who did not) had been placed. It remained

for Tienari and colleagues (Tienari et al., 1987, 2000, 2004) to add this feature to their research design. The Finnish Adoptive Family Study of Schizophrenia, as it is known, followed up the adopted-away children of all women in Finland who were hospitalized for schizophrenia between 1960 and 1979. As they grew to adulthood, the functioning of these index children was compared with the functioning of a control sample of adoptees whose biological mothers were psychiatrically healthy. Over the course of a 21-year follow-up, the index adoptees developed more schizophrenia and schizophrenia-related disorders than did the controls (Tienari et al., 2000, 2003). What sets this study apart, however, is what it tells us about the interaction between genes and environment.

One measure of the family environment that the researchers looked at was communication deviance (Wahlberg et al., 1997). Communication deviance is a measure of how understandable and "easy to follow" the speech of a family member is. Vague, confusing, and unclear communication reflects high communication deviance. What Wahlberg and colleagues found was that it was the combination of genetic risk and high communication deviance in the adopted families that was problematic. Children who were at genetic risk and who lived in families where there was high communication deviance showed high levels of thought disorder at the time of the follow-up. In contrast, the control adoptees who had no genetic risk for schizophrenia showed no thought disorder, regardless of whether they were raised in a high- or a low-communication-deviance family. Perhaps what was most remarkable, though, was the outcome for the high-risk children who were raised by adopted families low in communication deviance. These children were healthier at follow-up than any of the other three groups! In other words, if they are raised in a benign environment, even children who are at genetic risk for schizophrenia appear to do very well.

Tienari and colleague have provided further evidence of a genotype-environment interaction in schizophrenia (Tienari et al., 2004). (If you are unsure what these terms mean, check

Even if children are at genetic high risk for schizophrenia they are less likely to develop the disorder if they are raised in a healthy family environment.

back to Chapter 3.) Using interviews, the researchers first looked at the quality of the family environment in which the adopted children were raised. They then looked at what happened to the children who were raised in healthy versus dysfunctional families. The degree of adversity in the family environment predicted later problems in the adopted children. However, only those children who were raised in dysfunctional families *and* had high genetic risk for schizophrenia went on to develop schizophrenia-related disorders themselves. Children at high genetic risk who were raised in healthy family environments did not develop problems any more frequently than did children at low genetic risk.

These findings are important because they suggest that our genetic makeup may control how sensitive we are to certain aspects of our environments. If we have no genetic risk, certain kinds of environmental influences may not affect us very much. But if we have high genetic risk, we may be much more vulnerable to certain types of environmental risks such as high communication deviance or adverse family environments. Findings such as these also raise the exciting possibility that certain kinds of environments may protect people with a genetic susceptibility to schizophrenia from ever developing the illness.

In summary, these findings indicate a strong interaction between genetic vulnerability and an unfavorable family environment in the causal pathway leading to schizophrenia. Of course, it could be argued that the children who went on to develop problems caused the disorganization of their adoptive families. However, there is little support for this alternative interpretation (see Tienari et al., 2004; Wahlberg et al., 1997). Some independent work reported by Kinney and colleagues (1997) also fails to show diminished mental health in adoptive parents raising children who later developed schizophrenia. Everything considered, the Finnish Adoptive Family Study has provided strong confirmation of the diathesis-stress model as it applies to the origins of schizophrenia.

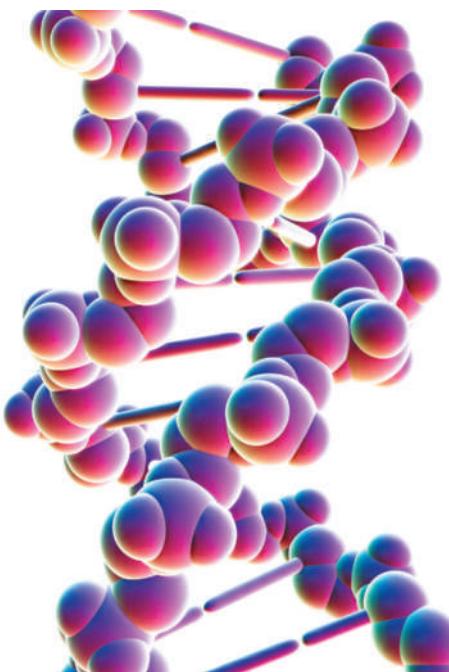

**MOLECULAR GENETICS** Family studies tell us that schizophrenia runs in families, and twin and adoption studies help us explore the relative contributions of genes and environment. These approaches also tell us about the genetic heterogeneity of schizophrenia. For example, in addition to higher rates of schizophrenia, higher rates of schizotypal personality disorder are also found in the relatives of patients with schizophrenia (Kendler et al., 1993). This supports the idea of the schizophrenia spectrum and suggests that a genetic liability to schizophrenia can sometimes manifest itself in a form of pathology that is “schizophrenia-like” but not exactly schizophrenia itself (see Lenzenweger, 2010).

Researchers no longer believe that schizophrenia will, like Huntington’s disease (see Chapter 14), be explained by one mutated gene on one specific chromosome. Rather, in most cases, schizophrenia probably involves many genes working together to confer susceptibility to the illness. The individual’s “dose” of schizophrenia genes may explain why one person

develops schizophrenia and another develops a milder variant within the schizophrenia spectrum, such as schizotypal personality disorder.

Researchers are now trying to locate and identify the genes that are involved in schizophrenia using the techniques of molecular genetics. In one approach, they are using known DNA markers to try to learn where aberrant genes might lie. As Faraone and colleagues (1999) aptly state, DNA markers are the “milemakers” on our chromosomal highways. Molecular geneticists capitalize on the fact that we know the locations of some important genes that are associated with observable traits (such as genes for color blindness, for blood group, and for the human leukocyte antigen). Because genes that are close together on the same chromosome tend to stay together when genetic information is shuffled (as happens during reproduction), researchers can see whether a disorder like schizophrenia tends to co-occur with any known DNA marker traits. This is the rationale behind **linkage analysis**. Linkage analysis has been very successful in helping locate the genes associated with diseases that have well-defined models of inheritance. Even newer approaches such as *genome-wide association methods* (which may be able to detect genes that have very small effects) are also now being used to identify susceptibility genes.

In much of the research to date, failures to replicate previously reported findings have been more the rule than the exception. Nonetheless, studies are suggesting specific regions on certain chromosomes that may contribute to schizophrenia. Currently, there is a great deal of interest in regions on chromosomes 1, 2, 6, 8, 13, and 22 among others (Karoutzou et al., 2008;

Many genes, each with a small effect, probably contribute to the development of schizophrenia. Genes that play a role in brain development may be especially implicated.

Maier, 2008; O'Donovan et al., 2008; Pogue-Geile & Yokley, 2010; Stefansson et al., 2008).

Why are these chromosomes of such interest? The reason is that, in some cases, they host genes that are known to be involved in processes that are believed to be aberrant in schizophrenia. These genes are known as **candidate genes**. An example is the COMT (catechol-O-methyltransferase) gene. This gene is located on chromosome 22 and is involved in dopamine metabolism. As you will soon learn, dopamine is a neurotransmitter that has long been implicated in psychosis (impaired reality testing). Interestingly, children who have a genetic syndrome (called *velocardiofacial syndrome*) that involves a deletion of genetic material on chromosome 22 are at high risk for developing schizophrenia as they move through adolescence (Gothenburg et al., 2007). Prior to the onset of any disorder, they often report transient psychotic symptoms (such as auditory hallucinations) and have poor social functioning and reduced IQ (Debbané et al., 2006). Furthermore, as we shall see later, people with a particular variant of the COMT gene are much more likely to become psychotic as adults if they use cannabis during adolescence. For obvious reasons, schizophrenia researchers are very interested in chromosome 22 and in the COMT gene in their search to understand the origins of the disorder. Other genes implicated in schizophrenia are the neuregulin 1 gene (located on chromosome 8), the dysbindin gene (on chromosome 6), the DISC1 (which stands for “disrupted in schizophrenia”) gene on chromosome 1, and several dopamine receptor genes (Gejman et al., 2011; Pogue-Geile & Yokley, 2010). These genes are involved in various neurobiological processes that are thought to have gone awry in schizophrenia.

**ENDOPHENOTYPES** Although we are certain that schizophrenia has a genetic basis, we are still a long way from understanding which genes are involved and what effects they have. Progress has been frustratingly slow because schizophrenia appears to be very complex genetically. A major collaborative study that examined 14 genes thought to be involved in schizophrenia has found no association between these genes and schizophrenia, disappointing many researchers (Sanders et al., 2008). However, it is possible that the genes involved may have only weak effects or else may be relevant in only certain population subgroups. A robust finding in one segment of the sample could therefore be washed out in a very large and mixed overall sample (Hamilton, 2008). Another difficulty is that researchers are still not sure exactly what phenotype (i.e., measurable characteristic of interest) they should be looking for (remember Bleuler's idea of “the schizophrenias”?). Because genetic analysis requires that we know who is “affected” and who is not, this is a big problem.

To simplify things, researchers are now focusing on less complex and more homogenous phenotypes (such as specific symptom clusters) that may potentially be under the control of a smaller number of genes. They are also exploring **endophenotypes**—discrete, stable, and measurable traits that

are thought to be under genetic control. By studying different endophenotypes, researchers hope to get closer to specific genes that might be important in schizophrenia (Gottesman & Gould, 2003; Lenzenweger, 2010). Accordingly, researchers are interested in people who score high on certain tests or measures that are thought to reflect a predisposition to schizophrenia. One example is subjects who score high on a self-report measure of schizotypal traits involving perceptual aberrations and magical ideation (the Per-Mag Scale; see Chapman et al., 1982; Chapman et al., 1994). Examples of items from these scales are shown in Table 13.2. Other endophenotypic risk markers for schizophrenia include abnormal performance on measures of cognitive functioning such as tests of working memory (see Barch, 2005; Lenzenweger, 2010). By studying these traits rather than the disorder itself, researchers hope to speed up progress in the search for the genes related to schizophrenia. Major collaborative studies designed to explore different endophenotypes are now under way (Greenwood et al., 2007).

### Prenatal Exposures

Whether or not a genotype is expressed depends on biological and environmental triggers. We now know that a range of environmental factors, including such things as maternal exposure to stress, are capable of influencing patterns of gene expression in the developing offspring. In the sections below we highlight some environmental risk factors that might either cause schizophrenia or trigger it in a genetically vulnerable person.

**VIRAL INFECTION** The idea that schizophrenia might result from some kind of virus is not new. Kraepelin (1919) suggests that “infections in the years of development might have a causal significance” for schizophrenia. We also know that in the

Northern Hemisphere, more people with schizophrenia are born between January and March than would be expected by chance (Waddington et al., 1999). Could some seasonal factor, such as a virus, be implicated?

In 1957 there was a major epidemic of influenza in Finland. Studying the residents of Helsinki, Mednick and colleagues (1988) found elevated rates of schizophrenia in children born to mothers who had been in their second trimester of pregnancy at the time of the influenza epidemic. The link between maternal influenza and subsequent schizophrenia in the grown offspring has now been well replicated using influenza epidemic information from other countries (see Wright et al., 1999). Risk of schizophrenia seems to be greatest when the mother gets the flu in the fourth to seventh month of gestation. Although the size of the effect is small and influenza clearly does not account for very many cases of schizophrenia, the fact that this association exists is very provocative. But how can maternal influenza set the stage for schizophrenia in a child two or three decades later? One possibility is that the mother's antibodies to the virus cross the placenta and somehow disrupt the neurodevelopment of the fetus (Waddington et al., 1999). Other maternal infections such as rubella (German measles) and toxoplasmosis (a parasitic infection) that occur during this time have also been linked to increased risk for the later development of schizophrenia (Brown, 2011).

**RHESUS INCOMPATIBILITY** The idea that the mother's immune system might somehow damage the developing brain of the fetus is not as far-fetched as it might sound. Rhesus (Rh) incompatibility occurs when an Rh-negative mother carries an Rh-positive fetus. (Rhesus-positive or -negative is a way of typing a person's blood.) Incompatibility between the mother and the fetus is a major cause of blood disease in newborns. Interestingly, Rh incompatibility also seems to be associated with increased risk for schizophrenia. Hollister, Laing, and Mednick (1996) have shown that the rate of schizophrenia is about 2.1 percent in males who are Rh-incompatible with their mothers. For males who have no such incompatibility with their mothers, the rate of schizophrenia is 0.8 percent—very near the expected base rate found in the general population. Hollister is another example of a schizophrenia researcher who has a family member with the disorder, in this case a sister who was Rh-incompatible with her mother.

How might Rh incompatibility increase the risk for schizophrenia? One possibility is that the mechanism involves oxygen deprivation, or hypoxia. This suggestion is supported by studies that have linked the risk for schizophrenia to birth complications. Recent research also suggests that incompatibility between the blood of the mother and the blood of the fetus may increase the risk of brain abnormalities of the type known to be associated with schizophrenia (Freedman et al., 2011).

**PREGNANCY AND BIRTH COMPLICATIONS** Patients with schizophrenia are much more likely to have been born following a pregnancy or delivery that was complicated in some way

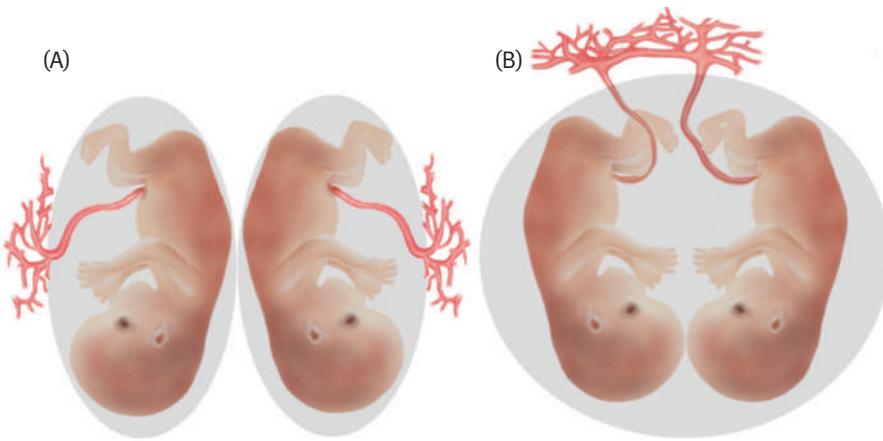

(Cannon et al., 2002). Although the type of obstetric complication varies, many delivery problems (e.g., breech delivery, prolonged labor, or the umbilical cord around the baby's neck) affect the oxygen supply of the newborn. Although we still have much to learn, the research again points toward damage to the brain at a critical time of development.

**EARLY NUTRITIONAL DEFICIENCY** Yet another piece of evidence that supports the idea that schizophrenia might be caused or triggered by environmental events that interfere with normal brain development comes from a tragedy that occurred in the Netherlands toward the end of World War II. In October 1944, a Nazi blockade resulted in a severe famine that affected people living in Amsterdam and other cities in the west of the country. The Dutch Hunger Winter (as it was known) continued until the Netherlands was liberated in May 1945. The population was severely malnourished during this time, and many died of starvation. Not surprisingly, fertility levels fell and the birth rate dropped precipitously. However, some children were born during this time. Those who were conceived at the height of the famine had a twofold increase in their risk of later developing schizophrenia (Brown, 2011). Early prenatal nutritional deficiency appears to have been the cause. Whether the problem was general malnutrition or the lack of a specific nutrient such as folate or iron is not clear. But again, something seems to have compromised the development of the fetus during a critical stage.

**MATERNAL STRESS** If a mother experiences an extremely stressful event late in her first trimester of pregnancy or early in the second trimester the risk of schizophrenia in her child is increased (King et al., 2010). For example, in a large population study conducted in Denmark, the death of a close relative during the first trimester was associated with a 67 percent increase in the risk of schizophrenia in the child (Khashan et al., 2008). Currently, it is thought that the increase in stress hormones that pass to the fetus via the placenta might have negative effects on the developing brain, although the mechanisms through which maternal stress increases risk for schizophrenia are not yet well understood.

## Genes and Environment in Schizophrenia: A Synthesis

Without question, schizophrenia has a strong genetic component. Current thinking is that genetic risk for schizophrenia emerges in one of two ways. The first is from large numbers (perhaps thousands) of common genes. The individual contribution of each of these genes is likely very small. However, when all of these genetic variants interact together, they set the stage for the development of the illness. The other way that schizophrenia may arise is because of very rare genetic mutations. These could be highly specific to certain people or to certain families (see Crow, 2007; McClellan, Susser, & King, 2007). These genetic events might involve microdeletions (bits of the DNA sequence that are missing in some places) or

**FIGURE 13.4**

**Chorionic Arrangements in Twins.** (A) Dichorionic twins, who can be either dizygotic or monozygotic, have separate placentas and separate fetal circulation. (B) Monochorionic twins, who are always monozygotic, have a single placenta and shared circulation.

Source: From Davis, J. O., Phelps, J. A., & Bracha, H. S. (1995). Prenatal development of monozygotic twins and concordance for schizophrenia. *Schizophrenia Bulletin*, 21(3), 357–66.

problems in the DNA sequence itself (such as repetitions of specific sections; St. Clair, 2009).

It is also possible that the focus on MZ concordance rates has caused us to overestimate the heritability of schizophrenia. This is because some MZ, and all DZ, twins do not have equally similar prenatal environments. Around two-thirds of MZ embryos are monochorionic, which means they share a placenta and blood supply. The remaining MZ twins and all DZ twins are dichorionic; they have separate placentas and separate fetal circulations. This is shown in Figure 13.4 above. The higher concordance rate for schizophrenia in MZ than in DZ twins might therefore be a consequence, at least in part, of the greater potential for monochorionic MZ twins to share infections. Davis, Phelps, and Bracha (1995) have found that MZ twins who are monochorionic are much more likely to be concordant for schizophrenia (around 60 percent concordance) than MZ twins who are dichorionic (around 11 percent concordance). The concordance figure for dichorionic MZ twins is very similar to that generally reported for DZ twins. Monochorionic MZ twins may therefore have inflated concordance rates in schizophrenia, which may have caused us to overattribute to genetics what might more accurately be attributed to environmental influences.

Finally, we need to keep in mind that genes get “turned on” and “turned off” in response to environmental changes. MZ twins who are discordant for schizophrenia show differences in their gene expression (Petronis et al., 2003). Perhaps some environmental “hits” turn on the genes for schizophrenia in one twin and not in the other. And perhaps some environments can keep the genes for schizophrenia from ever being turned on at all. Unfortunately, consistent with the diathesis-stress perspective, being at genetic risk does seem to make people more susceptible to environmental insults. In a study looking at the consequences of birth complications, Cannon and colleagues (1993) found that only the people who had a parent with schizophrenia and who had birth complications later showed brain abnormalities in adulthood such as enlarged ventricles (fluid-filled spaces in the brain). Moreover, for people who had two parents with

schizophrenia, the problems were even worse. In contrast, people with no family history of schizophrenia did not show enlarged ventricles regardless of whether they experienced delivery complications when they were born. The message seems to be clear: A genetic liability to schizophrenia may predispose an individual to suffer more damage from environmental insults than would be the case in the absence of the genetic predisposition.

### A Neurodevelopmental Perspective

Earlier in this chapter you learned that schizophrenia typically strikes people in late adolescence or early adulthood. Yet in the sections above, we saw that some of the factors thought to cause schizophrenia occur very early in life—in some cases before birth. How can this be? Current thinking is that schizophrenia is a disorder in which the development of the brain is disturbed very early on. Risk for schizophrenia may start with the presence of certain genes that, if turned on, have the potential to disrupt the normal development of the nervous system. Exposure to environmental insults in the prenatal period may turn on these genes or may create problems in other ways, independently of genotype. What this means is that the stage for schizophrenia, in the form of abnormal brain development, may be set very early in life. Nonetheless, problems may not be apparent until other triggering events take place or until the normal maturation of the brain reveals them. This may not occur until the brain is fully mature, typically late in the second decade of life (Conklin & Lacono, 2002; Weinberger, 1987).

What goes wrong? We are not yet certain. Brain development is a complex process that involves a programmed, orderly, and progressive sequence of events (Romer & Walker, 2007). Interestingly, some of the genes that have been implicated in schizophrenia are known to play a role in brain development and neural connections. (And organic solvents used in the dry cleaning business might disrupt fetal neurodevelopment and so explain why having a parent who works as a dry cleaner triples the risk of schizophrenia in the offspring.) If there were a disruption in cell migration some cells might fail to reach their target destinations, greatly affecting the “internal connectivity” of the

brain. Neuronal migration is known to occur during the second trimester—exactly the period in development during which the consequences of maternal influenza seem to be most devastating.

If the seeds of schizophrenia are sown so early in life, can we see early indications of vulnerability to the disorder before the illness itself strikes? An ingenious series of studies reported by Walker and colleagues nicely illustrates the association between early developmental deviation and schizophrenia risk. These investigators gathered family home movies made during the childhoods of 32 people who eventually developed schizophrenia. Trained observers made “blind” ratings (i.e., the observers were uninformed of outcomes) of certain dimensions of the emotional (Grimes & Walker, 1994) and facial expressions (Walker et al., 1993), motor skills, and neuromotor abnormalities (Walker et al., 1994) of these children and their healthy-outcome siblings from the same movie clips. The facial and emotional expressions and the motor competence of the “preschizophrenia” and the healthy-outcome children were found by the raters to differ significantly. The “preschizophrenia” children showed more motor abnormalities including unusual hand movements than their healthy siblings; they also showed less positive facial emotion and more negative facial emotion. In some instances these differences were apparent by age 2. Of course, we must keep in mind that these early problems do not characterize all children who will later develop schizophrenia. But they do tell us that subtle abnormalities can be found in children who are vulnerable to the disorder. We should also note that a major advantage of Walker’s research design was that it avoided the problem of retrospective bias. Rather than asking parents or siblings what patients were like when they were growing up, the study used home movies to provide an objective behavioral record.

Another way to explore childhood indicators without the problem of retrospective bias is to use a prospective research design (see Chapter 1). Jones and colleagues (1994) and Isohanni and colleagues (2001) studied whole cohorts of children born in particular years and followed them up over time. Both groups of researchers found evidence of delayed speech and delayed motor development at age 2 in children who later went on to develop schizophrenia.

Yet another approach is to follow children who are known to be at high risk for schizophrenia by virtue of their having been born to a parent with the disorder. This strategy, pioneered by Mednick and Schulsinger (1968), has led to several other studies of high-risk children (for reviews, see Cornblatt et al., 1992; Erlenmeyer-Kimling & Cornblatt, 1992; Neale & Oltmanns, 1980; Watt et al., 1984). Obviously, research of this kind is both costly and time consuming. It also requires a great deal of patience on the part of researchers because children at risk have to be identified early in their lives and then followed into adulthood. Moreover, because the majority of people with schizophrenia do not have a parent with the disorder (in fact, 89 percent of patients have no first- or second-degree relatives with

Ratings of clips of old home movies revealed that children who went on to develop schizophrenia showed more unusual hand movements than their healthy siblings, even when they were just 2 years old.

Source: Walker (1994).

schizophrenia [Gottesman, 2001]), high-risk samples are not particularly representative. Nonetheless, they have provided us with some valuable information about what people at risk look like prior to developing the full illness.

One of the most consistent findings from high-risk research is that children with a genetic risk for schizophrenia are more deviant than control children on research tasks that measure attention (Erlenmeyer-Kimling & Cornblatt, 1992). Adolescents at risk for schizophrenia are also rated lower in social competence than adolescents at risk for affective illness (Dworkin et al., 1994; Hooley, 2010). Some of the social problems that these high-risk children have may result from underlying attentional problems (Cornblatt et al., 1992).

Echoing the findings from Walker’s home movie study is evidence that early motor abnormalities might be an especially strong predictor of later schizophrenia. Using data from the New York High-Risk Study, Erlenmeyer-Kimling and colleagues (1998) reported that, of an initial group of 51 high-risk children, 10 developed schizophrenia or schizophrenia-like psychosis as adults. Of these, 80 percent had shown unusual motor behavior when they were between 7 and 12 years of age. In another study, adolescents at high risk for schizophrenia showed more movement abnormalities (e.g., facial tics, blinking, tongue thrusts) than either nonclinical controls or adolescents with personality or behavioral problems (Mittal et al., 2008). Moreover, these movement abnormalities became more marked with time and also became more strongly correlated with psychotic symptoms as the children got older. Although we might have suspected that schizophrenia would first begin to show itself via hallucinations or delusions, it may be that the first signs of the illness can instead be found in the way that children move. This could be because movement abnormalities and psychotic symptoms share some of the same neural circuitry in the brain. Problems in this neural circuitry might show themselves first via movement abnormalities. Then, as the brain matures, problems in the same

## Attenuated Psychosis Syndrome

DSM-5

**T**here was lively debate about whether a new diagnosis called attenuated psychosis syndrome should be added to the *DSM-5* (Carpenter & Van Os, 2011). In the end it was decided that the syndrome should be included in a provisional manner and placed in a section reserved for disorders in need of further study. But what is attenuated psychosis syndrome and why is it such a controversial diagnosis?

Attenuated psychosis syndrome is characterized by mild psychotic symptoms that are not severe enough to meet clinical criteria for another full-blown psychotic disorder. People with this syndrome are thought to be at risk for later psychosis. They are also experiencing some distress or disability and are seeking help for their problems. Proponents of including the syndrome in *DSM-5* argued that it would help clinicians identify these people and provide them with treatment at an early stage. This could, in theory, reduce distress in the short term and prevent the onset of a full-blown psychotic disorder in the long term. This is important because, once schizophrenia has developed, most patients are likely to experience recurring positive and negative symptoms, as well as persistent impairments in their work or social functioning for a large part of their lives (Jobe & Harrow, 2010).

Although these may seem like valid reasons to include the new diagnosis, there are also arguments against doing so. The potential for stigma is one problem (Yang et al., 2013). Another concern is that the majority of people who are identified as being

at high risk are not on their way to developing a psychotic disorder. Addington and colleagues (2011) followed 303 young adults who were showing prodromal symptoms of schizophrenia. At the end of the follow-up period the majority of these young people (71 percent) had not made the transition into psychosis. Although the follow-up period was relatively short it seems that the false positive rate here is very high (see also Fusar-Poli et al., 2012).

Another concern is that the existence of the diagnosis will increase the likelihood that antipsychotic medications will be used to treat it (see Weiser, 2011). But is it really appropriate and ethical to prescribe antipsychotic medications to someone who has only mild psychotic symptoms? As you have learned, second-generation antipsychotic medications are not as effective as had been initially hoped. They also appear to be associated with some very undesirable changes (such as tissue loss) in the brain (Ho et al., 2011; Lewis, 2011). When used long term, they may even perpetuate psychosis (see Unresolved Issues at the end of this chapter). Given this, it behooves us to be cautious with their use.

The inclusion of attenuated psychosis in Section III of the *DSM* may be a good interim solution. It will encourage more research into this new disorder. This may help us refine and improve the diagnostic criteria that are currently being used. More research may also stimulate the development of new treatment approaches capable of providing clinical benefits to patients without exposing them to unnecessary risks.

neural circuits manifest themselves in psychotic symptoms (see MacManus et al., 2011; Mittal et al., 2008).

The original high-risk studies have given us many insights into the problems that characterize people at risk for schizophrenia. But researchers have now changed their strategies. A new generation of high-risk studies is focusing on young people who are at clinical (as opposed to genetic) high risk. By focusing on those who are already showing some **prodromal**, or very early, signs of schizophrenia, researchers are hoping to improve their ability to detect, and also perhaps intervene with, people who appear to be on a pathway to developing the disorder (Addington et al., 2007; Cannon et al., 2007). Recognizing this, the new diagnosis of **attenuated psychosis syndrome** has entered *DSM-5* as a disorder in need of further study (see the “Thinking Critically About *DSM-5*” box).

### Structural and Functional Brain Abnormalities

Technological developments now allow us to study the brain in ways that used to be impossible. Positron emission tomography (PET), magnetic resonance imaging (MRI), and other even more

sophisticated approaches are in wide use. They are revealing abnormalities in the structure and function of the brain as well as in neurotransmitter activity in people who suffer from schizophrenia. In the sections that follow we describe some of the problems in cognitive functioning that have long been known to characterize people with this disorder. We then consider what abnormalities in the structure and functioning of the brain might be responsible for these and other problems.

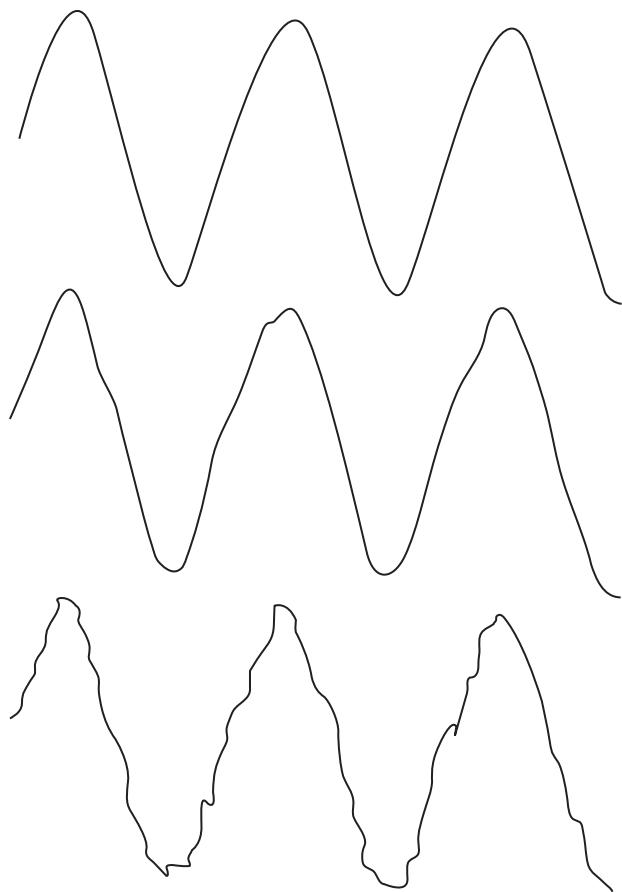

**NEUROCOGNITION** Schizophrenia patients experience many problems with their neurocognitive functioning (see Cornblatt et al., 2008; Green, 1997, for reviews). For example, they perform much worse than healthy controls on a broad range of neuropsychological tests (Heaton et al., 1994; Hoff et al., 1992; 2000). Furthermore, patients who have only recently become ill perform about the same on neuropsychological tests as patients who have been ill for many years (and both groups obviously perform worse than controls). In other words, cognitive difficulties can be seen right from the start of the illness and so are unlikely to be due to the effects of extended hospitalizations or medications.

Other cognitive deficits are also apparent. For example, when asked to respond to a stimulus as quickly and appropriately as possible (this is a measure of reaction time), schizophrenia patients do poorly compared with controls (see Nuechterlein, 1977). In addition, they show deficits on the Continuous Performance Task (CPT; e.g., Cornblatt et al., 1989). This task requires the subject to attend to a series of letters or numbers and then to detect an intermittently presented target stimulus that appears on the screen along with the letters or numbers (e.g., “Press when you see the number 7”). There are also problems with working memory (Barch, 2005; Park et al., 1995), which can be thought of as our “mental blackboard.” When they engage in tasks of working memory, patients with schizophrenia show less prefrontal brain activity compared to healthy controls (Cannon et al., 2005).

Somewhere between 54 and 86 percent of people with schizophrenia also show eye-tracking dysfunction (see Figure 13.5) and are deficient in their ability to track a moving target such as a pendulum (Cornblatt et al., 2008). This is a skill referred to as smooth-pursuit eye movement (Levy et al., 1993; Lieberman et al., 1993). In contrast, only about 6 to 8 percent of the general population shows problems with eye tracking. Especially interesting is that around 50 percent of the first-degree relatives of schizophrenia patients also show eye-tracking problems even though they do not have schizophrenia themselves (e.g., Iacono et al., 1992; Levy et al., 1993; Sporn et al., 2005). This suggests that disturbances in eye tracking have a genetic basis and that eye tracking may represent a viable endophenotype for genetic studies.

Perhaps the strongest finding in the area of neurocognition and schizophrenia, however, concerns a psychophysiological measure called P50 (see Heinrichs, 2001). When two clicks are heard in close succession, the brain (receiving the auditory signal) produces a positive electrical response to each click. This response is called P50 because it occurs 50 milliseconds after the click. In normal subjects, the response to the second click is less marked than the response to the first click because the normal brain dampens, or “gates,” responses to repeated sensory events. If this didn’t happen, habituation to a stimulus would never occur. Many patients with schizophrenia, in contrast, respond almost as strongly to the second click as to the first. This is referred to as “poor P50 suppression.” First-degree family members of patients with schizophrenia are also more likely than controls to have problems with P50 suppression (Clementz et al., 1998). It has been suggested that poor P50 suppression is the result of problems with specific receptors in the hippocampus of the medial temporal lobe (Adler et al., 1998). As you will soon learn, the hippocampus is one brain region that appears to be compromised in schizophrenia. Cells in the hippocampus are also especially susceptible to damage from hypoxia during brain development.

Taken together, the weight of the evidence suggests that patients with schizophrenia have problems with the active,

**FIGURE 13.5**

**Normal and Abnormal Eye Tracking of a Sinusoidal Wave.** The top pattern is the target, the middle pattern is a record of normal tracking, and the lowest pattern is the kind of abnormal record produced by some patients with schizophrenia.

Source: Figure from Levy et al. (1993). Eye tracking dysfunction and schizophrenia: A critical perspective. *Schizophrenia Bulletin*, 19(3), 461–536. Used with permission of Oxford University Press.

functional allocation of attentional resources. What this means is that they are unable to attend well on demand. Although many of the findings may not be highly specific to schizophrenia (some of the neurocognitive deficits can be found in patients with mood disorders, for example), it has long been suspected that attentional dysfunctions could be indicators of a biological susceptibility to at least some forms of schizophrenia (Cornblatt et al., 1992). In the following sections, we consider some of the reasons that this might be the case.

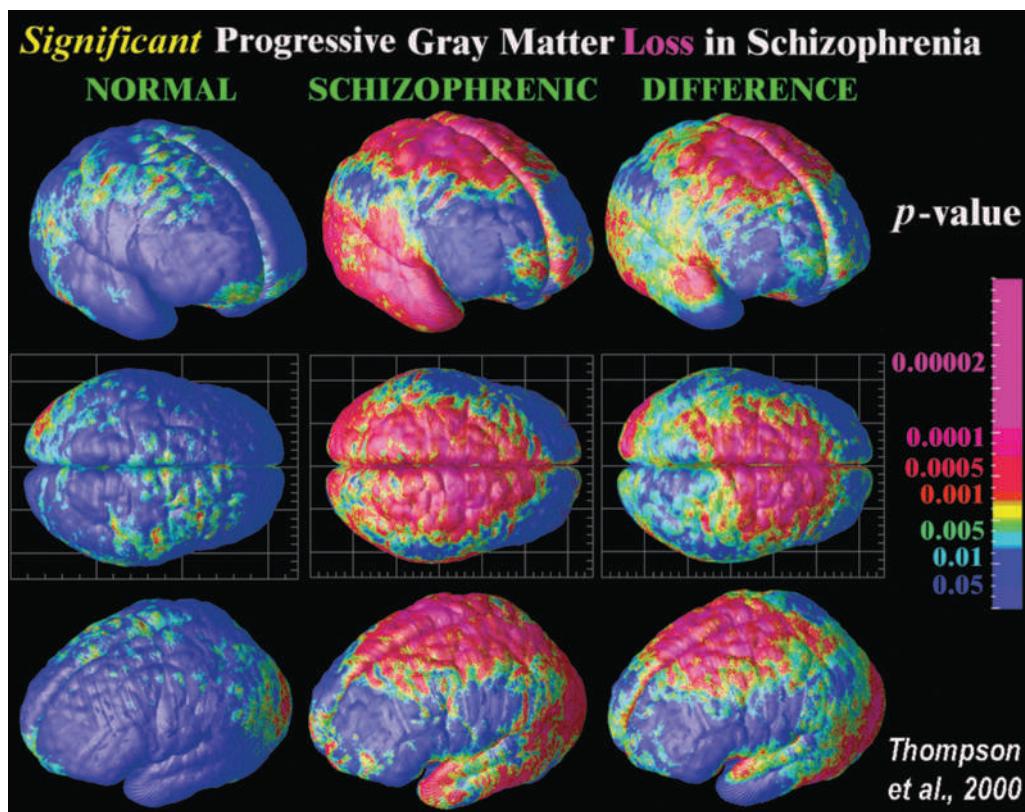

**LOSS OF BRAIN VOLUME** One of the most well-replicated findings concerns the brain ventricles. These are fluid-filled spaces that lie deep within the brain. Compared with controls, patients with schizophrenia have enlarged brain ventricles, with males possibly being more affected than females (Lawrie & Abukmeil, 1998; Shenton et al., 2001). However, we must also point out that enlarged brain ventricles are apparent only in a significant minority of patients. Enlarged brain ventricles also are not specific to schizophrenia and can be seen in patients with Alzheimer’s disease, Huntington’s disease, and chronic alcohol problems.

Enlarged brain ventricles are important because they are an indicator of a reduction in the amount of brain tissue. The brain normally occupies fully the rigid enclosure of the skull. Enlarged ventricles therefore imply that the brain areas that border the ventricles have somehow shrunk or decreased in volume, the ventricular space becoming larger as a result. In fact, MRI studies of patients with schizophrenia show about a 3 percent reduction in whole brain volume relative to that in controls (Hulshoff Pol & Kahn, 2008). This decrease in brain volume is present very early in the illness. Even patients with a recent onset of schizophrenia have lower overall brain volumes than controls (Steen et al., 2006; Vita et al., 2006) or else show evidence of enlarged ventricles (Cahn et al., 2002). These findings suggest that some brain abnormalities likely predate the illness rather than develop as a result of untreated psychosis or as a consequence of taking neuroleptic medications. Consistent with this, important new research shows that brain volume changes can be seen in genetically high-risk individuals as the illness is starting to develop. Indeed, it has been suggested that these changes may play a causal role in the onset of symptoms (Karlsgodt et al., 2010; Sun et al., 2009b).

We also know that the brain changes that characterize people in the early stages of the illness progressively get worse with time.

Cahn and colleagues (2002) measured changes in the overall volume of gray matter (which is made up of nerve cells) in patients who were experiencing their first episode of schizophrenia. Thirty-four patients and thirty six matched, healthy comparison subjects received MRI brain scans at the start of the study and then again 1 year later. The results showed that the volume of gray matter declined significantly over time in the patients but not in the controls. More specifically, there was almost a 3 percent decrease in the volume of gray matter in the patients in the 1-year period between the first and the second scans. Figure 13.6 illustrates the progressive loss of gray matter over a 5-year period in another sample of adolescents with schizophrenia compared to healthy controls.

Studies of more chronically ill patients suggest that decreases in brain tissue and increases in the size of the brain ventricles are not limited to the early phases of this illness. Instead, progressive brain deterioration continues for many years. Moreover, these brain changes can also be found in MZ twins where one has schizophrenia and the other does not. The fact that brain changes are present in the discordant twin (the one without schizophrenia) suggests that they cannot be explained by the influence of antipsychotic medications and may instead be under genetic control (Brans et al., 2008; Hulshoff Pol & Kahn, 2008). Overall, the research findings

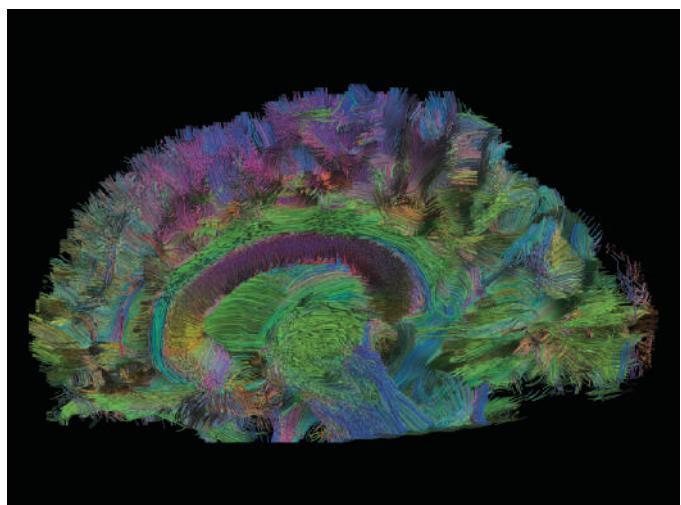

**FIGURE 13.6**

**Progressive Gray Matter Loss in Schizophrenia.** Compared with normal adolescents, young people with early-onset schizophrenia show a progressive loss of gray matter in their brains over time. MRI scans repeated over a 5-year period show a much greater loss of brain tissue in patients with schizophrenia than in healthy controls. Gray matter loss occurs in many brain areas, beginning in the parietal cortex and spreading to the temporal cortex and the frontal cortex.

suggest that in addition to being a neurodevelopmental disorder, schizophrenia is also a neuroprogressive disorder characterized by a loss of brain tissue over time. Kraepelin's use of the term *dementia praecox* may have been highly appropriate after all.

**AFFECTED BRAIN AREAS** Are there regions of the brain that are especially implicated in schizophrenia? Although much remains to be learned, there is evidence of reductions in the volume of regions in the frontal and temporal lobes. These brain areas play critical roles in memory, decision making, and in the processing of auditory information. More specifically, there is a reduction in the volume of such medial temporal areas as the amygdala—which is involved in emotion, the hippocampus—which plays a key role in memory, and the thalamus—a relay center that receives almost all sensory input (Ettinger et al., 2001; Keshavan et al., 2008; Shenton et al., 2001; Tamminga et al., 2002; Weinberger, 1997). Again, however, remember that the alterations in brain structure that are found in schizophrenia are not specific only to this diagnosis. As you know from other chapters in this book, problems in some of these brain areas are implicated in other conditions (e.g., severe mood disorders) as well.

**WHITE MATTER PROBLEMS** When we talk about volume loss in the brains of people with schizophrenia we are referring to the loss of brain cells or gray matter. However, evidence is growing that schizophrenia also involves problems with white matter. Nerve fibers are covered in a myelin sheath (which looks white in color in a chemically preserved brain). Myelin acts as an insulator and increases the speed and efficiency of conduction between nerve cells. White matter is therefore crucially important for the connectivity of the brain. If there are disruptions in the integrity of white matter, there will be problems in how well the cells of

Nerve fibers are covered in by a fatty myelin sheath, which looks white in a preserved brain (hence the term white matter). Myelin improves the electrical conductivity of nerve cells. This image illustrates white matter tracts (shown here in color for better clarity) and shows how interconnected the brain is.

the nervous system can function. For example, imagine the problems you would have in a group of networked computers if the connections that linked them were damaged in some way.

Studies of patients with schizophrenia show that they have reductions in white matter volume as well as structural abnormalities in the white matter itself. Interestingly, these abnormalities can be found in first-episode patients and also in people at genetic high risk for the disorder. This suggests that they are not a result of the disease itself or the effects of treatment.

At the clinical level, white matter abnormalities have been shown to be correlated with cognitive impairments (Kubicki et al., 2007). In people at high risk of developing schizophrenia, white matter changes in the temporal areas of the brain also predict later social functioning (Karlgodt et al., 2009). Another interesting recent finding is that children of people with schizophrenia, even though they are not psychotic themselves, have a reduction in the volume of the corpus callosum—a massive tract of white matter fibers that connects the two hemispheres of the brain (Francis et al., 2011). Although much remains to be learned, it is becoming increasingly clear that abnormalities in white matter, and in white matter development, may provide us with important additional insights into what goes wrong with the brain in schizophrenia.

**BRAIN FUNCTIONING** Studies of brain functioning tell us what is going on in the working brain, either when it is engaged in a task or at rest. You have already learned about the structural brain abnormalities associated with schizophrenia and the problems that patients with schizophrenia have on various neurocognitive tests. Given this, you will hardly be surprised to learn that neuroimaging research is showing us just how disrupted brain functioning is in patients with this disorder.

For example, some patients show abnormally low frontal lobe activation (known as “hypofrontality”) when they are involved in mentally challenging tasks such as the Wisconsin Card Sorting Test (WCST) or in other tests generally thought to require substantial frontal lobe involvement. Essentially, this brain area does not seem to be able to kick into action when patients perform complex tasks (see Figure 13.7). In other patients, hyperactivation in frontal brain areas is found, suggesting that they are having to work harder to be successful on the task. In both sets of circumstances, however, the brain is not functioning in an optimal and efficient way.

Impaired functioning of the frontal lobes during cognitive tasks is also found in patients in the early stages of schizophrenia as well as in people at high risk for developing the disorder (Fusar-Poli et al., 2007). Again, however, it is important to remember that such alterations in functioning are not characteristic of all patients (e.g., Buchsbaum et al., 1992; Heinrichs, 2001). Nonetheless, frontal lobe dysfunction is believed to account for some of the negative symptoms of schizophrenia and perhaps to be involved in some attentional-cognitive deficits (Cannon et al., 1998; Goldman-Rakic & Selemon, 1997).

## THE BRAIN IN SCHIZOPHRENIA

### BASAL GANGLIA

Involved in movement and emotions and in integrating sensory information. Abnormal functioning in schizophrenia is thought to contribute to paranoia and hallucinations. (Excessive blockade of dopamine receptors in the basal ganglia by traditional antipsychotic medicines leads to motor side effects.)

### FRONTAL LOBE

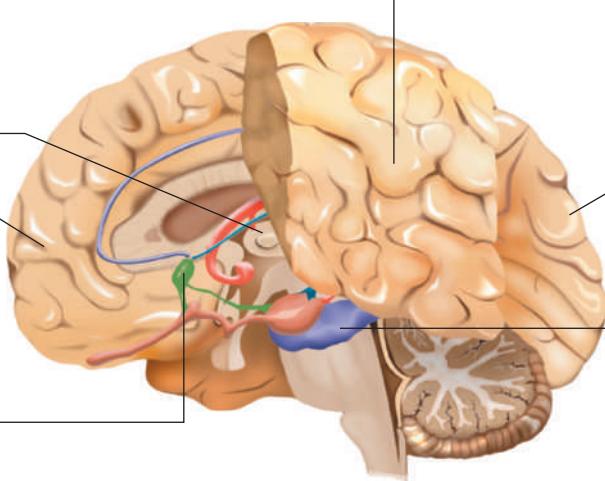

Critical to problem solving, insight, and other high-level reasoning. Perturbations in schizophrenia lead to difficulty in planning actions and organizing thoughts.

### LIMBIC SYSTEM

Involved in emotion. Disturbances are thought to contribute to the agitation frequently seen in schizophrenia.

### AUDITORY SYSTEM

Enables humans to hear and understand speech. In schizophrenia, overactivity of the speech area (called Wernicke's area) can create auditory hallucinations—the misperception that internally generated thoughts are real voices coming from the outside.

### OCCIPITAL LOBE

Processes information about the visual world. People with schizophrenia rarely have full-blown visual hallucinations, but disturbances in this area contribute to such difficulties as interpreting complex images, recognizing motion, and reading emotions on others' faces.

### HIPPOCAMPUS

Meditates learning and memory formation, intertwined functions that are impaired in schizophrenia.

**FIGURE 13.7**

**The Brain in Schizophrenia.** Many brain regions and systems operate abnormally in schizophrenia, including those highlighted here.

Dysfunction of the temporal lobe is also found, although here the findings are often not very consistent (Keshavan et al., 2008). However, what may be most important is that there may be a problem with the way activity in different brain regions gets *coordinated*. When we are at rest or relaxing there is activation in a network of brain regions that comprise the “default mode network.” You can think of this as the brain on standby. Then, when we are actively engaged in a task, activity in this network of brain areas has to be suppressed in favor of activity in brain areas that are relevant to the task at hand. But imagine what might happen if it was difficult to disengage from the default mode. Performance on the task would suffer. This is what researchers now think may be happening in people with schizophrenia. Whereas healthy people find it easy to suppress activity in the default mode network (tuning their brains into the “correct station” so to speak), people with schizophrenia may not be able to do this as efficiently (Guerrero-Pedrazza et al., 2011; Whitfield-Gabrieli et al., 2009). This lack of ability to disengage the default mode network may help us understand why people with schizophrenia have so many difficulties with a wide range of tasks across a broad array of areas (Karlgodt et al., 2010).

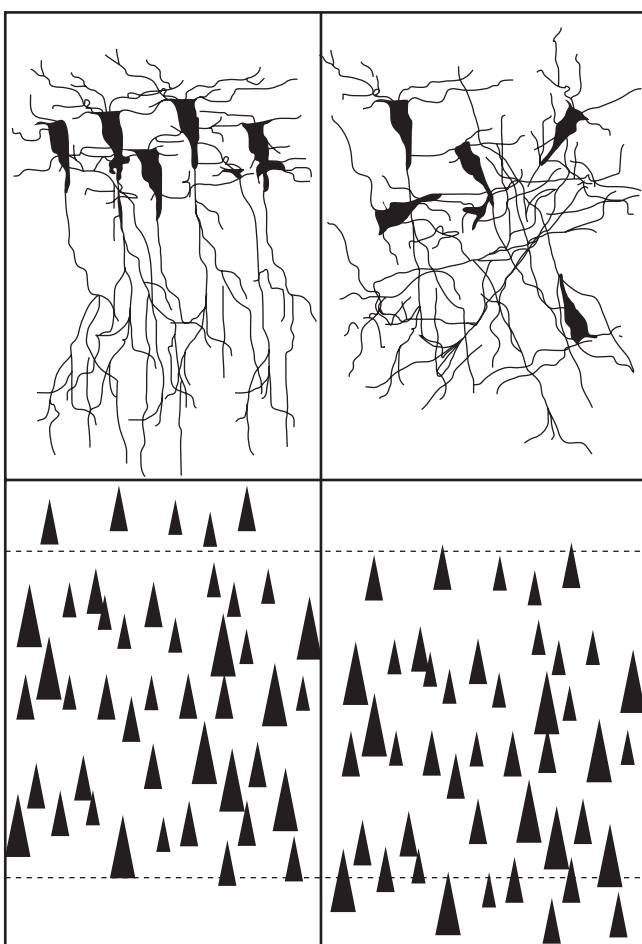

**CYTOARCHITECTURE** As we have seen, one hypothesis about schizophrenia is that genetic vulnerabilities, perhaps combined with prenatal insults, can lead to disruption of the migration of neurons in the brain. If this is true, some cells will fail to arrive

at their final destinations, and the overall organization of cells in the brain (the brain’s *cytoarchitecture*) will be compromised. This is illustrated in Figure 13.8.

There are also other ways in which the organization of cells in the brain appears to be disrupted. Some researchers, using complex, three-dimensional counting techniques, have reported an increase in neuronal density in some areas of the brains of patients with schizophrenia (see Selemon, 2004). There are also abnormalities in the distribution of cells in different layers of the cortex and hippocampus (Arnold, 2000; Kalus et al., 1997; Selemon et al., 1995), as well as evidence that patients with schizophrenia are missing particular types of neurons known as “inhibitory interneurons” (Benes & Beretta, 2001). These neurons are responsible for regulating the excitability of other neurons. Their absence may mean that bursts of activity by excitatory neurons in the brain go unchecked. Again, research suggests that the brains of patients with schizophrenia may be less able to regulate or dampen down overactivity in certain key neural circuits (see Daskalakis et al., 2002). As we will see shortly, patients with schizophrenia have difficulty handling even normal levels of stress. Given what we have just learned, this makes a great deal of sense.

**BRAIN DEVELOPMENT IN ADOLESCENCE** Although we have every reason to believe that risk genes and early prenatal experiences compromise brain development in the fetus, the story may not end so early. The brain continues to develop and

**NORMAL CYTOARCHITECTURE      ABNORMAL CYTOARCHITECTURE**

**FIGURE 13.8**

**Cytoarchitecture and Neural Development.** The upper diagram shows examples of normal and abnormal pyramidal cell orientation in the hippocampus. The lower diagram is a schematic representation of stained neurons and the “downward-shift” phenomenon. Premature arrest of cell migration during development may underlie the high frequency of cells in lower regions close to white matter and their relative paucity near the cortical surface.

Recent advances in defining the neuropathology of schizophrenia. *Acta Neuropathologica*, 92, 217–31 and Kolb, B., & Wishaw, I. Q. (1996). *Fundamentals of human neuropsychology* (4th ed.). New York: Freeman.

mature through adolescence and into young adulthood. For example, we all have an excess of synapses well into our late teens. However, normal processes that occur during adolescence prune (or reduce) these synapses, so decreasing “neuronal redundancy.” There is also a normal reduction in gray matter volume that occurs in adolescence, as well an increase both in white matter and in the volume of the hippocampus and the amygdala. In addition, the number of excitatory synapses decreases and the number of inhibitory synapses increases. All of these processes are thought to occur to enhance brain function overall and to make the brain more “adult” (Insel, 2010; Walker et al., 2010).

Major brain changes take place during adolescence as the brain matures. If problems occur during this critical phase of development schizophrenia may be the result.

But what if these processes fail to occur in a normal way? We might expect to see many of the differences (reduced gray matter volume, less white matter, reduced volume of the hippocampus) that we do actually see in schizophrenia. Of course, we still have much to learn. The etiology of schizophrenia is very complicated. But many of the answers lie in what goes wrong in the brain at critical periods of development.

**SYNTHESIS** The brain is compromised in schizophrenia, although the compromise is often very subtle. Some of the brain abnormalities that are found are likely to be genetic in origin. Others may reflect environmental insults. For example, Baaré and colleagues (2001) used MRI to study the brains of MZ and DZ twins who were discordant for schizophrenia and then compared the results for these groups to results from a group of healthy twins. What these researchers found was that the patients with schizophrenia had smaller brain volumes than their well co-twins. What was interesting, however, was that these well co-twins also had smaller brains than the healthy control twins. Baaré and colleagues (2001) propose that genetic risk for schizophrenia may be associated with reduced brain development early in life. This is why the healthy twins who had a co-twin with schizophrenia had smaller brain volumes than the healthy controls. Baaré and colleagues also hypothesize that patients who develop schizophrenia suffer additional brain abnormalities that are not genetic in origin. This explains why the twins with schizophrenia had smaller brain volumes than their discordant co-twins. In people at genetic risk for schizophrenia (but not in those without genetic risk), a history of fetal oxygen deprivation has been shown to be associated with brain abnormalities in later life (Cannon et al., 2002). In other words, what we may have here is an excellent example of how genes can create an enhanced

susceptibility to potentially aversive environmental events. Moreover, even when both members of a twin pair have identical genes (as is the case for MZ twins), if only one of them experiences the environmental insult (i.e., a birth cord around the neck, creating hypoxia), only one twin might be pushed across the threshold into illness while the co-twin remains healthy.

Finally, we emphasize that it is unlikely that schizophrenia is the result of any one problem in any one specific region of the brain. The brain is comprised of *functional circuits*—regions that are linked to other regions by a network of interconnections. If there is a problem at any point in the circuit, the circuit will not function properly. The focus now is on learning how the brain is wired and what regions are functionally linked. Research on the default mode network is an example of this. Subtle brain abnormalities in some key functional circuits (or deficiencies in the ability to switch from one functional circuit to another) may wreak havoc with normal functioning. As we gain more knowledge about how the brain does its job, we will understand more about how exactly the brain is compromised in schizophrenia.

**NEUROCHEMISTRY** After researchers discovered in 1943 that LSD could cause profound mental changes, those interested in schizophrenia began to consider the possible biochemical basis of the disorder. Now the idea that serious mental disorders are due to “chemical imbalances” in the brain is commonplace. This phrase is often used to provide a general explanation of why someone has a disorder like schizophrenia. But the notion of “chemical imbalance” is vague and imprecise. All it really conveys is the widely accepted notion that alterations in brain chemistry may be associated with abnormal mental states.

The most well-studied neurotransmitter implicated in schizophrenia is **dopamine**. The *dopamine hypothesis* dates back to the 1960s and was derived from three important observations. The first was the pharmacological action of the drug chlorpromazine (Thorazine). Chlorpromazine was first used in the treatment of schizophrenia in 1952. It rapidly became clear that this drug was helpful to patients. Eventually, it was learned that the therapeutic benefits of chlorpromazine were linked to its ability to block dopamine receptors.

The second piece of evidence implicating dopamine in schizophrenia came from an entirely different direction. Amphetamines are drugs that produce a functional excess of dopamine (i.e., the brain acts as if there is too much dopamine in the system). In the late 1950s and early 1960s, researchers began to see that abuse of amphetamines led, in some cases, to a form of psychosis that involved paranoia and auditory hallucinations (Connell, 1958; Kalant, 1966; Tatetsu, 1964). There was thus clinical evidence that a drug that gave rise to a functional excess of dopamine also gave rise to a psychotic state that looked a lot like schizophrenia.

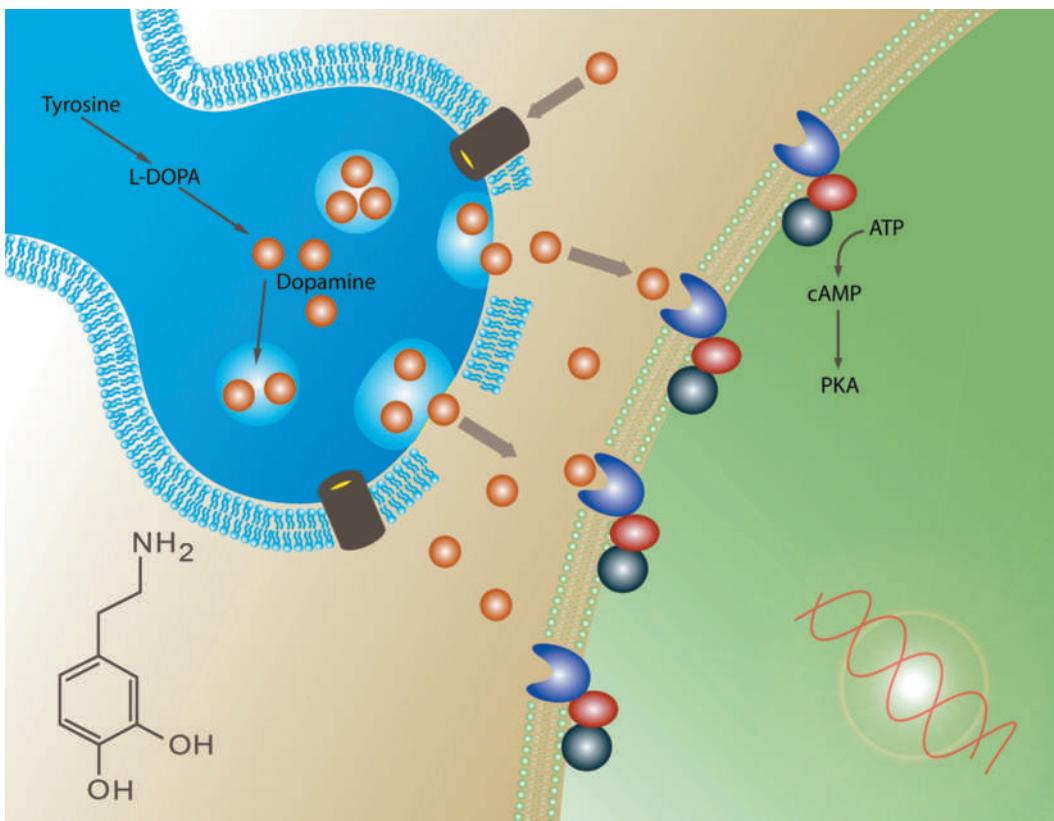

The third piece of indirect evidence linking dopamine to schizophrenia came from clinical studies that actually treated patients by giving them drugs that increase the availability of

dopamine in the brain. An example here is Parkinson’s disease, which is caused by low levels of dopamine in a specific brain area (the basal ganglia; see Figure 13.7 on p. 466) and is treated with a drug called L-DOPA. Psychotic symptoms are a significant complication of treatment with L-DOPA. Again, then, the circumstantial evidence pointed to the role of dopamine in inducing psychosis.

How could dopamine induce psychosis? Activity in the dopamine system may play a role in determining how much salience we give to internal and external stimuli. Dysregulated dopamine transmission may actually make us pay more attention to and give more significance to stimuli that are not especially relevant or important. This is called “aberrant salience” (see Kapur, 2003). If this is the case, it is quite easy to see why patients might develop delusions or experience hallucinations and why psychotic experiences might be so shaped by the patient’s culture and history. In the early stages of their illnesses, patients often report heightened sensory awareness (“My senses were sharpened. I became fascinated by the little insignificant things around me”) or increased meaning in events (“I felt that there was some overwhelming significance in this”). If dopamine creates aberrant salience, the person will struggle to make sense of everyday experiences that were previously in the background but that now have become inappropriately important and worthy of attention. In this way, the hum of a refrigerator could become a voice talking; or the arrival of a package could signal a threat, which then prompts the patient to look carefully at the subtle behaviors of others to see who could be a source of harm and persecution.

But how might a functional excess of dopamine in the system come about? One way is through too much dopamine available in the synapse (the gap between nerve cells that has to be “bridged” by a neurotransmitter for a nerve impulse to be carried from one neuron to another). This could come about by increasing the synthesis or production of dopamine, by releasing more of it into the synapse, by slowing down the rate at which dopamine is metabolized or broken down once it is in the synapse, or by blocking neuronal reuptake (the “recycling” of dopamine back into the neuron). Any or all of these could increase the overall availability of dopamine. There are also ways in which a functional excess of dopamine could be produced or, more accurately, mimicked. If the receptors that dopamine acts on (i.e., those on the postsynaptic membrane) are especially dense and prolific or if they are especially sensitive (or both), the effects of a normal amount of dopamine being released into the synapse would be multiplied. In other words, the system acts as though there were more dopamine available even though there really isn’t.

Before the development of highly sophisticated imaging techniques, researchers interested in learning about dopamine in the brains of people with schizophrenia could use one of two approaches. They could measure dopamine in the (postmortem) brains of deceased patients, or they could study dopamine indirectly by measuring its major metabolite (what most

After being synthesized, dopamine is stored until it is released into the synapse. Dopamine binds to receptors on the post-synaptic neuron (shown in blue) triggering other reactions. It is then recycled back into the neuron to be used again. Watch the [Video In the Real World: Neurotransmitters](#) on [MyPsychLab](#).

of it is converted into). The major metabolite of dopamine is homovanillic acid, or HVA. However, HVA is best collected in cerebrospinal fluid (CSF). This requires that the patient agree to a lumbar puncture, which involves a large needle being inserted into the spine to draw off fluid. Not only is this potentially dangerous, it also leaves the patient with a violent headache.

The early studies that examined concentrations of HVA in the CSF of patients with schizophrenia and in controls yielded generally negative results (see Heinrichs, 2001; Owen & Simpson, 1995). The same was true of postmortem studies. Researchers were forced to conclude that there was no strong evidence to support the idea that patients with schizophrenia were producing more dopamine than controls were. Research efforts therefore moved toward exploring the idea that the problem lay not in overall dopamine levels (dopamine turnover) but in receptor density and receptor sensitivity. These studies were facilitated by technological developments, such as PET scans, which allow us to study the working brain and to look at the density of dopamine receptors in living patients.

There are five subtypes of dopamine receptors (D1–D5). Of these, the D2 receptor is the most relevant clinically, and most of the research has focused on this. In general, postmortem studies show that there are about 1.4 times more D2 receptors in the brains of deceased patients with schizophrenia than there are in controls (Seeman, 2011). Early PET studies also found evidence for a more-than-twofold increase in D2 receptors in living patients with schizophrenia compared with controls (Wong

et al., 1986; Gjedde & Wong, 1987), although some nonsignificant findings (Farde et al., 1987, 1990) led to a great deal of debate and controversy.

Subsequent research, however, has now established that the density of D2 receptors is indeed increased in patients with schizophrenia (Kestler et al., 2001; Seeman, 2011). Although some of this increase is no doubt related to medication effects (older patients, who have taken more medications over their lives, have the highest densities of D2 receptors), medication effects do not explain all the findings. Importantly, we now have evidence that D2 receptors are also elevated in the healthy co-twins of patients with schizophrenia (Hirvonen et al., 2005). Not only does this tell us that the elevation in D2 receptors is not simply attributable to taking medications, but it also tells us that having more D2 receptors doesn't necessarily mean that someone will develop psychosis.

So what else is going on? Current thinking is that people with schizophrenia are supersensitive to dopamine (Seeman, 2011). This arises because they have greater numbers of a form of D2 receptor (called a D2<sub>high</sub> receptor) that has a very high affinity for dopamine. What is also exciting is that animal studies suggest that anoxia (oxygen deprivation) at the time of birth can lead to dopamine supersensitivity. What this means is that we now have a bridge between problems with dopamine system and some of the prenatal problems (e.g., birth complications) that we discussed earlier.

But dopamine is not the only neurotransmitter implicated in schizophrenia. Before leaving our discussion of

neurochemistry, we take a quick look at another key neurotransmitter that is attracting a lot of attention.

**Glutamate** is an excitatory neurotransmitter that is widespread in the brain. As was the case for dopamine, there are a number of reasons why researchers suspect that a dysfunction in glutamate transmission might be involved in schizophrenia. First, PCP, or angel dust, is known to block glutamate receptors. PCP also induces symptoms (both positive and negative) that are very similar to those of schizophrenia. Moreover, when people with schizophrenia take PCP, it exacerbates their symptoms.

Second, physicians had to stop using ketamine, which is an anesthetic, because when it is given intravenously to healthy volunteers, it produces schizophrenia-like positive and negative symptoms (see Krystal et al., 2005). When given to patients whose schizophrenia is stable and well controlled, ketamine exacerbates hallucinations, delusions, and thought disorder. But what is all the more remarkable about ketamine is that it does not cause any of these problems when it is administered to children, for whom it continues to be used as an anesthetic. This suggests that age (and brain maturity) determines whether ketamine causes psychosis.

Like PCP, ketamine blocks glutamate receptors. Researchers are now exploring concentrations of glutamate in postmortem brains of patients with schizophrenia and finding lower levels of glutamate in both the prefrontal cortex and the hippocampus compared with the levels in control subjects (Goff & Coyle, 2001). Recent results from a meta-analysis further suggest that glutamate levels are also low in the brains of living patients who have schizophrenia (Marsman et al., 2011). This is exciting because, many years ago, Olney and Farber (1995) proposed that diminished activity at certain types of glutamate receptors (known as “NMDA” receptors) may not only trigger schizophrenia-like symptoms but may also cause the degeneration of neurons in key brain areas. In other words, if the NMDA receptors are not normally active (perhaps because glutamate levels are low), subtle brain damage may result.

For all of these reasons, the *glutamate hypothesis* of schizophrenia is now attracting a lot of research attention. It is also prompting the development of new experimental drugs that might provide additional ways to treat schizophrenia. For example, amino acids such as glycine and D-serine are now being used to enhance neurotransmission at NMDA receptor sites. This research is still in its early stages; nonetheless, the initial findings look very promising (Javitt, 2008; Lane et al., 2008).

Finally, does the importance of glutamate challenge the importance of dopamine in the neurochemistry of schizophrenia? No. One action of dopamine receptors is to inhibit the release of glutamate. Simply stated, an overactive dopaminergic system could result in excessive suppression of glutamate, leading to the underactivity of the NMDA receptors. The dopamine hypothesis of schizophrenia is actually made all the more credible by discoveries about glutamate.

## Psychosocial and Cultural Factors

**DO BAD FAMILIES CAUSE SCHIZOPHRENIA?** Years ago, parents were routinely assumed to have caused their children’s disorders through hostility, deliberate rejection, or gross parental ineptitude. Many professionals blamed parents, and their feedback to them was often angry and insensitive. Mothers were particularly singled out for criticism. The idea of the “schizophrenogenic mother,” whose cold and aloof behavior was the root cause of schizophrenia, was very influential in many clinical circles (Fromm-Reichman, 1948). This was very distressing for families. Not only were they faced with the difficulties of coping with a son or daughter who had a devastating illness, but they suffered all the more because of the blame that was directed toward them by mental health professionals.

Today, things are very different. Theories that were popular many decades ago—for example, the idea that schizophrenia was caused by destructive parental interactions (Lidz et al., 1965)—have foundered for lack of empirical support. Another idea that has not stood the test of time is the *double-bind hypothesis* (Bateson, 1959, 1960). A double bind occurs when the parent presents the child with ideas, feelings, and demands that are mutually incompatible (e.g., a mother may complain about her son’s lack of affection but freeze up or punish him when he approaches her affectionately). According to Bateson’s etiologic hypothesis, such a son is continually placed in situations where he cannot win, and he becomes increasingly anxious. Presumably, over time, such disorganized and contradictory communications in the family come to be reflected in his own thinking. However, no solid support for these ideas has ever been reported.

Instead, we have learned from past research that disturbances and conflict in families that include an individual with schizophrenia may well be caused by having a person with psychosis in the family (e.g., Hirsch & Leff, 1975). In other words, rather than causing the schizophrenia, family communication problems could be the result of trying to communicate with someone who is severely ill and disorganized (Liem, 1974; Mishler & Waxler, 1968). Of course, some families do show unusual communication patterns that we now refer to as “communication deviance” and which we described earlier. These amorphous and fragmented communications may actually reflect genetic susceptibility to schizophrenia on the part of the relative (Hooley & Hiller, 2001; Miklowitz & Stackman, 1992). However, as we know from the Finnish Adoptive Study, adverse family environments and communication deviance probably have little pathological consequence if the child who is exposed has no genetic risk for schizophrenia (Tienari et al., 2004; Wahlberg et al., 1997).

**FAMILIES AND RELAPSE** Although schizophrenia is often a chronic disorder, its symptoms may be especially severe at some times (i.e., when there is a relapse) and less severe at other times (e.g., during a period of remission). Decades ago, George Brown

and his colleagues (1958) observed that the kind of living situation patients with schizophrenia had after they left the hospital predicted how well they would fare clinically. Surprisingly, patients who returned home to live with parents or with a spouse were at higher risk of relapse than patients who left the hospital to live alone or with siblings. Brown reasoned that highly emotional family environments might be stressful to patients. Unlike his counterparts across the Atlantic, he suspected that what might be important was not the presence of markedly disturbed or pathological patient–family relationships (although those certainly existed in some families) but something much more ordinary and commonplace. Brown’s hunch was that researchers should focus on “the range of feelings and emotions to be found in ordinary families” (see Brown, 1985, p. 22). This was an unusual insight at the time. But viewed today in the context of the diathesis-stress model, we see just how prescient Brown was.

In a series of studies, Brown and his colleagues went on to develop and refine the construct of **expressed emotion**, or **EE**. Expressed emotion is a measure of the family environment that is based on how a family member speaks about the patient during a private interview with a researcher (Hooley, 2007). It has three main elements: criticism, hostility, and emotional overinvolvement (EOI). The most important of these is criticism, which reflects dislike or disapproval of the patient. Hostility is a more extreme form of criticism that indicates a dislike or rejection of the patient as a person. Finally, EOI reflects a dramatic or overconcerned attitude on the part of the family member toward the patient’s illness.

Expressed emotion is important because it has been repeatedly shown to predict relapse in patients with schizophrenia. In a meta-analysis of 27 studies, Butzlaff and Hooley (1998) demonstrated that living in a high-EE home environment more than doubled the baseline level of relapse risk for schizophrenia patients in the 9 to 12 months after hospitalization. Moreover, even though EE predicts relapse regardless of whether the patients studied have been ill for a short, medium, or long time, EE seems to be an especially strong predictor of relapse for patients who are chronically ill.

Of course, it could be that families simply tend to be more critical of patients who are more severely ill and that is why EE and relapse are correlated. However, a review of the literature provides no strong support for this assumption (see Hooley et al., 1995). Also, EE predicts relapse even when potentially important patient variables are controlled statistically (Nuechterlein et al., 1992). Finally, research shows that when EE levels in families are lowered (usually by clinical interventions), patients’ relapse rates also decrease (Falloon et al., 1985; Hogarty et al., 1986; Leff et al., 1982; McFarlane et al., 1995). This suggests that EE may play a causal role in the relapse process.

But how might EE trigger relapse? There is a great deal of evidence that patients with schizophrenia are highly sensitive to stress. Consistent with the diathesis-stress model, environmental

stress is thought to interact with preexisting biological vulnerabilities to increase the probability of relapse (Nuechterlein et al., 1992). We know, for example, that independent stressful life events occur more frequently just prior to psychotic relapse than at other times (Ventura et al., 1989, 1992) and may exert their effects over longer periods of time too. Furthermore, one of the primary manifestations of the stress response in humans is the release of cortisol (a glucocorticoid) from the adrenal cortex. Animal and human studies show that cortisol release triggers dopamine activity (McMurray et al., 1991; Rothschild et al., 1985). Glucocorticoid secretion also affects glutamate release (Walker & Diforio, 1997). In other words, two of the major neurotransmitters implicated in schizophrenia (dopamine and glutamate) are affected by cortisol, which is released when we are stressed.

Along these lines, Hooley and Gotlib (2000) have suggested that, to the extent that high-EE behaviors exhibited by family members are perceived as stressful by patients, these behaviors are likely to trigger the release of cortisol. In support of this idea, high-EE relatives have been found to be more behaviorally controlling of patients than low-EE relatives are (Hooley & Campbell, 2002). When they try to help, they seem to do so in rather intrusive ways (e.g., “She wouldn’t go to sleep so I held her head down onto the pillow”). Furthermore, controlling behaviors such as these predict relapse in patients with schizophrenia. Quite possibly, relatives’ well-meaning attempts to get patients to function better simply backfire. If patients are stressed by what their relatives do, this could increase cortisol levels, affect important neurotransmitter systems, and perhaps eventually lead to a return of symptoms.

At the present time, we have no direct evidence that this happens. However, one study is worthy of note. A group of researchers studied the behavior of patients with schizophrenia when they were involved in interactions with high-EE and low-EE relatives (Rosenfarb et al., 1995). The researchers observed that when patients said something strange (e.g., “If that kid bites you, you’ll get rabies”), high-EE relatives tended to respond by being critical of the patient. What was interesting was that when this happened, it tended to be followed by another unusual remark from the patient. In other words, an increase in patients’ unusual thinking occurred immediately after the patient was criticized by a family member. Although other interpretations of the findings are possible, the results of this study are consistent with the idea that negative (stress-inducing) behaviors by relatives can trigger increases in unusual thinking in patients with schizophrenia. Although we have no way of knowing what was happening to the cortisol levels of these patients, it is intriguing to speculate that increased cortisol release might somehow be involved.

Researchers are now using functional neuroimaging techniques (see Chapter 1) to learn more directly how EE affects the brain. Recent findings show that hearing criticism or being exposed to emotionally overinvolved comments leads to different patterns of brain activity in people who are vulnerable to psychopathology compared to healthy controls (Hooley et al., 2009,

Patients with schizophrenia who live in families where there is a high level of emotional tension have more than twice the risk of relapse.

2010). We do not yet know if people who show this pattern of brain activation are at increased risk of relapse, although this might be expected.

**URBAN LIVING** Being raised in an urban environment seems to increase a person's risk of developing schizophrenia. Pederson and Mortensen (2001) studied a sample of 1.9 million people in Denmark, a country in which information about where people live is recorded in a national registry and people have to notify authorities when they change addresses in order to retain eligibility for benefits. The researchers found that children who had spent the first 15 years of their lives living in an urban environment were 2.75 times more likely to develop schizophrenia in adulthood than were children who had spent their childhoods in more rural settings. Other methodologically sound studies also confirm this association (Sundquist et al., 2004). It has been estimated that if this risk factor could be removed (that is, if we all lived in relatively rural settings) the number of cases of schizophrenia could decrease by about 30 percent (see Brown, 2011).

**IMMIGRATION** The findings showing that urban living raises a person's risk for developing schizophrenia suggest that stress or social adversity might be important factors to consider with respect to this disorder. Supporting this idea, research is also showing that recent immigrants have much higher risks of developing schizophrenia than do people who are native to the country of immigration. Looking at the results of 40 different studies involving immigrant groups from many different parts of the world, Cantor-Graae and Selten (2005) found that first-generation immigrants (i.e., those born in another country) had 2.7 times the risk of developing schizophrenia; for second-generation immigrants (i.e., those with one or both parents having been born abroad), the relative risk was even higher at 4.5. In other words, there is something about moving to another country that appears to be a risk factor for developing schizophrenia. The following case study illustrates this.

→ **Schizophrenia in an Immigrant from China** After she lost her job, Lian, young Chinese woman, was sent by her parents to live in Ireland. Upon arrival, Lian lived first in a boarding house. She then moved into a house that she shared with eight other young Chinese. Lian enrolled in a language school and also began to study for a degree in business administration. She made very few friends and spent most of her time on her own reading or playing games. The people who knew her described her as being a very private person who usually preferred to be alone.

Lian's difficulties began after she learned that two young Chinese students in Dublin had died under suspicious circumstances. She became exceedingly alarmed – so much so that she left the language school and moved back into the boarding house to be with her former landlady. She began to believe that her abdomen contained a "presence" that was living there. She also reported hearing multiple voices coming from the "presence". These voices, which spoke both Chinese and English, included the voices of teachers from Lian's language school, her landlady, and her family from China. Lian reported that she had received a banknote from her family and that the picture on the banknote had spoken to her saying, "You are no longer welcome here". Lian also developed a delusion that the family who had raised her were not her real family. She rapidly cut off all contact with them and talked about wanting to find her "real mother". Lian also said that the CIA was searching for her. When questioned about why this should be the case, she was unable to say. (Based on Feeney et al., 2002).

Why should immigration be associated with an elevated risk of developing schizophrenia? One possibility is that immigrants are more likely to receive this diagnosis because of cultural misunderstandings (Sashidharan, 1993). However, there is no convincing evidence that this is the case (Harrison et al., 1999; Takei et al., 1998). Another hypothesis is that people who are genetically predisposed to develop schizophrenia are more likely to move to live in another country. However, some of the impairments associated with the early stages of schizophrenia seem incompatible with this idea because negative symptoms and frontal lobe dysfunctions may make it harder to be organized enough to emigrate (see Cantor-Graae & Selten, 2005).

Perhaps the strongest clue comes from the finding that immigrants with darker skin have a much higher risk of developing schizophrenia than do immigrants with lighter skin (Cantor-Graae & Selten, 2005). This raises the possibility that experiences of being discriminated against could lead some immigrants to develop a paranoid and suspicious outlook on the world, which could set the stage for the development of schizophrenia. In support of this idea, the results of a prospective study show that healthy people who felt discriminated against were more likely to develop psychotic symptoms over time than were healthy people who did not perceive any discrimination (Janssen et al., 2003). Another possibility suggested by animal studies is that the stress that results from social disadvantage and social defeat may have an effect on dopamine release or dopamine activity in key neural

Immigration has been found to be a risk factor for developing schizophrenia. People who leave their native land to live in another country have almost 3 times the risk of developing schizophrenia compared to people who remain living in their home country. What factors may contribute to this increased risk?

circuits (Tidey & Miczek, 1996). Moreover, some of these biological changes could make people more sensitive to the effects of using illicit substances (Miczek et al., 2004). This is especially interesting in light of evidence linking cannabis abuse to the development of schizophrenia.

**CANNABIS ABUSE** People with schizophrenia are twice as likely as people in the general population to smoke cannabis (van Os et al., 2002). This has prompted researchers to ask whether there is a causal link between cannabis abuse and the development of psychosis. A methodologically rigorous study of conscripts to the Swedish army shows that, compared to those who had never used cannabis, young men who were heavy cannabis users by the time they were 18 were more than 6 times more likely to have developed schizophrenia 27 years later (Zammit et al., 2002). This association also remained even after people who had used other kinds of drugs were removed from the statistical analysis.

Other studies have now replicated this link (Arsenault et al., 2002, 2004; Fergusson et al., 2003; van Os et al., 2002) and highlighted early cannabis use as being particularly problematic. For example, Arsenault and colleagues (2002) report that 10.3 percent of those who used cannabis by age 15 were diagnosed with signs of schizophrenia by age 26, compared with only 3 percent of the controls who did not use cannabis. Taken together, the research findings suggest that using cannabis during adolescence more than doubles a person's risk of developing schizophrenia at a later stage of life.

A major methodological concern in studies of this kind is whether people who are in the early stages of developing psychosis are more likely to use cannabis. If this were the case, cannabis use would simply be a correlate of schizophrenia and not a cause. However, even after childhood psychotic symptoms are considered and accounted for statistically, cannabis use has still been found to be a predictor of later schizophrenia (Fergusson et al., 2003). Moreover, a meta-analysis involving 8,167 patients

with psychosis has shown that those who used cannabis (but not those who used alcohol) had an earlier onset of their symptoms compared to nonusers. These findings are consistent with the idea that cannabis use might trigger or bring forward the onset of psychosis (Large et al., 2011).

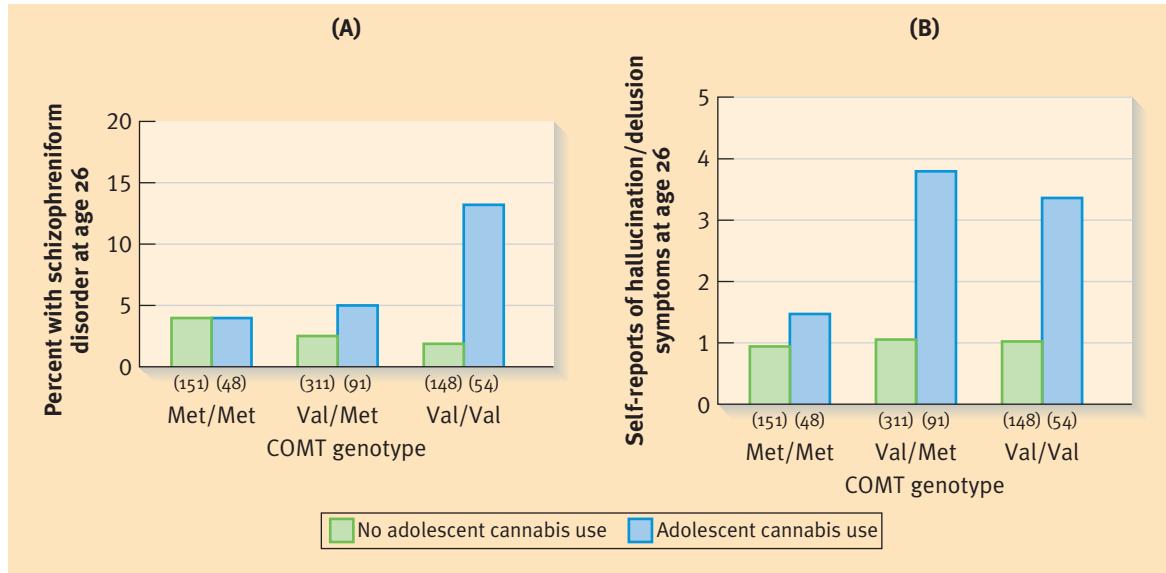

Of course, the vast majority of people who use cannabis do not develop schizophrenia. So can we predict who is at higher risk? Using a large population sample, Caspi and colleagues (2005) have reported that people who carry a particular form of the COMT gene (one or two copies of the valine or val allele) are at increased risk for developing psychotic symptoms (hallucinations or delusions) in adulthood if they used cannabis during adolescence. In contrast, using cannabis has no adverse influence on those who have a different form of the COMT gene (two copies of the methionine or met allele). This is an exciting finding because it illustrates the importance of gene–environment interactions in the development of schizophrenia (see Figure 13.9 on p. 474).

Why should the val allele of the COMT gene be a risk factor? We do not know exactly. However, the finding is provocative because the COMT gene (which you may recall is on chromosome 22) codes for a protein that plays a role in the breakdown of dopamine. One of the active ingredients of cannabis (called THC) is also thought to increase the synthesis of dopamine. We further know that cannabis makes symptoms worse in patients who already have schizophrenia (D'Souza et al., 2005). So again, we have evidence of the importance of dopamine in schizophrenia and of the problems associated with cannabis use, although how everything fits together remains to be discovered.

Finally, we note that new research is showing that cannabis may actually accelerate the progressive brain changes that seem to go along with schizophrenia. Rais and colleagues (2008) collected brain scan data from 51 patients with recent-onset schizophrenia and 31 healthy controls. Nineteen of the patients were using cannabis (but not other illicit drugs) and 32 patients were not. When MRI scans were conducted again 5 years later, the patients who had continued to use cannabis during this time showed more marked decreases in brain volume relative to the patients who did not use cannabis. The changes in gray matter (brain cell) volume in the healthy controls, cannabis-using patients, and patients who did not use cannabis over the 5-year period are shown in Figure 13.10 on page 474. Although both groups of patients lost more brain tissue over time than the healthy controls did, loss of brain tissue was especially pronounced in the patients who used cannabis. The conclusion is obvious. If you have schizophrenia, cannabis is probably very bad for your brain.

## A Diathesis-Stress Model of Schizophrenia

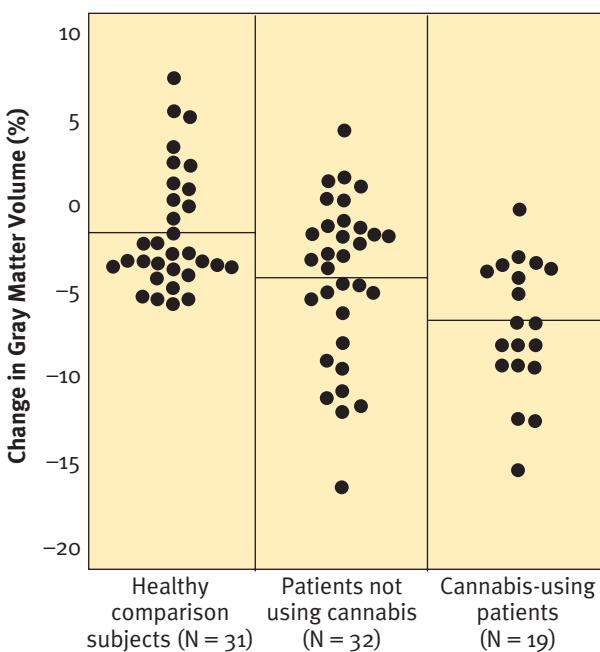

Biological factors undoubtedly play a role in the etiology of schizophrenia. But genetic predispositions can be shaped by environmental factors such as prenatal exposures, infections, and stressors that occur during critical periods of brain development. Favorable environments may also reduce the chance that a genetic predisposition will result in schizophrenia. As we have discussed, children

at genetic risk who are adopted into healthy family environments do very well (Tienari et al., 2004; Wahlberg et al., 1997). What you should take away from this section of the chapter therefore is an understanding that schizophrenia is a genetically influenced, not a genetically determined, disorder (Gottesman, 2001).

The diathesis-stress model, whose origins largely derive from schizophrenia research, predicts exactly these sorts of scenarios (e.g., Walker & Diforio, 1997; Zubin & Spring, 1977).

Figure 13.11 on page 475 provides a general summary of the interplay between genetic factors, prenatal events, brain maturational processes, and stress in the development of schizophrenia.

The bottom line is that there is no simple answer to the question of what causes schizophrenia. The etiology of this disorder (or group of related disorders) is complicated and complex. In the case of a person who develops schizophrenia, predisposing genetic factors must have combined in additive and interactive ways with multiple environmental risk factors, some known and some still unknown, that operate prenatally, perinatally, and also postnatally (see Gottesman, 2001; Walker & Tessner, 2008).

The net result of this is that brain pathways develop abnormally. It is also very likely that these same pathways can be damaged in a host of different ways (in much the same way as a car engine can be damaged by lack of oil, lack of coolant, or from using the wrong kind of fuel). In other words, lots of roads may lead to the same end point, which is schizophrenia or a schizophrenia-like illness. This helps explain why past efforts to find the single cause of schizophrenia were doomed to fail, although no one

**FIGURE 13.11**

**A Diathesis-Stress Model of Schizophrenia.** Genetic factors and acquired constitutional factors (such as prenatal events and birth complications) combine to result in brain vulnerability. Normal maturational processes, combined with stress factors (family stress, cannabis use, urban living, immigration, etc.), may push the vulnerable person across the threshold and into schizophrenia.

could know this at the time. How we are born and how we live makes a major contribution. As one researcher has so aptly stated, “Schizophrenia may be the uniquely human price we pay as a species for the complexity of our brain; in the end, more or less by genetic and environmental chance, some of us get wired for psychosis” (Gilmore, 2010, p. 9).

### in review

- What evidence supports a genetic contribution to schizophrenia?
- What is the dopamine hypothesis? Describe the current status of this explanation for schizophrenia.
- What neuroanatomical abnormalities differentiate people with schizophrenia from people who do not suffer from this disorder?
- What environmental factors are important in the development of schizophrenia?
- Why is avoiding cannabis so important for people with schizophrenia?
- Why do we believe that schizophrenia is both a developmental and a neuroprogressive disorder?
- Why is the diathesis-stress perspective so appropriate for understanding schizophrenia?

## Treatments and Outcomes

Before the 1950s the prognosis for schizophrenia was bleak. Treatment options were very limited. Agitated patients might be put in straitjackets or treated with electroconvulsive “shock” therapy. Most

lived in remote and forbidding institutions that they were expected never to leave (Deutsch, 1948).

Dramatic improvement came in the 1950s when a class of drugs known as antipsychotics were introduced. Pharmacotherapy (treatment by drugs) with these medications rapidly transformed the environment of mental hospitals by calming patients and virtually eliminating their wild, dangerous, and out-of-control behaviors. A new and more hopeful era had arrived.

### Clinical Outcome

Studies of clinical outcome show that 15 to 25 years after developing schizophrenia, around 38 percent of patients have a generally favorable outcome and can be thought of as being recovered (Harrison et al., 2001). This does not mean that patients return to how they were before they became ill, however. Rather, it means that with the help of therapy and medications, patients can function quite well. For a minority of patients (around 12 percent), long-term institutionalization is necessary. And around a third of patients show continued signs of illness, usually with prominent negative symptoms.

When more stringent criteria are used to define recovery (i.e., remission of symptoms and good general social functioning with improvements in at least one of these areas lasting 2 years or more) rates of recovery are even more modest. Recent estimates suggest that they are around 14 percent (Jääskeläinen et al., 2013). What this means is that, despite many advances in treatment over the last 50 to 60 years, a “cure” for schizophrenia has not materialized.

Interestingly, patients who live in less industrialized countries tend to do better overall than patients who live in more industrialized nations (Jablensky et al., 1992). This may be because levels of EE are much lower in countries such as India than in the United States and Europe. For example, in highly industrialized cultures, more than 50 percent of families are high in EE. In contrast, studies with Mexican American and Hindi-speaking Indian samples show that only 24 percent and 41 percent of families, respectively, are high in EE (see Karno et al., 1987; Leff et al., 1987). These differences may help explain why the clinical outcome of patients is different in different parts of the world.

Sometimes, patients who have been very severely impaired by schizophrenia show considerable improvement late in the course of their illness. As illustrated in the case on page 476, these spontaneous improvements can occur even when there is no change in the medications that patients are taking.

**MORTALITY** The health risks of having schizophrenia cannot be understated. This is a disorder that reduces life expectancy. Recent data from the United Kingdom show that men with

schizophrenia die 14.6 years earlier than would be expected based on national norms. For women with schizoaffective disorder the reduction in lifespan is 17.5 years (Chang et al., 2011). Some of the factors implicated in the early deaths of patients with schizophrenia and schizophrenia-related illnesses are long-term use of antipsychotic medications, obesity, smoking, poor diet, use of illicit drugs, and lack of physical activity. The risk of suicide in patients with schizophrenia is also high compared to the general population, with about 12 percent of patients ending their lives in this way (Dutta et al., 2010). In general, overall mortality is lower in patients who are treated with antipsychotic medications compared to untreated patients (Tiihonen et al., 2011). This no doubt reflects the extent to which people who are actively psychotic are a risk to themselves.

**→ From Impairment to Improvement** The patient is a 46-year-old man who first became ill when he was 17 years old. At the time his illness began, he was hearing voices and he had grandiose delusions. He also had delusions of being persecuted.

By the time he was 30, he was living in the hospital. He experienced continuous symptoms including delusions, hallucinations, and incoherent speech. His self-care was also very poor. His symptoms showed only minimal improvement after he was treated with clozapine.

Spontaneous clinical improvement was noted when the patient was in his 40s. He became less isolated and he began to spend more time doing activities. Although he had previously been incoherent when he spoke, he began to speak rationally, although there was still some poverty in the content of his speech. His self-care also improved. However, hospital staff still needed to prompt him to bathe and change his clothes.

## Pharmacological Approaches

Medications are widely used in the treatment of schizophrenia. Over 60 different antipsychotic drugs have been developed. The common property that they all share is their ability to block dopamine D2 receptors in the brain (Seeman, 2011).

**FIRST-GENERATION ANTIPSYCHOTICS** First-generation **antipsychotics** are medications like chlorpromazine (Thorazine) and haloperidol (Haldol), which were among the first to be used to treat psychotic disorders. Sometimes referred to as **neuroleptics** (literally, “seizing the neuron”), these medications revolutionized the treatment of schizophrenia when they were introduced in the 1950s and can be regarded as one of the major medical advances of the twentieth century (Sharif et al., 2007). They are called first-generation antipsychotics (or typical antipsychotics) to distinguish them from a new class of antipsychotics that was developed much more recently. These are referred to as second-generation (or atypical) antipsychotics.

There is overwhelming evidence that antipsychotic medications help patients. Large numbers of clinical trials have demonstrated the efficacy and effectiveness of these drugs (Sharif et al., 2007). Also, the earlier patients receive these medications, the better they tend to do over the longer term (Marshall et al., 2005; Perkins et al., 2004). As we discussed earlier, first-generation antipsychotics are thought to work because they are dopamine antagonists. This means that they block the action of dopamine, primarily by blocking (occupying) the D2 dopamine receptors.

Some clinical change can be seen within the first 24 hours of treatment (Kapur et al., 2005). This supports the idea that these medications work by interfering with dopamine transmission at the D2 receptors because dopamine blockade begins within hours after the patient is given the medication. However, it may take several weeks or even months for maximal clinical benefit to be achieved, although how a patient does on a particular medication in the first 2 to 4 weeks of treatment is a good predictor of how much he or she will benefit overall (Tandon et al., 2010).

First-generation antipsychotics work best for the positive symptoms of schizophrenia. In quieting the voices and diminishing delusional beliefs, these medications provide patients with significant clinical improvement (Tandon et al., 2010). This comes at a cost, however. Common side effects of these medications include drowsiness, dry mouth, and weight gain. Many patients on these antipsychotics also experience what are known as *extrapyramidal side effects* (EPS). These are involuntary movement abnormalities (muscle spasms, rigidity, shaking) that resemble Parkinson’s disease.

African Americans and other ethnic minorities appear to be at increased risk of extrapyramidal side effects (Lawson, 2008). Such side effects are usually controlled by taking other medications. Some patients who have been treated with neuroleptics for long periods of time may also develop *tardive dyskinesia*. This involves marked involuntary movements of the lips and tongue (and sometimes the hands and neck). Rates of tardive dyskinesia are about 56 percent when patients have taken neuroleptics for 10 years or more, with females being especially susceptible (Bezchlibnyk-Butler & Jeffries, 2003). Finally, in very rare cases there is a toxic reaction to the medication that is called *neuroleptic malignant syndrome* (Strawn et al., 2007). This condition is characterized by high fever and extreme muscle rigidity, and if left untreated it can be fatal.

**SECOND-GENERATION ANTIPSYCHOTICS** In the 1980s a new class of antipsychotic medications began to appear. The first of these to be used clinically was clozapine (Clozaril). This drug was introduced in the United States in 1989, although clinicians in Europe had been using it prior to this. Although initially reserved for use with treatment-refractory patients (those who were not helped by other medications), clozapine is now used widely.

Other examples of second-generation antipsychotic medications are risperidone (Risperdal), olanzapine (Zyprexa), quetiapine (Seroquel), and ziprasidone (Geodon). More recent additions include aripiprazole (Abilify) and lurasidone (Latuda). The

reason why these medications are called “second-generation antipsychotics” is that they cause fewer extrapyramidal symptoms than the earlier antipsychotic medications such as Thorazine and Haldol. Although it was initially believed that second-generation antipsychotics were more effective at treating the symptoms of schizophrenia, recent research findings provide no support for this view (Lieberman & Stroup, 2011; Tandon et al., 2010). The exception here concerns clozapine, which does seem to be more valuable than other medications for treatment refractory patients. Nonetheless, most patients are now treated with these newer (and more expensive) medications.

Although they are less likely to cause movement problems, the newer neuroleptic medications are not without other side effects. Drowsiness and considerable weight gain are very common. Diabetes is also a very serious concern (Sernyak et al., 2002). In rare cases, clozapine also causes a life-threatening drop in white blood cells known as agranulocytosis. For this reason, patients taking this medication must have regular blood tests.

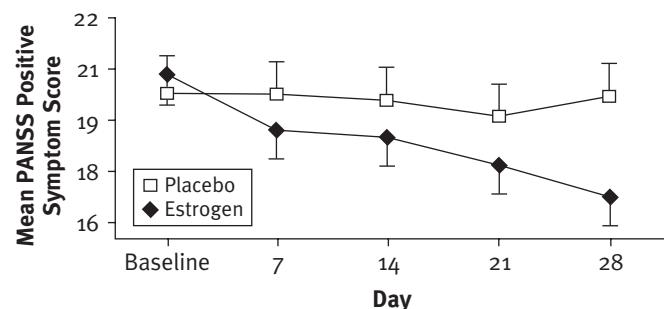

The disappointing findings about the efficacy of second-generation antipsychotic treatments mean that there is an urgent need for innovative approaches and new medications that work better than the ones currently available. This is all the more important in light of new research showing that antipsychotic medications may actually contribute to the progressive brain tissue loss we see in schizophrenia (Ho et al., 2011). In the meantime, researchers continue to seek other ways to help patients.

**OTHER APPROACHES** At the beginning of the chapter, you learned that women with schizophrenia tend to do better than men. They have a later age of onset and, often, seem to have a less severe form of the illness. This has prompted some researchers to explore the potentially beneficial role of estrogen in the treatment of the disorder (Begemann et al., 2012).

In an interesting study, 102 young women with schizophrenia (all of whom were receiving antipsychotic medications) were randomly assigned to one of two conditions (Kulkarni et al., 2008). Some were given a transdermal (skin) patch containing estrogen; the others received a similar (placebo) patch that contained no active ingredient. The women’s symptoms were assessed at baseline. They then wore the patches for a period of 28 days, receiving new patches twice a week. At the end of the study period, symptoms were reassessed.

What were the findings? Remarkably, the women who had worn the genuine (estrogen containing) patches reported significantly fewer overall symptoms at the end of the 1-month study compared to the placebo group, with the difference for positive symptoms (shown in Figure 13.12) being most striking. Overall, the results suggest that estrogen has antipsychotic effects and that providing supplemental estrogen to women with schizophrenia may give them additional clinical benefits.

**THE PATIENT’S PERSPECTIVE** Not all patients benefit from antipsychotic medications, and many who do show clinical

**FIGURE 13.12**

**Estrogen Treatment and Positive Symptoms.** Positive symptoms at baseline (day 0) and on days 7, 14, 21, and 28 for the estrogen and placebo groups.

improvement will still have problems functioning without a great deal of additional help. We must also not lose sight of what it is like for patients with schizophrenia to have to take medications every day, often for years or for a lifetime. Side effects that can sound trivial to someone on the outside can be so bad for patients that they refuse to take their medications, even when those medications give them relief from their hallucinations and delusions.

Research using PET also shows that increased blockade of D2 dopamine receptors is associated with patients reporting more negative subjective experiences such as feeling tired and depressed even when other side effects (such as movement problems) are absent (Mizrahi et al., 2007). This highlights the need for better medications and for using lower dosages wherever this is clinically feasible. We also need to remember that some patients may try to avoid taking medications because, to them, needing to take medications confirms that they are mentally ill. The following comes from the mother of a daughter who suffers from schizophrenia:

As a parent I also know that medication is not perfect and that the side effects can be distressing. When my daughter goes back on her medication, I feel bad seeing her shuffling or experiencing involuntary arm and mouth movements. These symptoms usually subside over time; but she also gains weight, and she hates being heavy. I think she hates taking medication most of all because she is, in a sense, admitting she is mentally ill, something she very much wants to deny. (From Slater, 1986.)

## Psychosocial Approaches

Medications play a central role in the treatment of schizophrenia. But they are not the only treatment approaches that are available. Psychosocial treatments are also of value. Some of these approaches, which are typically used in conjunction with medication, are briefly described below.

**FAMILY THERAPY** The literature that links relapse in patients with schizophrenia to high family levels of EE inspired several investigators to develop family intervention programs. The idea

Patients with schizophrenia benefit from psychosocial treatments. These include individual therapy, case management, cognitive remediation, and family therapy.

was to reduce relapse in schizophrenia by changing those aspects of the patient–relative relationship that were regarded as central to the EE construct. At a practical level, this generally involves working with patients and their families to educate them about schizophrenia, to help them improve their coping and problem-solving skills, and to enhance communication skills, especially the clarity of family communication.

In general, the results of research studies in this area have shown that patients do better clinically and relapse rates are lower when families receive family treatment (see Pfammatter et al., 2006). Studies done in China indicate that these treatment approaches can also be used in other cultures (Xiong et al., 1994). Despite this, family treatment is still not a routine element in the accepted standard of care for patients with schizophrenia (Lehman et al., 1998). Given its clear benefits to patients and its considerable cost-effectiveness (Tarrier et al. 1991 calculated that family treatment results in an average cost savings of 27 percent per patient), this seems very unfortunate.

**CASE MANAGEMENT** Case managers are people who help patients find the services they need in order to function in the community. Essentially, the case manager acts as a broker, referring the patient to the people who will provide the needed service (e.g., help with housing, treatment, employment, and the like). Assertive community treatment programs are a specialized and more intensive form of case management. Typically, they involve multidisciplinary teams with limited caseloads to ensure that discharged patients don't get overlooked and “lost in the system.” The multidisciplinary team delivers all the services the patient needs (see DeLuca et al., 2008; Mueser et al., 2013).

Assertive community treatment programs are cost-effective because they reduce the time that patients spend in the hospital. They also enhance the stability of patients' housing arrangements.

These approaches seem to be especially beneficial for patients who are already high utilizers of psychiatric and community services (see Bustillo et al., 2001).

**SOCIAL-SKILLS TRAINING** Even when their symptoms are controlled by medications, patients with schizophrenia often have trouble forming friendships, finding and keeping a job, or living independently. How well patients do in their everyday lives is referred to as *functional outcome*. (This is in contrast to *clinical outcome*, which is concerned with symptoms.) Improving the functional outcomes of patients with schizophrenia is now an active area of research.

One way to help improve the functional outcomes of patients with schizophrenia is through social-skills training. Patients with schizophrenia often have very poor interpersonal skills (for a review, see Hooley, 2008). Social-skills training is designed to help patients acquire the skills they need to function better on a day-to-day basis.

These skills include employment skills, relationship skills, self-care skills, and skills in managing medications or symptoms. Social routines are broken down into smaller, more manageable components. For conversational skills, these components might include learning to make eye contact, speaking at a normal and moderate volume, taking one's turn in a conversation, and so on. Patients learn these skills, get corrective feedback, practice their new skills using role-playing, and then use what they have learned in natural settings (Bellack & Mueser, 1993). As Green (2001, p. 139) has noted, engaging in social-skills training is a bit like taking dance lessons. It does not resemble traditional “talk therapy” in any obvious manner.

Although the results of some early studies were mixed, the most recent research findings look more positive. Social-skills training does seem to help patients acquire new skills, be more assertive, and improve their overall levels of social functioning. These improvements also seem to be maintained over time. Importantly, patients who receive social-skills training are less likely to relapse and need hospital treatment (Kurtz & Mueser, 2008; Pfammatter et al., 2006).

**COGNITIVE REMEDIATION** Earlier we described some of the cognitive problems that go along with having schizophrenia. Researchers are now recognizing that these cognitive problems are likely to place limits on how well patients can function in the community. Because of this, the neurocognitive deficits of schizophrenia are becoming targets for treatment in their own right. The search is on to develop new medications that will enhance cognitive functioning in patients (Green, 2007; Nuechterlein et al., 2008).

A major treatment effort is also being devoted to **cognitive remediation** training. Using practice and other compensatory

techniques, researchers are trying to help patients improve some of their neurocognitive deficits (e.g., problems with verbal memory, vigilance, and performance on card-sorting tasks). The hope is that these improvements will translate into better overall functioning (e.g., conversational skills, self-care, job skills, and so on). Overall, the findings give cause for optimism. Cognitive remediation training does seem to help patients improve their attention, memory, and executive functioning skills. Patients who receive cognitive remediation training also show improvements in their social functioning. Especially encouraging is that even when patients have been ill for many years, they still seem to benefit from this treatment approach (Pfammatter et al., 2006; Wykes et al., 2007). Cognitive remediation approaches may work best when they are added to other existing rehabilitation (employment skills) strategies and offered to patients who are already clinically stable (Wykes et al., 2011).

**COGNITIVE-BEHAVIORAL THERAPY** As you have already learned, cognitive-behavioral therapy (CBT) approaches are widely used in the treatment of mood and anxiety disorders as well as many other conditions (Beck, 2005). Until fairly recently, however, researchers did not consider using them for patients with schizophrenia, no doubt because patients with schizophrenia were considered too impaired. Pioneered by researchers and clinicians in the United Kingdom, cognitive-behavioral approaches have gained momentum in the treatment of schizophrenia. The goal of these treatments is to decrease the intensity of positive symptoms, reduce relapse, and decrease social disability. Working together, therapist and patient explore the subjective nature of the patient's delusions and hallucinations, examine evidence for and against their veracity or veridicality, and subject delusional beliefs to reality testing.

Although the results from the early research studies were encouraging, whether CBT is an effective treatment for schizophrenia is now the subject of some debate. Current data suggest that CBT is not very helpful for negative symptoms (Tandon et al., 2010). A recent meta-analysis also suggests that CBT is no better than control interventions (often supportive counselling) in the treatment of schizophrenia (Lynch et al., 2010). Nonetheless, the possibility that CBT works very well for some subgroups of patients is still a very real possibility.

**INDIVIDUAL TREATMENT** Before 1960 the optimal treatment for patients with schizophrenia was psychoanalytically oriented therapy based on a Freudian type of approach. This is what Nobel Prize-winning mathematician John Nash received when he was a patient at McLean Hospital in Massachusetts in 1958 (the movie *A Beautiful Mind* is based on Nash's story). By 1980, however, things had changed. Research began to suggest that in some cases, psychodynamic treatments made patients worse (see Mueser & Berenbaum, 1990). This form of individual treatment thus fell out of favor.

Individual treatment for schizophrenia now takes a different form. Hogarty and colleagues (1997a, 1997b) have reported on a controlled 3-year trial of what they call "personal therapy." Personal therapy is a nonpsychodynamic approach that equips patients with a broad range of coping techniques and skills. The therapy is staged, which means that it comprises different components that are administered at different points in the patient's recovery. For example, in the early stages, patients examine the relationship between their symptoms and their stress levels. They also learn relaxation and some cognitive techniques. Later, the focus is on social and vocational skills. Overall, this treatment appears to be very effective in enhancing the social adjustment and social role performance of discharged patients.

Educating patients about the illness and its treatment (this approach is called psychoeducation) is also helpful (Xia et al., 2011). Patients who receive psychoeducation in addition to standard treatment are less likely to relapse or be readmitted to the hospital compared to patients who receive standard treatment only. These patients also function better overall and are more satisfied with the treatment they receive. All of this highlights the importance of including patients in their own care and increasing their knowledge and understanding about their illness.

In summary, although rigorous psychoanalytic approaches may be too demanding and stressful for patients with schizophrenia, supportive forms of therapy that offer an opportunity to learn skills and yet are low-key and responsive to patients' individual concerns might well be very beneficial. Just as progress in research on schizophrenia requires a partnership between scientists across many areas, progress in the treatment of schizophrenia requires balancing pharmacology with a consideration of the specific needs of the patient. For patients who are at high risk of relapse and who live with their families, family-based interventions will be required. If patients have continuing and disturbing hallucinations and delusions, CBT may be appropriate. When patients are clinically stable, social-skills training and rehabilitation efforts may be helpful. But in all of this, we must not lose sight of the need of patients (and their families) for support, validation, and respectful care. The treatment of patients with schizophrenia is not easy, and there is no "quick fix." Although many treatment advances have occurred, we still need more effective, high quality, and clinically sensitive care.

### in review

- What kinds of clinical outcomes are associated with schizophrenia? Is full recovery possible or typical?
- Why do patients with schizophrenia have increased rates of early mortality?
- In what ways are first- and second-generation (conventional and atypical) neuroleptic medications similar, and in what ways are they different? How effective are these treatments for patients with schizophrenia?
- Describe the major psychosocial approaches used in treating schizophrenia.

## UNRESOLVED issues

### Why are recovery rates in schizophrenia not improving?

After the introduction of the first neuroleptic medication (Thorazine) in 1955, there was great optimism that this, and other new “wonder drugs” would revolutionize the treatment of schizophrenia. Today, many decades later, clinicians have a broad array of first- and second-generation antipsychotic medications at their disposal. But if our treatment options are so much more sophisticated, why are recovery rates in schizophrenia so low?

The standard length of a clinical trial that compares a given drug against a placebo is 6 weeks. Numerous clinical studies have demonstrated that antipsychotic medications are effective for the treatment of acute symptoms. So there is little doubt that antipsychotic medications benefit patients in the short term. But what about the longer term? Does staying on antipsychotic medications provide long-term benefits for patients?

The answer may be no. Concerns are now being raised that long-term exposure to neuroleptics may set into play biological process that increase the likelihood that patients will remain chronically ill (Whitaker, 2010). This is particularly worrisome because patients who take neuroleptic medications tend to stay on them for very long periods of time.

But how could something that is clinically beneficial in the short term be potentially harmful in the longer term? Standard antipsychotic medications block D2 receptors in the brain. This is the basis of their therapeutic action. But one result of dopamine blockade is that the density of receptors on the post-synaptic neuron increases, creating a supersensitivity to dopamine. Put more simply, neuroleptics put a brake on dopamine transmission. To compensate for this, the brain responds by pressing the dopamine accelerator (in the form of extra dopamine receptors). Withdrawal of neuroleptics removes the brake and puts the system out of balance because the system is now in an “accelerator-on” mode. Moreover, any return of symptoms is taken as evidence that the drugs were working and preventing relapse. This

impression gets confirmed when the patient goes back on drugs again and the psychosis abates. As one physician noted, “The use of neuroleptics is a trap. … It is like having a psychosis-inducing agent built into the brain.” (Whitaker, 2010, pp. 107).

As you might expect, the idea that antipsychotic medications may help psychosis in the short term but create it in the longer term is highly controversial. However, it may not be as far fetched as it might seem. Data from a 15-year follow-up study show that over time, patients with schizophrenia who are not taking antipsychotic medications fare far better than those who continue to take medications (Harrow, 2007). However, difference in recovery rates between the medicated and unmedicated groups only really start to be apparent after about 4.5 years. It is also the case that patients who stop taking medications tend not to see their psychiatrists. So clinicians don’t see the people who recover. This may be one reason why psychiatry as a whole has been slow to recognize that non-medicated patients might be doing far better than expected. Also relevant here is the observation that patients in less industrialized countries tend to do better clinically than those in more developed countries. And these are the very patients who are much less likely to be maintained on antipsychotic medications.

Perhaps most provocative are the following statistics about chronic mental illness. In 1955 one in every 617 Americans was hospitalized with schizophrenia in a state or county mental hospital. These were chronic long-term patients. Today, the proportion of people with chronic schizophrenia or some other psychotic disorder is much higher—1 in every 125 people. In his efforts to understand why psychiatric medications have not improved the long-term clinical outcomes for patients with severe mental illness, Whitaker (who is an investigative reporter) has caused a storm of controversy. Nonetheless, his arguments warrant serious consideration by all mental health professionals. If the medications that are so helpful in a crisis make things worse when used long term, we need to radically re-think how we manage the treatment of patients with schizophrenia.

## summary

### 13.1 What are the symptoms of schizophrenia?

- Schizophrenia is the most severe form of mental illness. It is characterized by impairments in many domains. Characteristic symptoms of schizophrenia include hallucinations, delusions,

disorganized speech, disorganized and catatonic behavior, and negative symptoms such as flat affect or social withdrawal.

### 13.2 What is the prevalence of schizophrenia and when does it begin? Who is most affected?

- Schizophrenia affects just under 1 percent of the population. Most cases begin in late adolescence or early adulthood. The disorder begins earlier in men than in women. Overall, the clinical symptoms of schizophrenia tend to be more severe

in men than in women. Women also have a better long-term outcome.

- Even though schizophrenia first shows itself clinically in early adulthood, researchers believe that it is a neurodevelopmental disorder. Problems with brain development are implicated. Some of the genes implicated in schizophrenia play a role in brain development.

### 13.3 What are the risk and causal factors associated with schizophrenia?

- Genetic factors are clearly implicated in schizophrenia. Having a relative with the disorder significantly raises a person's risk of developing schizophrenia.
- Other factors that have been implicated in the development of schizophrenia include prenatal exposure to the influenza virus, early nutritional deficiencies, rhesus incompatibility, maternal stress, and perinatal birth complications.
- Urban living, immigration, and cannabis use during adolescence have also been shown to increase the risk of developing schizophrenia.
- Current thinking about schizophrenia emphasizes the interplay between genetic and environmental factors.

### 13.4 How is the brain affected in schizophrenia?

- Patients with schizophrenia have problems in many aspects of their cognitive functioning. They show a variety of attentional deficits (e.g., poor P50 suppression and deficits on the Continuous Performance Test). They also show eye-tracking dysfunctions.
- Many brain areas are abnormal in schizophrenia, although abnormalities are not found in all patients. The brain abnormalities that have been found include enlarged ventricles (which reflects decreased brain volume), frontal lobe dysfunction, reduced volume of the thalamus, and abnormalities in temporal lobe areas such as the hippocampus and amygdala.
- Major changes in the brain occur during adolescence. These include synaptic pruning, decreases in the number of excitatory neurons, and increases in the number of inhibitory neurons. There is also an increase in white matter which enhances the

connectivity of the brain. Some of these changes may be abnormal in people who will later develop schizophrenia.

- Some of the brain abnormalities that are characteristic of schizophrenia get worse over time. This suggests that, in addition to being a neurodevelopmental disorder, schizophrenia is also a neuropsychiatric disorder.

### 13.5 What neurotransmitters are implicated in schizophrenia?

- The most important neurotransmitters implicated in schizophrenia are dopamine and glutamate. Research shows that the dopamine (D2) receptors of patients with schizophrenia are supersensitive to dopamine.

### 13.6 Why is the family environment important for the well-being of patients with schizophrenia?

- Patients with schizophrenia are more likely to relapse if their relatives are high in expressed emotion (EE). High-EE environments may be stressful to patients and may trigger biological changes that cause dysregulations in the dopamine system. This could lead to a return of symptoms.

### 13.7 What is the clinical outcome of schizophrenia and how is it treated?

- For many patients, schizophrenia is a chronic disorder requiring long-term treatment or institutionalization. However, when treated with therapy and medications, around 38 percent of patients can show a reasonable recovery. Only about 14 percent of patients recover to the extent that they have minimal symptoms and function well socially.
- Patients with schizophrenia are usually treated with first- or second-generation antipsychotic (neuroleptic) medications. Second-generation antipsychotics are about as effective as first-generation antipsychotics but cause fewer extrapyramidal (motor abnormality) side effects. Antipsychotic drugs work by blocking dopamine receptors.
- Psychosocial treatments for patients with schizophrenia include cognitive-behavioral therapy, social-skills training, cognitive remediation training, and other forms of individual treatment, as well as case management. Family therapy provides families with communication skills and other skills that are helpful in managing the illness. Family therapy also reduces high levels of expressed emotion.

## learning objectives

### 14.1

What forms of neurocognitive disorders are recognized in *DSM-5*? What is presumed to be the cause of these disorders?

### 14.2

What are the clinical features of neurocognitive disorders?

### 14.3

What is delirium and how is it treated?

### 14.4

What are the risk factors for Alzheimer's disease? What changes in the brain are found in patients with Alzheimer's disease?

### 14.5

How is Alzheimer's disease treated?

### 14.6

What is an amnestic disorder? What causes amnestic disorders?

### 14.7

What are some of the clinical consequences of head trauma? What factors are related to the degree of impairment that results?

→ **A Simple Case of Mania?** A highly successful businessman, age 45, with no previous history of psychiatric disorder, began to act differently from his usual self. He seemed driven at work. His working hours gradually increased until finally he was sleeping only 2 to 3 hours a night; the rest of the time he worked. He became irritable and began to engage in uncharacteristic sprees of spending beyond his means.

Although he felt extremely productive and claimed he was doing the work of five men, the man's boss felt otherwise. He was worried about the quality of that work, having observed several recent examples of poor business decisions. Finally, when the man complained of headaches, his boss insisted that he seek help.

Source: Adapted from Jamieson & Wells, 1979.

The case you have just read concerns a man who, on first glance, looks as if he might be having an episode of mania. In fact, he is suffering from four tumorous masses in his brain. Clues that this man has a brain disorder rather than a mood disorder include the facts that he is experiencing headaches at the same time as a major change in behavior and that he has no prior history of psychopathology (see Taylor, 2000). Clinicians always need to be alert to the possibility that brain impairment itself may be directly responsible for their patients' symptoms. Failure to do so could result in serious diagnostic errors, as when a clinician

falsely attributes a mood change to psychological causes and fails to consider a neuropsychological origin such as a brain tumor.

The brain is an astonishing organ. Weighing around 3 pounds and having the consistency of firm jelly, it is the most complex structure in the known universe (Thompson, 2000). It is also the only organ capable of studying and reading about itself. It is involved in every aspect of our lives from eating and sleeping to falling in love. The brain makes decisions, and it contains all the memories that make us who we are. Whether we are physically ill or mentally disturbed, the brain is involved.

Because it is so important, the brain is protected in an enclosed space and covered by a thick outer membrane called the dura mater (literally, "hard mother" in Latin). For further protection, the brain is encased by the skull. The skull is so strong that, if it were placed on the ground and weight were applied very slowly, it could support as much as 3 tons (Rolak, 2001, p. 403)! These anatomical facts alone indicate just how precious the brain is.

Even though it is highly protected, the brain is vulnerable to damage from many sources. When the brain is damaged, cognitive changes result, as you saw in the case study above. Although there may be other signs and symptoms (such as mood or personality changes) as well, changes in cognitive functioning are the most obvious signs of a damaged brain.

In this chapter we focus on disorders that arise because of changes in brain structure, function, or chemistry. In some cases, such as with Parkinson's disease or Alzheimer's disease, these are caused by internal changes that lead to destruction of brain tissue. In others, they result from damage caused by external influences such as trauma from accidents or from the repeated blows to the head that can occur in boxing, soccer, or football.

Why are neurocognitive disorders discussed at all in a textbook on abnormal psychology? There are several reasons. First, as their inclusion in the *DSM* indicates, these disorders are regarded as psychopathological conditions. Second, as you just saw in the *case study*, some brain disorders cause symptoms that look remarkably like other abnormal psychology disorders. Third, brain damage can cause changes in behavior, mood, and personality. You will recognize this more clearly later when we describe the case of Phineas Gage (who survived a metal bar being blown through his head). Understanding what brain areas are involved when behavior, mood, and personality change after brain damage may help

## research CLOSE-UP

### Case Study

Case studies are descriptions of one specific case. Case studies can be a useful source of information and can help researchers generate hypotheses. Because of their highly selective nature, however, they cannot be used to draw any scientific conclusions.

researchers better understand the biological underpinnings of many problems in abnormal psychology. Fourth, many people who suffer from brain disorders (e.g., people who are diagnosed as having Alzheimer's disease) react to the news of their diagnosis with depression or anxiety. Prospective studies also suggest that depressive symptoms may herald the onset of disorders such as Alzheimer's disease by several years and that episodes of depression can double the risk for Alzheimer's disease even 20 years later (Speck et al., 1995). Finally, neurocognitive disorders of the type we describe in this chapter take a heavy toll on family members, who, for many patients, must shoulder the burden of care. Again, depression and anxiety in relatives of the patients themselves are not uncommon.

## Brain Impairment in Adults

The causes of neurocognitive disorders are often much more specific than is the case for many of the disorders we have discussed so far in this book. In *DSM-5*, the disorders that used to be known as "Delirium, Dementia, and Amnestic and Other Cognitive Disorders" are now grouped into a new diagnostic category called Neurocognitive Disorders. This term is more straightforward than its predecessor. It is also more conceptually coherent. Disorders in this category are those that involve a loss of cognitive ability that is presumed to be caused by brain damage or disease. Subsections of this diagnostic category include delirium, **major neurocognitive disorder** (formerly dementia), and a new category of **mild neurocognitive disorder**. The distinction between major and mild neurocognitive disorder is based on severity. As the "Thinking

Critically About *DSM-5*" box illustrates, the inclusion of a mild neurocognitive disorder in *DSM-5* raises some important issues.

Within each broad diagnostic category, the specific diagnosis is to be determined by what is thought to be the cause of the problem. For example, the diagnosis of major neurocognitive disorder associated with Alzheimer's disease is used for patients thought to have Alzheimer's. For patients whose brain damage is caused by a traumatic brain injury the diagnosis would be major (or mild) neurocognitive disorder associated with traumatic brain injury. In this way the diagnosis provides information about both the cause of the neurocognitive disorder as well as its degree of severity.

### Clinical Signs of Brain Damage

With a few exceptions, cell bodies and neural pathways in the brain do not appear to have the power of regeneration, which means that their destruction is permanent. When brain injury occurs in an older child or adult, there is a loss in established functioning. Often, the person who has sustained this loss is painfully aware of what he or she is no longer able to do, adding a pronounced psychological burden to the physical burden of having the lesion. In other cases the impairment may extend to the capacity for realistic self-appraisal (a condition called anosognosia), leaving these patients relatively unaware of their losses and hence poorly motivated for rehabilitation.

The degree of mental impairment is usually related to the degree of damage to the brain. However, this is not invariably so. Much depends on the nature and location of the damage as well as the premorbid (predisorder) competence and personality of the individual. In some cases involving relatively severe brain

### THINKING CRITICALLY about *DSM-5*

#### Is the Inclusion of Mild Neurocognitive Disorder a Good Idea?

**DSM-5**

An important addition to *DSM-5* is the new diagnosis of mild neurocognitive impairment. This change reflects an effort to recognize that cognitive problems that do not reach the level of affecting everyday functioning may still warrant clinical attention. But this new diagnostic category is not without controversy.

Some people are concerned that the use of the word "mild" trivializes the cognitive impairments that are being experienced. It may also imply that there is no need for services to be provided. On the other hand, refraining from using a term like **dementia** until the cognitive impairment is more severe may alleviate anxiety and reduce stigma.

But if minor cognitive disorder is considered to be a prodromal stage before the onset of more severe impairment, will receiving the more mild diagnosis still not be a source of anxiety? People experiencing minor cognitive impairment (MCI) are thought to

be at increased risk for the development of Alzheimer's disease. If these people can now be formally diagnosed with a disorder (MCI is not a diagnosis but mild neurocognitive impairment is) will we be scaring large numbers of people needlessly? Many people with MCI do not go on to develop more severe cognitive problems. We also have no way to treat Alzheimer's disease successfully, yet alone prevent it. So, from a practical perspective, how helpful will this new diagnosis be to those who will receive it?

Finally, how do we separate mild neurocognitive disorder from normal aging? This is all the more important because many examples of mild cognitive problems (e.g., finding that thinking is easier when not distracted by phone, TV, or other conversations or needing occasional reminders to keep track of characters in a movie or a novel) are problems that are hardly unusual for older adults. Every time we lose our keys or forget whether or not we have paid a bill should we now be worried that we have mild neurocognitive impairment?

damage, mental change is astonishingly slight. In other cases of seemingly mild and limited damage, there may be quite marked alterations in functioning, as in the following case example.

**→ Hit on the Head With a Rake** A 17-year-old girl was referred by her father for neuropsychiatric evaluation because of the many changes that had been observed in her personality during the past 2 years. She had been an A student and had been involved in many extracurricular activities during her sophomore year in high school. But now, as a senior, she was barely able to maintain a C average, was “hanging around with the bad kids,” and was frequently using marijuana and alcohol. A careful history revealed that 2 years before, her older brother had hit her in the forehead with a rake, which stunned her but did not cause her to lose consciousness. Although she had a headache after the accident, no psychiatric or neurological follow-up was pursued.

Neuropsychological testing at the time of evaluation revealed a significant decline in intellectual functioning from her “preinjury” state. Testing revealed poor concentration, attention, memory, and reasoning abilities. Academically, she was unable to “keep up” with the friends she had had before her injury. She began to socialize with a group of students who had little interest in academics, and she began to see herself as a rebel. When the neuropsychological test results were explained to the patient and her family as a consequence of the brain injury, she and her family were able to understand the “defensive” reaction to her changed social behavior.

Source: Adapted from Silver et al., 2002.

The brain can be damaged by exposure to solvents. Nail studios frequently use a variety of organic solvents that are known to be potentially damaging to the central nervous system.

deprivation or the ingestion of toxic substances such as mercury. Such a person may complain of memory problems due to an inability to sustain focused retrieval efforts, while his or her ability to store new information remains intact.

In an illustration of this, LoSasso, Rapport, and Axelrod (2001, 2002) found that nail salon technicians reported significantly more cognitive and neurological impairments than controls did. The nail salon technicians also performed more poorly than the controls on tests of attention and information processing. This is likely due to routine exposure to (meth)acrylates and a variety of organic solvents such as toluene, acetone, and formaldehyde that are known to be potentially damaging to the central nervous system. Such findings highlight the consequences of even low-level exposure to neurotoxic substances that can be found in places where many people work and where many others routinely visit.

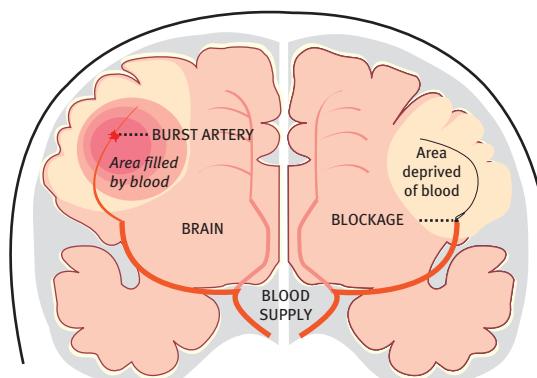

In contrast to diffuse damage, *focal* brain lesions involve circumscribed areas of abnormal change in brain structure. This is the kind of damage that might occur with a sharply defined traumatic injury or an interruption of blood supply (a stroke) to a specific part of the brain. Figure 14.1 explains how a stroke occurs.

## Diffuse Versus Focal Damage

The disorders discussed in this section are characterized by neurocognitive problems, although psychopathological problems (such as psychosis or mood change) may also be associated with them. Some of these disorders are generally well understood, with symptoms that have relatively constant features in people whose brain injuries are comparable in location and extent. For example, attention is often impaired by mild to moderate *diffuse*—or widespread—damage, such as might occur with moderate oxygen

### HEMORRHAGIC STROKE

1. An artery in the brain bursts and either floods the surrounding tissue with blood or floods the surface and grooves of the brain.
2. The blood irritates brain cells, disrupting their functions and causing the brain to swell with fluid.
3. If the swelling continues, the brain is stopped by the skull and squeezed through the opening in the bottom of the skull, crushing the centers for consciousness and breathing.

### ISCHEMIC STROKE

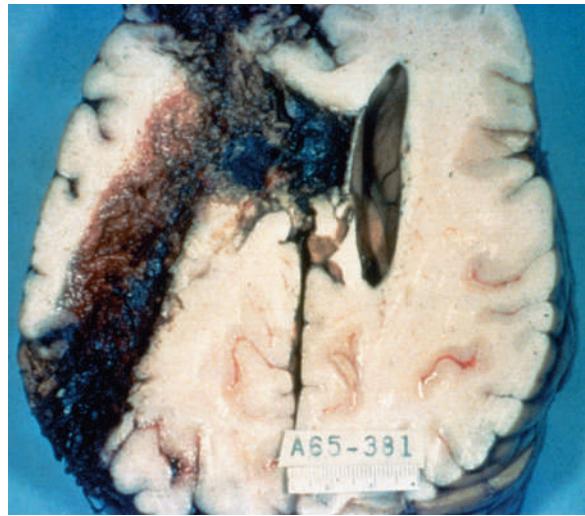

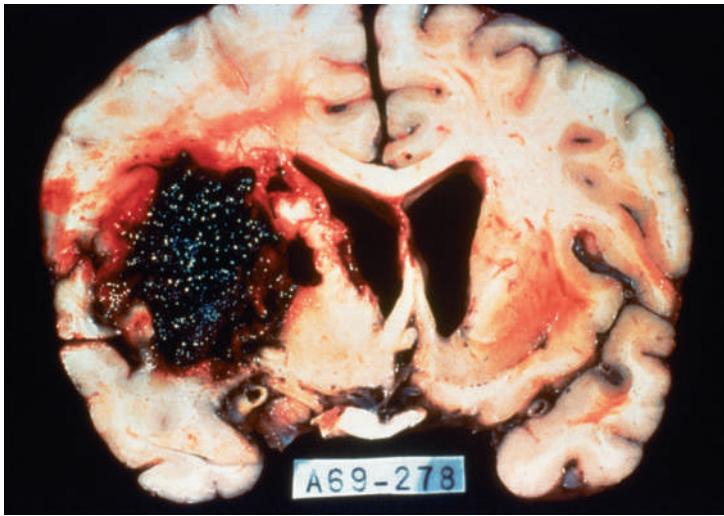

1. A blood clot forms and is swept into the brain where it blocks an artery. Clots usually form in the heart or in arteries of the neck that are damaged by atherosclerotic plaque.
2. The brain tries to protect itself by raising blood pressure, trying to clear the artery. Meanwhile, the brain cells, deprived of blood, shut down.
3. If the problem persists, brain cells swell and die.

**FIGURE 14.1**

**How a Stroke Occurs.** Most strokes occur when an artery in the brain is blocked by a clot. The others, about 13 percent of strokes, occur when a brain artery bursts. Both types can be disastrous.

Cross sections of damaged brains. The brain on the left shows damage from a stroke. Damage from a bullet is shown on the right.

The location and extent of the damage determine what problems the patient will have. As you are aware, the brain is highly specialized. Although the two hemispheres are closely interrelated, they are involved in somewhat different types of mental processing. At the risk of oversimplifying, it is generally accepted that functions that are dependent on serial processing of familiar information, such

as language and solving mathematical equations, take place mostly in the left hemisphere for nearly everyone. Conversely, the right hemisphere appears to be generally specialized for grasping overall meanings in novel situations; reasoning on a nonverbal, intuitive level; and appreciating of spatial relations. Even within hemispheres, the various lobes and regions mediate specialized functions (see Figure 14.2).

**TABLE 14.1**  
**Impairments Associated With Brain Disorders**

The following types of difficulties are often the consequences of brain disease, disorder, or damage.

1. *Impairment of memory.* The individual has trouble remembering recent events, although memory for past events may remain more intact. Some patients with memory problems may confabulate—that is, invent memories to fill in gaps. In severe instances, no new experience can be retained for more than a few minutes.
2. *Impairment of orientation.* The individual may not know where he or she is, what the day is, or who familiar people are.
3. *Impairment of learning, comprehension, and judgment.* The individual's thinking becomes clouded, sluggish, or inaccurate. The person may lose the ability to plan with foresight or to understand abstract concepts and hence to process complex information (described as "thought impoverishment").
4. *Impairment of emotional control or modulation.* The individual is emotionally overreactive: laughing, crying, or flying into a rage with little provocation.
5. *Apathy or emotional blunting.* The individual is emotionally underreactive and seems indifferent to people or events.
6. *Impairment in the initiation of behavior.* The individual lacks self-starting capability and may have to be reminded repeatedly about what to do next, even when the behavior involved remains well within the person's range of competence. This is sometimes referred to as "loss of executive function."
7. *Impairment of controls over matters of propriety and ethical conduct.* The individual may manifest a marked lowering of personal standards in areas such as appearance, personal hygiene, sexuality, or language.
8. *Impairment of receptive and expressive communication.* The individual may be unable to comprehend written or spoken language or may be unable to express his or her own thoughts orally or in writing.
9. *Impaired visuospatial ability.* The individual has difficulty coordinating motor activity with the characteristics of the visual environment, a deficit that affects graphomotor (handwriting and drawing) and constructional (e.g., assembling things) performance.

Although none of these relationships between brain location and behavior can be considered universally true, it is possible to make broad generalizations about the likely effects of damage to particular parts of the brain. Damage to the frontal areas, for example, is associated with one of two contrasting clinical pictures: (1) being unmotivated and passive and with limited thoughts and ideas or (2) featuring impulsiveness and distractibility. Damage to specific areas of the right parietal lobe may produce impairment of visual-motor coordination, and damage to the left parietal area may impair certain aspects of language function, including reading and writing, as well as arithmetical abilities. Damage to certain structures within the temporal lobes disrupts an early stage of memory storage. Extensive bilateral temporal damage can produce a syndrome in which remote memory remains relatively intact but nothing new can be stored for later retrieval. Damage to other structures within the temporal lobes is associated with disturbances of eating, sexuality, and emotion. Occipital damage produces a variety of visual impairments and visual association deficits, the nature of the deficit depending on the particular site of the lesion. For example, a person may be unable to recognize familiar faces. Unfortunately, many types of brain disease are general and therefore diffuse in their destructive effects, causing multiple and widespread interruptions of the brain's circuitry. Some consequences of brain disorders are described in Table 14.1 above.

### The Neurocognitive/Psychopathology Interaction

Most people who have a neurocognitive disorder do not develop psychopathological symptoms such as panic attacks, dissociative episodes, or delusions. However, many show at least mild deficits

in cognitive processing and self-regulation. Similarly, some people who suffer from psychopathological disorders also have cognitive deficits. For example, patients with bipolar disorder have persistent cognitive deficits that can be detected even during periods of illness remission (Bora et al., 2011). This highlights the close link between psychopathological and neuropsychological conditions.

The psychopathological symptoms that do sometimes accompany brain impairment are not always predictable and can reflect individual nuances consistent with the patient's age (see Tateno et al., 2002), her or his prior personality, and the total psychological situation confronting the patient. We should also never just assume that a psychological disorder—for example, a serious depression that follows a brain injury—is always attributable to the patient's brain damage. Certainly that could be the case. However, it is also possible that the depression might be better explained by the patient's awareness of dramatically lessened competence and the loss of previous skills. After a traumatic brain injury caused by an accident or a fall, for example, around 18 percent of patients make a suicide attempt (Simpson & Tate, 2002).

People with more favorable life situations tend to fare better after brain injury than people whose lives are more disorganized or disadvantaged (Yeates et al., 1997). Intelligent, well-educated, mentally active people have enhanced resistance to mental and behavioral deterioration following significant brain injury (e.g., see Mori et al., 1997a; Schmand et al., 1997). Because the brain is the organ responsible for the integration of behavior, however, there are limits to the amount of brain damage that anyone can tolerate or compensate for without exhibiting abnormal behavior.

## in review

- Describe some of the major ways in which the brain can become damaged.
- What kinds of clinical symptoms are often associated with damage to the frontal, parietal, temporal, and occipital lobes of the brain?
- List nine impairments that are typical of focal and diffuse brain damage.

## Delirium

**Delirium** is a state of acute brain failure that lies between normal wakefulness and stupor or coma (see Figure 14.3). The word comes from the Latin *delirare*, meaning to be out of one's furrow or track.

### Clinical Picture

A commonly occurring syndrome, delirium is characterized by confusion, disturbed concentration, and cognitive dysfunction (see the *DSM-5* table on page 489 for diagnostic criteria). Although the *DSM-IV-TR* criteria stated that delirium involved a disturbance in consciousness, this word was removed in *DSM-5*. This is because the essence of delirium is better captured by the idea of a disturbance in awareness. Think of delirium as a condition with a sudden onset that involves a fluctuating state of reduced awareness. Delirium is treated as a distinct disorder in *DSM-5* (rather than as a type of major or mild neurocognitive disorder) because it can quickly fluctuate in severity. It can also coexist with a major or mild neurocognitive disorder (such as Alzheimer's disease). It therefore does not fit well with being categorized as a major or mild form of neurocognitive disorder.

In addition to a disturbance in level of awareness, delirium also involves impairments of memory and attention as well as disorganized thinking. Hallucinations and delusions are quite common (see Trzepacz et al., 2002). In addition, the syndrome often includes abnormal psychomotor activity such as wild thrashing about and disturbance of the sleep cycle. A delirious person is essentially unable to carry out purposeful mental

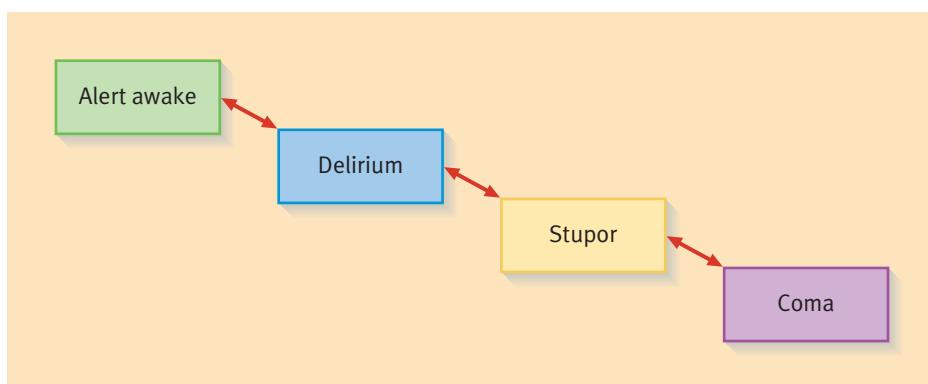

activity of any kind. The intensity of the symptoms also fluctuates over the course of a 24-hour period, as described in the following case study.

### Delirium Following a Routine Operation

Mrs. Patterson was 75 years old when she was admitted to the hospital. A widow who lived alone, she had broken her leg, and she needed a routine operation. The operation was successful. However, shortly afterward, Mrs. Patterson began to show signs of confusion. She had problems with awareness and attention, and she had no idea of what had happened to her or why she was in the hospital. During the day, she seemed agitated and aimlessly wandered around. She was unable to focus enough to watch television or to read. She was also unable to recognize friends and relatives who came to visit her. On several occasions, nursing staff saw her staring at an imaginary spot on the ceiling of her room and having conversations with imaginary people. Mrs. Patterson refused to take any medications. She would knock her meals onto the floor when they were brought to her. Between these outbursts, Mrs. Patterson was able to calm down, sleeping for short periods of about 30 minutes at a time. However, at night, she could hardly sleep at all. Instead, she wandered around the hospital ward. She went into the rooms of other patients, waking them up, and sometimes even trying to get into their beds. On a number of occasions, she was found in her nightdress, trying to leave the hospital. However, the staff always stopped her and carefully escorted her back to her room.

Source: Based on Üstün et al., 1996.

Delirium can occur in a person of any age. However, the elderly are at particularly high risk, perhaps because of brain changes caused by normal aging that lead to reduced "brain reserve." As described in the case of Mrs. Petersen, delirium is very common in the elderly after they have had surgery, with patients over 80 being particularly at risk (Trzepacz et al., 2002). At the other end of the age spectrum, children are also at high risk of delirium, perhaps because their brains are not yet fully developed. In addition to advanced age, other risk factors for delirium include dementia, depression, and tobacco use (Fricchione et al., 2008).

**FIGURE 14.3**

### Continuum of Level of Awareness.

- A. A disturbance in attention (i.e., reduced ability to direct, focus, sustain, and shift attention) and awareness (reduced orientation to the environment).
- B. The disturbance develops over a short period of time (usually hours to a few days), represents a change from baseline attention and awareness, and tends to fluctuate in severity during the course of a day.
- C. An additional disturbance in cognition (e.g., memory deficit, disorientation, language, visuospatial ability, or perception).

- D. The disturbances in Criteria A and C are not better explained by another preexisting, established, or evolving neurocognitive disorder and do not occur in the context of a severely reduced level of arousal, such as coma.
- E. There is evidence from the history, physical examination, or laboratory findings that the disturbance is a direct physiological consequence of another medical condition, substance intoxication or withdrawal (i.e., due to a drug of abuse or to a medication), or exposure to a toxin, or is due to multiple etiologies.

Estimates of the prevalence of delirium vary widely with the age of the population studied. However, somewhere between 10 and 51 percent of patients who have had surgery will experience delirium; patients who have had cardiac surgery seem to be at especially high risk. The presence of delirium is also a bad prognostic sign. Delirium is correlated with cognitive decline, longer hospital stays, more health problems, and increased mortality; 25 percent of elderly patients with delirium die within the following 6 months (Fricchione et al., 2008; Witlox et al., 2010).

Delirium may result from several conditions including head injury and infection. However, the most common cause of delirium is drug intoxication or withdrawal. Toxicity from medications also causes many cases of delirium. This may explain why delirium is so common in the elderly after they have had surgery.

### Treatments and Outcomes

Delirium is a true medical emergency, and its underlying cause must be identified and managed. Most cases of delirium are reversible, except when the delirium is caused by a terminal illness or by severe brain trauma. Treatment involves medication, environmental manipulations, and family support. The medications that are used for most cases are neuroleptics (Fricchione et al., 2008; Lee et al., 2004). These are the same drugs that are used to treat schizophrenia. For delirium caused by alcohol or drug withdrawal, benzodiazepines (such as those used in the treatment of anxiety disorders) are used (Trzepacz et al., 2002). In addition, environmental manipulations that help patients stay oriented, such as good lighting, clear signage, and easily visible calendars and clocks, can be helpful. It is also important that staff members introduce themselves when they work with patients, explain what their role is, and provide reorienting prompts whenever necessary. Some patients, however, especially elderly ones, may still have orientation problems, sleep problems, and other difficulties even months after an episode of delirium.

- Describe some common causes of delirium. Who is most at risk of developing this clinical condition?
- How is delirium treated?

## Major Neurocognitive Disorder (Dementia)

In *DSM-5* the broad diagnostic category of *dementia* has been renamed. The term major neurocognitive disorder is now used. One reason for this is to reduce stigma. It is also the case that, although the term *dementia* is widely accepted for older adults it is not a very appropriate term for younger adults who have cognitive problems (e.g., those who have sustained damage from head injuries).

Major neurocognitive disorders are those that involve marked deficits in cognitive abilities. These may be apparent in such areas as attention, executive ability, learning and memory, language, perception, and social cognition (skills required for understanding, interpreting, and responding to the behavior of others). What is crucial is that there is a decline from a previously attained level of functioning (see the *DSM-5* table for diagnostic criteria for major neurocognitive disorder).

In older people the onset of cognitive deficits is typically quite gradual. Early on, the individual is alert and fairly well attuned to events in the environment. Even in the early stages, however, memory is affected, especially memory for recent events. As time goes on, patients show increasingly marked deficits in abstract thinking, the acquisition of new knowledge or skills, visuospatial comprehension, motor control, problem solving, and judgment. These are often accompanied by impairments in emotional control and in moral and ethical sensibilities; for example, the person

- A. Evidence of significant cognitive decline from a previous level of performance in one or more cognitive domains (complex attention, executive function, learning and memory, language, perceptual-motor, or social cognition) based on:
1. Concern of the individual, a knowledgeable informant, or the clinician that there has been a significant decline in cognitive function; and
  2. substantial impairment in cognitive performance, preferably documented by standardized neuropsychological testing or, in its absence, another quantified clinical assessment.

- B. The cognitive deficits interfere with independence in everyday activities (i.e., at a minimum, requiring assistance with complex instrumental activities of daily living such as paying bills or managing medications).
- C. The cognitive deficits do not occur exclusively in the context of a delirium.
- D. The cognitive deficits are not better explained by another mental disorder (e.g., major depressive disorder, schizophrenia).

may engage in crude solicitations for sex. Deficits may be progressive (getting worse over time) or static, but is more often the former. Occasionally a major neurocognitive disorder is reversible if it has an underlying cause that can be removed or treated (such as vitamin deficiency). Some treatable causes of major neurocognitive disorder are listed in Table 14.2.  [Watch the Video](#)  
*Alvin: Dementia (Alzheimer's Type)* on [MyPsychLab](#).

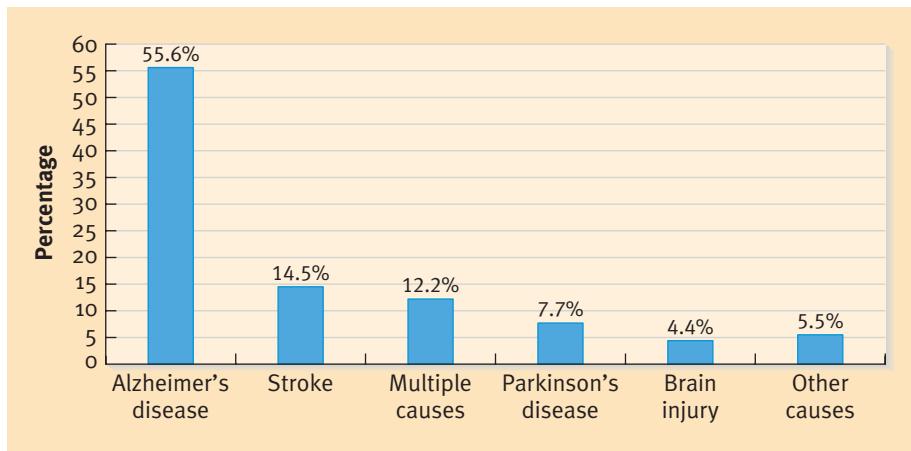

At least 50 different disorders are known to cause the types of cognitive deficits that are now included in the category of major neurocognitive disorders (Bondi & Lange, 2001). They include degenerative diseases such as Huntington's disease and Parkinson's disease (which are described below). Other causes are strokes (see Ivan et al., 2004); certain infectious diseases such as syphilis, meningitis, and AIDS; intracranial tumors and abscesses; certain dietary deficiencies (especially of the B vitamins); severe or repeated head injury; anoxia (oxygen deprivation); and the ingestion or inhalation of toxic substances such as lead or mercury. As

Figure 14.4 on page 491 illustrates, the most common cause of major neurocognitive disorder is degenerative brain disease, particularly Alzheimer's disease. In this chapter we will focus primarily on this greatly feared disorder. We will also briefly discuss neurocognitive disorders that result from HIV infection and stroke (vascular dementia).

### Parkinson's Disease

Named after James Parkinson, who first described it in 1817, **Parkinson's disease** is the second most common neurodegenerative disorder (after Alzheimer's disease). It is more often found in men than in women, and it affects between 0.5 and 1 percent of people between ages 65 and 69 and 1 to 3 percent of people over 80 (Toulouse & Sullivan, 2008). However, the actor Michael J. Fox developed Parkinson's disease when he was only 30 years old. His book *Lucky Man* (2002) offers a moving personal account of his struggle with the illness and well describes some of its major symptoms.

Parkinson's disease is characterized by motor symptoms such as resting tremors or rigid movements. The underlying cause of this is loss of dopamine neurons in an area of the brain called the substantia nigra. Dopamine is a neurotransmitter that is involved in the control of movement. When dopamine neurons are lost, a person is unable to move in a controlled and fluid manner. In addition to motor symptoms, Parkinson's disease can involve psychological symptoms such as depression, anxiety, apathy, cognitive problems, and even hallucinations and delusions (Chaudhuri et al., 2011). Later on in the illness, cognitive deficits may also become apparent. Over time, 25 to 40 percent of patients with Parkinson's disease will show signs of cognitive impairment (Marsh & Margolis, 2009). The causes of Parkinson's disease are not clear, although both genetic and environmental factors are suspected. Genetic factors may be more important in cases where the Parkinson's disease develops

**FIGURE 14.4**

Causes of Dementia (major neurocognitive disorder). Causes are presented according to the percentage of all cases they account for.

earlier in life, and environmental factors may be more relevant in later onset cases (Wirdefeldt et al., 2011). Interestingly, smoking and drinking coffee may provide some protection against the development of Parkinson's disease, although the reasons for this remain unclear (Toulouse & Sullivan, 2008; Wirdefeldt et al., 2011).

The symptoms of Parkinson's disease can be temporarily reduced by medications, such as Mirapex (pramipexole), that increase the availability of dopamine in the brain. However, once the medications wear off, the symptoms return. Another treatment approach that is now being tried is deep brain stimulation (described in Chapter 16). In the future, stem cell research may also offer some hope for patients with this disease.

### Huntington's Disease

**Huntington's disease** is a rare degenerative disorder of the central nervous system that afflicts about 1 in every 10,000 people (Phillips et al., 2008). It was first described in 1872 by the American neurologist George Huntington. The illness begins in midlife (the mean age of onset is around 40 years), and it affects men and women in equal numbers. Huntington's disease is characterized by a chronic, progressive chorea (involuntary and irregular movements that flow randomly from one area of the body to another). However, subtle cognitive problems often predate the onset of motor symptoms by many years. These cognitive problems are no doubt due to the progressive loss of brain tissue (detectable with brain imaging) that occurs as much as a decade before the formal onset of the illness (Shoulson & Young, 2011). Patients eventually develop dementia, and death usually occurs within 10 to 20 years of first developing the illness. There are currently no effective treatments that can restore functioning or slow down the course of this terrible and relentless disorder. American folk singer Woody Guthrie, whose song "This Land Is Your Land" is well known, died of the disease in 1967 when he was 55 years of age.

Huntington's disease is caused by a single dominant gene (the Huntington gene) on chromosome 4. This genetic mutation was discovered as a result of intense research on people living in villages around Lake Maracaibo in Venezuela, where this disease is extremely common (Marsh & Margolis, 2009). Because the Huntington gene is a dominant gene, anyone who has a parent with the disease has a 50 percent chance of developing the disease himself or herself. A genetic test can be given to at-risk individuals to determine whether they will eventually develop the disorder. However, in the United States, only about 10 percent of people who are eligible for testing choose to know what their genetic destiny is (Shoulson & Young, 2011). If you were in this situation, what would you do? One interesting finding here is that the majority of people who have asked to be tested are women (Hayden, 2000).

### Alzheimer's Disease

**Alzheimer's disease** is a progressive and fatal neurodegenerative disorder. It takes its name from Alois Alzheimer (1864–1915), the German neuropathologist who first described it in 1907. It is the most common cause of dementia (Jalbert et al., 2008). In the *DSM-5* it is called "major (or mild) neurocognitive disorder associated with Alzheimer's disease." Alzheimer's disease is associated with a characteristic dementia syndrome (see the case study below) that has an imperceptible onset and a usually slow but progressively deteriorating course, terminating in delirium and death.

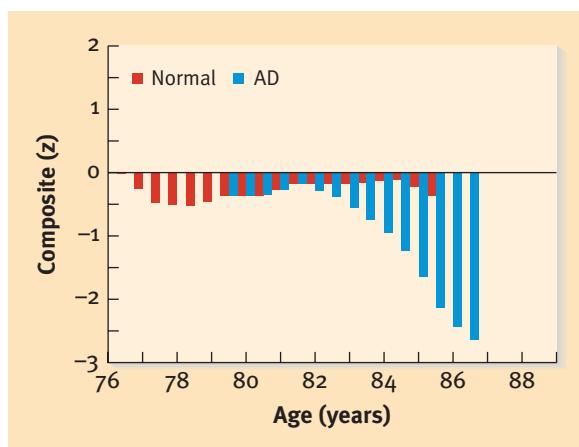

→ **The Forgetful Mail Carrier** At the age of 60, Harold took early retirement from his government job because, for the previous 5 years, he had been having difficulty performing his work properly. A mail carrier, he was constantly making errors and delivering mail to the wrong places. He also began to become more withdrawn, gradually giving up hobbies that had been important to him. At first, his increasing forgetfulness was

not very noticeable when he was at home. Then, one day when he was 62, Harold was hiking in an area he knew well and was unable to find his way home. Since that time, his memory problems have grown increasingly worse. He loses things, forgets appointments, and can no longer find his way around his hometown. Now, at the age of 66, Harold no longer recognizes his close friends and is uninterested in reading or watching television. Things are so bad that his wife is afraid to leave him alone in the house because he is so forgetful.

Source: Based on Üstün et al., 1996.

**CLINICAL PICTURE** The diagnosis of Alzheimer's disease is made after a thorough clinical assessment of the patient. However, the diagnosis can only be confirmed after the patient's death. This is because an autopsy must be performed to see the brain abnormalities that are such distinctive signs of this disease. In the living patient, the diagnosis is normally given only after all other potential causes of dementia are ruled out by medical and family history, physical examination, and laboratory tests.

Alzheimer's disease usually begins after about age 45 (Malspina et al., 2002). Contrary to what many people believe, it is characterized by multiple cognitive deficits, not just problems with memory. There is a gradual declining course that involves slow mental deterioration. Figure 14.5 shows the performance of two men on a battery of cognitive tests repeated over a period of several years. Both men were of similar age and level of education, and both were initially free of Alzheimer's disease. However, for the man who subsequently developed Alzheimer's disease (confirmed on autopsy), a progressive, downward course in his cognitive performance is apparent (see Storandt, 2008).

**FIGURE 14.5**  
**Test Performance in a Healthy Man and a Man Who Developed Alzheimer's Disease**

Source: Figure 1 on page 198 from Martha Storandt. (2008). Cognitive deficits in the early stages of Alzheimer's disease. *Current Directions in Psychological Science*, 17(3), 198–2202 (Copyright © 2008). Association for Psychological Science. Reproduced with permission of Blackwell Publishing Ltd.

In its earliest stages, Alzheimer's disease involves minor cognitive impairment. For example, the person may have difficulty recalling recent events, make more errors at work, or take longer to complete routine tasks. In the later stages, there is evidence of dementia; deficits become more severe, cover multiple domains, and result in an inability to function. For example, the person may be easily disoriented, have poor judgment, and neglect his or her personal hygiene. Because they have impaired memory for recent events, many patients have "empty" speech in which grammar and syntax remain intact but vague and seemingly pointless expressions replace meaningful conversational exchange (e.g., "It's a nice day, but it might rain"). The case study below, which involves a man who had retired some 7 years prior to his hospitalization, is typical.

→ **Restless and Wandering** During the past 5 years, the patient had shown a progressive loss of interest in his surroundings and during the last year had become increasingly "childish." His wife and eldest son had brought him to the hospital because they felt they could no longer care for him in their home, particularly because of the grandchildren. They stated that he had become careless in his eating and other personal habits and was restless and prone to wandering about at night. He could not seem to remember anything that had happened during the day but was garrulous concerning events of his childhood and middle years.

After admission to the hospital, the patient seemed to deteriorate rapidly. He could rarely remember what had happened a few minutes before, although his memory for remote events of his childhood remained good. When visited by his wife and children, he mistook them for old friends, and he could not recall anything about the visit a few minutes after they had departed. The following brief conversation with the patient, which took place after he had been in the hospital for 9 months (and about 3 months before his death), shows his disorientation for time and person.

DOCTOR: How are you today, Mr. \_\_\_\_\_?

PATIENT: Oh . . . hello [looks at doctor in rather puzzled way as if trying to make out who he is].

DOCTOR: Do you know where you are now?

PATIENT: Why yes . . . I am at home. I must paint the house this summer. It has needed painting for a long time but it seems like I just keep putting it off.

DOCTOR: Can you tell me the day today?

PATIENT: Isn't today Sunday . . . why, yes, the children are coming over for dinner today. We always have dinner for the whole family on Sunday. My wife was here just a minute ago but I guess she has gone back into the kitchen.

The temporal lobes of the brain are the first regions to be damaged in the person with Alzheimer's disease. Because the hippocampus is located here, memory impairment is an

Cognitive difficulties are not an inevitable consequence of aging. Betty White hosted *Saturday Night Live* when she was 89 years old.

early symptom of the disease. Loss of brain tissue in the temporal lobes may also explain why delusions are found in some patients (Lyketsos et al., 2000). Although delusions of persecution are predominant, delusional jealousy is sometimes seen. Here, the person persistently accuses his or her partner or spouse—who is often of advanced age and physically debilitated—of being sexually unfaithful. Family members may be accused of poisoning the patient's food or of plotting to steal the patient's funds. One study of physically aggressive patients with Alzheimer's disease found that 80 percent of them were delusional (Gilleley et al., 1997).

With appropriate treatment, which may include medication and the maintenance of a calm, reassuring, and unprovocative social environment, many people with Alzheimer's disease show some alleviation of symptoms. In general, however, deterioration continues its downward course over a period of months or years. Eventually, patients become oblivious to their surroundings, bedridden, and reduced to a vegetative state. Resistance to disease is lowered, and death usually results from pneumonia or some other respiratory or cardiac problem. The median time to death is 5.7 years from the time of first clinical contact (Jalbert et al., 2008).

**PREVALENCE** Alzheimer's disease is becoming a major public health problem, straining societal and family resources. It accounts for most cases of dementia (Lyketsos et al., 2000). Although this disease is not an inevitable consequence of aging

(Betty White hosted *Saturday Night Live* when she was 89), age is a major risk factor.

It has been estimated that the rate of Alzheimer's disease doubles about every 5 years after a person reaches the age of 40 (Hendrie, 1998). Whereas fewer than 1 percent of 60- to 64-year-olds have the disease, up to 40 percent those aged 85 and older do (Jalbert et al., 2008). In the United States, more than 5 million people are living with this disease. Worldwide, the figure is over 35 million (Selkoe, 2012). By 2030 it is expected that this number will rise to a staggering 66 million (Vreugdenhil et al., 2012). The future prospects are therefore somewhat alarming. If we have not solved the problem of preventing Alzheimer's disease (or arresting it in its early stages) by around that time, society will be faced with the overwhelming problem of caring for millions of demented senior citizens.

For reasons that are not yet clear, women seem to have a slightly higher risk of developing Alzheimer's disease than men (Jalbert et al., 2008). Indeed, Alois Alzheimer's original case was a 51-year-old woman. Women tend to live longer than men, but this may not entirely explain the increased prevalence of women with Alzheimer's disease. However, a relevant factor may be loneliness. In one study of 800 elderly people (the majority of whom were female), those who reported that they felt lonely had twice the risk of developing Alzheimer's disease over the course of the 4-year follow-up. This association was independent of their scores on a measure of cognition, suggesting that loneliness is not an early sign of cognitive impairment or a consequence of impaired cognitive skill (Wilson, Krueger et al., 2007). It is reasonable to suggest that women are more likely to experience loneliness because they live longer and so outlive their husbands. This may be important when trying to understand sex differences in the risk for Alzheimer's disease.

In addition to advanced age and being female, other risk factors for Alzheimer's disease include being a current smoker, having fewer years of formal education, having lower income, and having a lower occupational status (Jalbert et al., 2008). Table 14.3 provides a summary of the most well-researched risk factors to date.

The prevalence of Alzheimer's disease is higher in North America and Western Europe and lower in such places as

**TABLE 14.3**  
**Summary of Risk Factors for Alzheimer's Disease**

Advanced age
Female
Current smoker
Fewer years of education
Lower income
Lower occupational status
Head trauma

Africa, India, and South East Asia (Ballard et al., 2011; Ferri et al., 2005). Such observations have led researchers to suspect that lifestyle factors such as a high-fat, high-cholesterol diet are implicated in the development of Alzheimer's disease (Sjogren & Blennow, 2005). Also implicating diet, researchers have found that high levels of an amino acid called homocysteine (which is a risk factor for heart disease) seem to increase a person's risk of developing Alzheimer's disease later in life (Ravaglia et al., 2005). Levels of homocysteine in the blood can be reduced by taking folic acid and certain B vitamins. Taking statin drugs to lower cholesterol also seems to offer some protection against Alzheimer's disease (Sparks et al., 2005).

**CAUSAL FACTORS** When we picture a typical Alzheimer's patient, we imagine a person of very advanced age. Sometimes, however, the disease begins much earlier and affects people in their 40s or 50s. In such cases, cognitive decline is often rapid. Considerable evidence suggests a substantial genetic contribution in early-onset Alzheimer's disease, although different genes may be involved in different families (see Gatz, 2007). Genes also play a role in late-onset Alzheimer's disease.

Cases of **early-onset Alzheimer's disease** appear to be caused by rare genetic mutations. So far, three such mutations have been identified (Ballard et al., 2011). One involves the *APP* (amyloid precursor protein) gene, which is located on chromosome 21. Mutations of the *APP* gene are associated with an onset of Alzheimer's disease somewhere between 55 and 60 years of age (Cruts et al., 1998).

The fact that a mutation of a gene on chromosome 21 has been found to be important is interesting because it has long been known that people with Down syndrome (which is caused by a tripling, or trisomy, of chromosome 21) who survive beyond about age 40 develop an Alzheimer's-like dementia (Bauer & Shea, 1986; Janicki & Dalton, 1993). They also show similar neuropathological changes (Schapiro & Rapoport, 1987). In addition, cases of Down syndrome tend to occur more frequently in the families of patients with Alzheimer's disease (Heyman et al., 1984; Schupf et al., 1994). One study has found that mothers who gave birth to a child with Down syndrome before age 35 had a 4.8 times greater risk of developing Alzheimer's disease when they were older compared to mothers of children with other types of mental retardation (Schupf et al., 2001).

Other cases of even earlier onset appear to be associated with mutations of a gene on chromosome 14 called *presenilin 1* (PS1) and with a mutation of the *presenilin 2* (PS2) gene on chromosome 1. These genes are associated with an onset of Alzheimer's disease somewhere between 30 and 50 years of age (Cruts et al., 1998). One carrier of the PS1 mutation is even known to have developed the disorder at age 24 (Wisniewski et al., 1998). Remember, however, that these mutant genes, which are autosomal dominant genes and so nearly

always cause disease in anyone who carries them, are extremely rare. The APP, PS1, and PS2 genetic mutations probably account, together, for no more than about 5 percent of cases of Alzheimer's disease.

A gene that plays an important role in cases of late-onset Alzheimer's disease is the *APOE* (apolipoprotein) gene on chromosome 19. This gene codes for a blood protein that helps carry cholesterol through the bloodstream. We know that differing forms (genetic alleles) of *APOE* differentially predict risk for **late-onset Alzheimer's disease**. Three such alleles have been identified, and everyone inherits two of them, one from each parent. One of these alleles, the **APOE-E4 allele**, significantly enhances risk for late-onset disease. Thus a person may inherit zero, one, or two of the APOE-E4 alleles, and his or her risk for Alzheimer's disease increases correspondingly. For example, having two APOE-E4 alleles results in a sevenfold increase in a person's chances of developing the disease (Ballard et al., 2011). Another such allele, APOE-E2, seems to convey protection against late-onset Alzheimer's disease. The remaining and most common allele form, APOE-E3, is of neutral significance. The alleles differ in how efficient they are in clearing amyloid, with APOE-E2 being most efficient and APOE-E4 least efficient (Karran et al., 2011).

APOE-E4 has been shown to be a significant predictor of memory deterioration in older individuals with or without clinical dementia (Hofer et al., 2002). The APOE-E4 allele is relatively uncommon in Chinese people compared to its frequency in people from Europe or North America. In contrast, people of African descent are especially likely to have this allele (Waters & Nicoll, 2005). Table 14.4 summarizes the genes that have been implicated in Alzheimer's disease.

The APOE-E4 allele (which can be detected by a blood test) is overrepresented in all types of Alzheimer's disease including the early-onset and late-onset forms. Approximately 65 percent of patients have at least one copy of the APOE-E4 allele (see Malaspina et al., 2002). Exciting as they are, however, these discoveries still do not account for all cases of Alzheimer's disease, not even all late-onset cases (e.g., Bergem et al., 1997). Many people who inherit the most risky APOE pattern (two APOE-E4 alleles) do not succumb to the disorder. One study found that only 55 percent of people who had two APOE-E4 alleles had

### Depression Increases the Risk of Alzheimer's Disease

**H**aving a history of depression seems to put a person at higher risk for the later development of Alzheimer's disease (Ownby et al., 2006). Although we are not yet sure why this is, researchers speculate that some of the changes in the brain that are known to be associated with depression and with stress may somehow leave the brain more vulnerable to problems down the road (Wilson et al., 2008).

Depression may also be an early warning sign of the onset of dementia. In a large, community-based prospective study of people aged 65 and older, researchers found that people who had no early (before age 50) history of depression but who developed symptoms of depression later in life were about 46 percent more likely to develop dementia over the course of the (approximately 7-year) follow-up period (Li et al., 2011). What this means is that late-life depression may be more than a risk factor for depression. Rather, it could be an early manifestation of the dementia itself. This raises the interesting question

of whether treating depression might delay the clinical onset of dementia.

People with a genetic risk for Alzheimer's disease because they carry the APOE-E4 gene may be especially vulnerable to developing Alzheimer's disease if they also have a history of depression. In one study, depressed men who had the APOE-E4 gene were more than seven times more likely to develop Alzheimer's disease over the course of a 6-year follow-up compared to men who had neither the gene nor a history of depression. For men who did not have the gene but did have a history of depression, the risk of later Alzheimer's disease was also higher (1.6-fold increase), but not nearly as high as the risk for the men who had the gene and the history of depression (Irie et al., 2008). Having the APOE-E4 allele does not make a person more likely to develop depression; however, when the gene and depression occur together, the risk of later Alzheimer's disease is especially high.

developed Alzheimer's disease by age 80 (Myers et al., 1996). And others with Alzheimer's disease have no such APOE-E4 risk factor. In addition, substantial numbers of monozygotic twins are discordant for the disease (Bergem et al., 1997; Breitner et al., 1993).

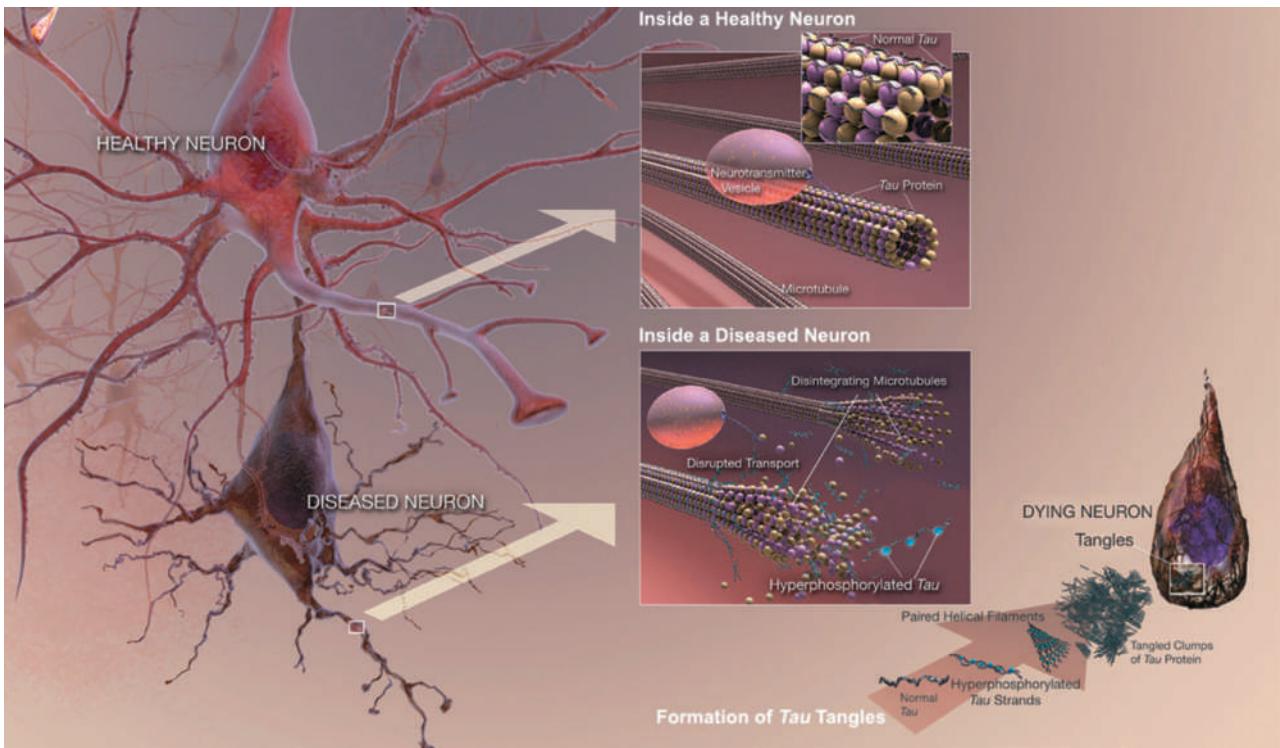

Why should this be? Current thinking is that our genetic susceptibility interacts with other genetic factors and with environmental factors to determine whether we will succumb to any particular disorder. Clearly, other genes involved in the development of Alzheimer's disease still remain to be found. However, environmental factors may also play a key role. As we have noted, the differences in the prevalence of Alzheimer's disease across different parts of the world suggest that diet may be an important mediating environmental variable. Being overweight, having Type 2 diabetes, or not being physically active have also been implicated as risk factors. The association with diabetes is interesting because researchers have found that insulin levels are abnormally low in some of the brain areas that are most affected by Alzheimer's disease. Other environmental factors under consideration include exposure to metals such as aluminum and experiencing head trauma. One prospective study has found that traumatic brain injury is associated, for up to 5 years after the injury, with a fourfold increase in risk of developing Alzheimer's disease (see Malaspina et al., 2002). And, as illustrated in Developments in Research box above, depression also elevates risk of later Alzheimer's disease. On the other hand, exposure to non-steroidal anti-inflammatory drugs such as ibuprofen may be protective and lead to a lower risk of Alzheimer's disease (Breitner et al., 1994; in't Veld et al., 2001; Weggen et al., 2001). People with more cognitive reserve (a concept combining education,

occupation, and mental engagement) also seem to be at reduced risk (Ballard et al., 2011). Recent research with mice further suggests that exposure to a more stimulating and novel environment slows down the development of Alzheimer-related changes in the brain (Li et al., 2013). In other words, it may be possible to reduce or delay the occurrence of Alzheimer's disease by deliberately limiting exposure to risks, living a more interesting life, and taking other preventive measures.

**NEUROPATHOLOGY** When Alois Alzheimer performed the first autopsy on his patient (she was known as Auguste D.), he identified a number of brain abnormalities that are now known to be characteristic of the disease. These are (1) amyloid plaques, (2) neurofibrillary tangles, and (3) atrophy (shrinkage) of the brain. Although plaques and tangles are also found in normal brains, they are present in much greater numbers in patients with Alzheimer's disease, particularly in the temporal lobes.

Current thinking is that, in Alzheimer's disease, neurons in the brain secrete a sticky protein substance called *beta amyloid* much faster than it can be broken down and cleared away. This beta amyloid then accumulates into **amyloid plaques** (see Figure 14.6, p. 496). These are thought to interfere with synaptic functioning and to set off a cascade of events that leads to the death of brain cells. Beta amyloid has been shown to be neurotoxic (meaning it causes cell death). Amyloid plaques also trigger local chronic inflammation in the brain and release cytokines (see Chapter 5) that may further exacerbate this process.

Having the APOE-E4 form of the *APOE* gene is associated with the more rapid buildup of amyloid in the brain (Jalbert et al., 2008). Animal studies also suggest that stress makes the

**FIGURE 14.6**

Brain Damage in Alzheimer's Disease. Watch the Video *Alzheimer's and Dementia* in **MyPsychLab**

neurocognitive consequences of amyloid accumulation much worse (Alberini, 2009; Srivareerat et al., 2009). Insulin may also play a role in regulating amyloid. Although some scientists believe that the accumulation of beta amyloid plays a primary role in the development of Alzheimer's disease, others suspect that it may be a defensive response rather than a causal factor. Importantly, amyloid deposits can be present as many as 10 years before clinical signs of Alzheimer's disease first show themselves (Shim & Morris, 2011). It is not yet known if symptoms become apparent when the amyloid burden in the brain crosses a certain threshold or if amyloid buildup itself triggers other destructive processes that eventually culminate in symptoms (Karran et al., 2011).

**Neurofibrillary tangles** are webs of abnormal filaments within a nerve cell. These filaments are made up of another protein called *tau*. In a normal, healthy brain, tau acts like a scaffolding, supporting a tube inside neurons and allowing them to conduct nerve impulses. In Alzheimer's disease the tau is misshaped and tangled. This causes the neuron tube to collapse.

Although abnormal tau aggregation can occur independently, there is reason to believe that buildup of tau protein is accelerated by an increasing burden of amyloid in the brain (Shim & Morris, 2011). Animal studies of mice that have been genetically modified to be highly susceptible to developing Alzheimer's disease (so-called transgenic mice) support this idea (Götz et al., 2001; Lewis et al., 2001). If correct, it suggests that the most promising drug treatments for

Alzheimer's disease may be those that can target and prevent amyloid buildup.

Another notable alteration in Alzheimer's disease concerns the neurotransmitter *acetylcholine* (ACh). This neurotransmitter is known to be important in the mediation of memory. Although there is widespread destruction of neurons in Alzheimer's disease, particularly in the area of the hippocampus (Adler, 1994; Mori

This photomicrograph of a brain tissue specimen from an Alzheimer's patient shows the characteristic plaques (dark patches) and neurofibrillary tangles (irregular pattern of strand-like fibers).

et al., 1997b), evidence suggests that among the earliest and most severely affected structures are a cluster of cell bodies located in the basal forebrain and involved in the release of ACh (Schliebs & Arendt, 2006). The reduction in brain ACh activity in patients with Alzheimer's disease is correlated with the extent of neuronal damage (i.e., plaques, tangles) that they have sustained.

The loss of cells that produce ACh makes a bad situation much worse. Because ACh is so important in memory, its depletion contributes greatly to the cognitive and behavioral deficits that are characteristic of Alzheimer's disease. For this reason, drugs (called cholinesterase inhibitors) that inhibit the breakdown of ACh (and so increase the availability of this neurotransmitter) can be clinically beneficial for patients (Winblad et al., 2001).

**TREATMENT AND OUTCOME** Despite extensive research efforts, we still have no treatment for Alzheimer's disease that will restore functions once they have been destroyed or lost. Current treatments, targeting both patients and family members, aim to diminish agitation and aggression in patients and reduce distress in caregivers as much as possible (Practice Guideline, 2007).

Some common problematic behaviors associated with dementia are wandering off, incontinence, inappropriate sexual behavior, and inadequate self-care skills. These can be somewhat controlled via behavioral approaches (see Chapter 16). Behavioral treatments need not be dependent on complex cognitive and communication abilities (which tend to be lacking in patients with dementia). Because of this, they may be particularly well suited for therapeutic intervention with Alzheimer's disease. In general, reports of results are moderately encouraging in terms of reducing unnecessary frustration and embarrassment for the patient and difficulty for the caregiver (Fisher & Carstensen, 1990; Mintzer et al., 1997; Teri et al., 1997).

As we noted earlier, some patients with Alzheimer's disease develop psychotic symptoms and are very agitated. Antipsychotic medications (like those used in the treatment of schizophrenia) are sometimes given to alleviate these symptoms. However, these medications must be used with great caution. The Food and Drug Administration has issued a warning that patients with dementia who receive atypical antipsychotic medications are at increased risk of death (Schultz, 2008). Moreover, although antipsychotic medications may alleviate some symptoms to a very modest degree, there is no good evidence that they are better than placebo when it comes to patients' overall daily functioning and cognition (Sultzer et al., 2008).

Treatment efforts to improve cognitive functioning have focused on the consistent findings of acetylcholine depletion in Alzheimer's disease. The reasoning here is that it might be possible to improve functioning by administering drugs that enhance the availability of brain ACh. Currently, the most effective way of doing so is by inhibiting the production of acetylcholinesterase, the principal enzyme involved in the metabolic breakdown of acetylcholine. This is the rationale for administering drugs such

as tacrine (Cognex) and donepezil (Aricept). Winblad and colleagues (2001) studied 286 patients who were randomly assigned to receive either medication (donepezil) or placebo for a 1-year period. Patients' cognitive functioning and ability to perform daily activities were measured at the start of the study and again at regular intervals over the study period. Patients who received the medication did better overall than patients who received the placebo. However, all patients declined in their functioning over the course of the study. Furthermore, although donepezil does help patients a little, these gains do not mean that patients taking the drug are any less likely to avoid institutionalization than those who are not taking the medication (AD2000 Collaborative Group, 2004).

The newest medication that has been approved to treat Alzheimer's disease is memantine, which is marketed as Namenda. Unlike other approved medications, memantine is not a cholinesterase inhibitor. Instead, it appears to regulate the activity of the neurotransmitter glutamate, perhaps by protecting cells against excess glutamate by partially blocking NMDA receptors. Memantine, which can be used alone or in combination with donepezil, appears to provide patients with some cognitive benefits (Forchetti, 2005; Reisberg et al., 2003). However, when it comes to day-to-day functioning, the improvements that come from taking medications are still very small (Ballard et al., 2011; Hansen et al., 2007).

Yet another line of treatment research is focused on developing vaccines that might help clear away any accumulated amyloid plaques. Although initial findings from animal research looked promising (e.g., McLaurin et al., 2002), human clinical trials of a vaccine were terminated prematurely because of dangerous side effects. Nonetheless, researchers continue to explore novel treatment approaches (Gestwicki et al., 2004; Hardy, 2004; Hutter-Paier et al., 2004). To date, however, all efforts to develop new drugs to treat Alzheimer's disease have been unsuccessful. No new medications have become available since Namenda was approved in 2003. This is very disappointing for patients and for their families, who live in hope of major breakthroughs.

Unfortunately, once most types of neuronal cells have died they are permanently lost. This means that even if some new treatment could halt a patient's progressive loss of brain tissue, he or she would still be left seriously impaired. This makes the research effort to detect Alzheimer's disease in its earliest stages all the more important.

**EARLY DETECTION** Most researchers believe that signs of Alzheimer's disease might be detectable long before clinical symptoms appear. To explore this, they are using a range of brain-imaging techniques to study the brains of people at high risk for developing the disease. People at high risk include those who have the APOE-E4 allele as well as people who are experiencing minor cognitive impairment (MCI). MCI is thought to be on a continuum between healthy aging and the earliest signs of dementia (Risacher & Saykin, 2013). Some people with MCI report problems with memory. However, other

## Exercising Your Way to a Healthier Brain?

If you want to preserve your brain function as you age, you may be surprised to learn that one of the best things you can do is to exercise regularly. A growing amount of research suggests that exercise has considerable neurocognitive benefits. For example, in one prospective study of 299 elderly people (average age 78 years), those who walked 6 to 9 miles per week had much less loss of gray matter over time than did those who were more sedentary (Erikson et al., 2010). In another year-long study, people aged 55 to 80 years who had no dementia were randomly assigned to a program of 40-minute walks three times a week or a program of stretching and toning that lasted the same amount of time. At the end of 1 year, those who had exercised by walking showed a 2 percent increase in the size of their hippocampus. In contrast, those in the stretching and toning control group showed a decline in their hippocampal volume

(which is expected with normal aging). In other words, exercise seemed to reverse the age-related loss whereas stretching and toning did not. What is also interesting is that increases in the volume of the hippocampus were also directly related to improvements in memory (Erikson et al., 2011).

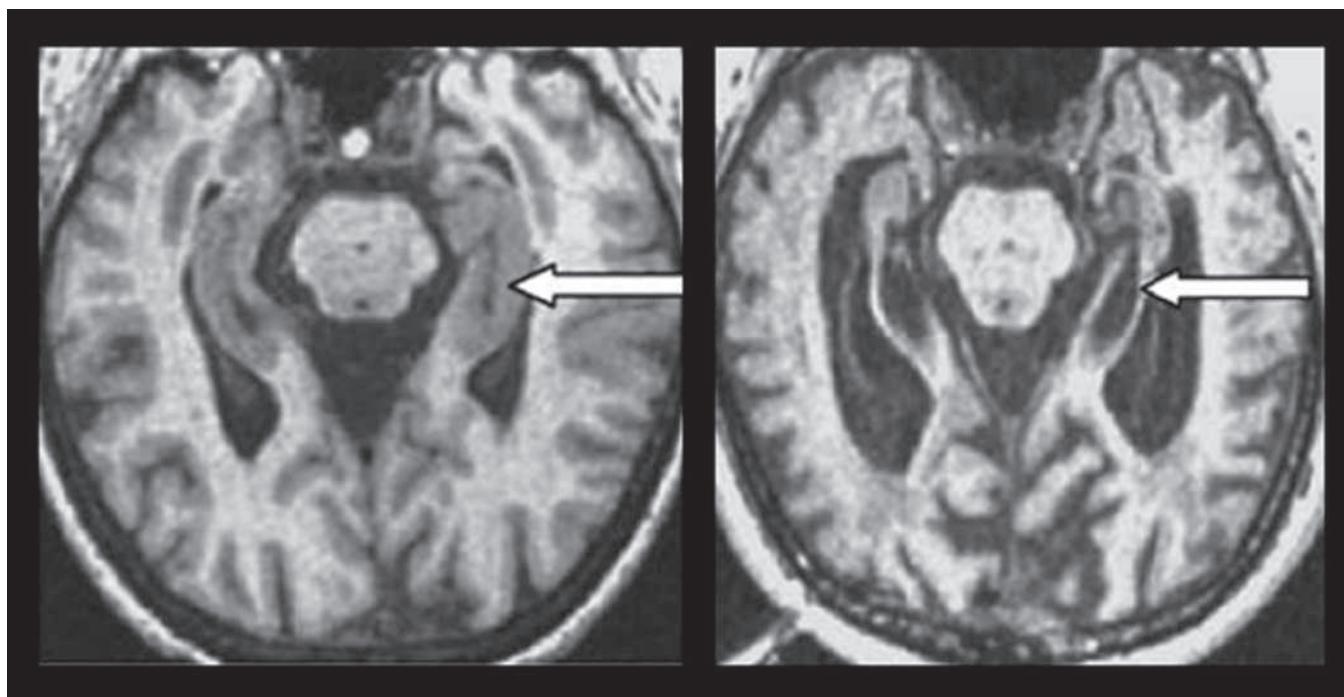

Not surprisingly, researchers are now actively studying the effects of exercise in patients with Alzheimer's disease. Recent findings suggest that even a short program of exercise for 4 months conducted at home under the supervision of a carer or other family member can improve cognitive and physical functioning in elderly patients with Alzheimer's disease (Vreugdenhil et al., 2012). Inexpensive and easy to implement, exercise programs are now providing some much needed hope for patients and families coping with dementia.

(non-memory-related) cognitive problems are also predictive of later Alzheimer's disease (Storandt, 2008).

Brain scans of people with MCI show that, like patients with Alzheimer's disease, they have atrophy in a number of brain areas, including the hippocampus (which you may recall is involved in memory) (Chételat et al., 2003; Kubota et al., 2005; Devanand et al., 2007). Moreover, reduction in the size of the

hippocampus predicts the later development of Alzheimer's disease both in people with MCI and in elderly people who do not report any memory or cognitive impairments (De Leon et al., 2004; den Heijer et al., 2006). This suggests that atrophy of this brain area is an early sign of the disease.

Functional imaging techniques also show that the hippocampus is less active when patients with Alzheimer's disease

Atrophy of the hippocampus, a brain area critical for memory, is an early sign of Alzheimer's disease. In these pictures, arrows highlight the body of the hippocampus. Note the atrophy in the image on the right.

(compared to controls) are engaged in memory tasks (Kato et al., 2001; Sperling et al., 2003). Again, this is also true of people with MCI (Chételat et al., 2003; De Santi et al., 2001). These findings are in contrast to those found in people who are cognitively normal but who are at high risk because they carry the APOE-E4 allele. These people do not show a lack of activation in the hippocampus when they are involved in memory tasks. Instead, brain-imaging studies reveal the opposite. Rather than underactivity, people who are at genetic high risk show increased activity in various parts of the brain, including the hippocampus, when they engage in memory tasks (Bookheimer et al., 2000; Smith, Andersen et al., 2002).

How can we explain these rather contradictory findings? Current thinking is that the greater degree of brain activation in people who are cognitively normal but at high risk for developing Alzheimer's disease reflects the greater effort they need to make to manage cognitive tasks. Simply put, carriers of the APOE-E4 allele may have to work harder. Because their brain tissue is still healthy (unlike in people with Alzheimer's disease or MCI), we see an *increase* in brain activation in response to a cognitive challenge rather than the decrease in activation that is more typical of Alzheimer's disease patients or those with MCI. A similar pattern of increased brain activation in certain key areas is also found in people with MCI who are able to perform better on cognitive tests compared to those who perform worse (Clément & Belleville, 2010).

Does brain-imaging research allow us to identify people who are going to develop dementia? Not yet. None of the changes found to date are specific enough to be used to make an early diagnosis. This, however, is the goal for the future. In the meantime, if you want to preserve your brain, you might consider reading The World Around Us box on page 498. And if you think this information is just for older people, keep in mind that the brain starts to decrease in size after about age 18. By the time we reach the age of 80, our brain has lost about 15 percent of its original weight (Perl, 1999).

**SUPPORTING CAREGIVERS** In the past few decades there has been a sharp increase in the number of dementia special care units in nursing homes. The vast majority of patients with dementia will be institutionalized before they die. Until patients reach the stage of being severely impaired, however, most live in the community, cared for by their family members. Very often, the burden of care falls on a single person.

Any comprehensive approach to therapeutic intervention must consider the stresses experienced by caregivers. Some of the heartbreak losses that they encounter are depicted in such movies as *Iris* and *Away from Her*. In 2008 former Supreme Court justice Sandra Day O'Connor disclosed that her husband, who suffered from Alzheimer's disease, had found new happiness by developing a romantic relationship with a fellow Alzheimer's sufferer in the facility in which he lived. Although this story garnered a great deal of media attention, it is far from a rare

Why must therapeutic interventions also consider the caregivers of Alzheimer's patients?

occurrence. Not all families are able to cope with this difficult situation with the love and grace that characterized Sandra Day O'Connor and her family.

Not surprisingly, as a group, caregivers are at high risk for becoming socially isolated and for developing depression (Richards & Sweet, 2009). One study showed that in those caregivers who were not clinically depressed, cortisol levels were essentially similar to those in patients with major depression (Da Roza et al., 2001). Caregivers of patients with Alzheimer's disease tend to consume high quantities of psychotropic medication themselves and to report many stress symptoms and poor health (Cummings, 2004; Hinrichsen & Niederehe, 1994). Providing caregivers with counseling and supportive therapy is very beneficial and produces measurable reductions in their levels of depression (Mittelman et al., 2004).

### Neurocognitive Disorder Associated with HIV-1 Infection

Infection with the human immunodeficiency virus (HIV) wreaks havoc on the immune system. Over time, this infection can lead to acquired immune deficiency syndrome, or AIDS. Worldwide, the HIV type 1 virus has infected more than 36 million people and resulted in approximately 20 million deaths (Kaul et al., 2005).

In addition to devastating the body, the HIV virus is also capable of inducing neurological disease that can result in neurocognitive problems. This can happen in two ways. First, because the immune system is weakened, people with HIV are more susceptible to rare infections caused by parasites and fungi. However, the virus also appears capable of damaging the brain more

directly, resulting in neuronal injury and destruction of brain cells (see Kaul et al., 2005; Snider et al., 1983).

The neuropathology of **HIV-associated neurocognitive impairment** involves various changes in the brain, among them generalized atrophy, edema (swelling), inflammation, and patches of demyelination (Adams & Ferraro, 1997; Sewell et al., 1994). No brain area may be entirely spared, but the damage appears to be concentrated in subcortical regions, notably the central white matter, the tissue surrounding the ventricles, and deeper gray matter structures such as the basal ganglia and thalamus. Ninety percent of patients with AIDS show evidence of such changes on autopsy (Adams & Ferraro, 1997).

The neuropsychological features of AIDS tend to appear as a late phase of HIV infection, although they often appear before the full development of AIDS itself. They begin with mild memory difficulties, psychomotor slowing, and diminished attention and concentration (see Fernandez et al., 2002, for a review). Progression is typically rapid after this point, with clear-cut dementia appearing in many cases within 1 year, although considerably longer periods have been reported. The later phases also include behavioral regression, confusion, psychotic thinking, apathy, and marked withdrawal.

Estimates from the early 1990s suggested HIV-related dementia was present in 20 to 30 percent of people with advanced HIV disease. Fortunately, the arrival of highly active antiretroviral therapy has not only resulted in infected people living longer but has also reduced the prevalence of HIV-related dementia to around 10.5 percent (Kaul et al., 2005). However, although rates of frank dementia have decreased, around 30 percent of people who are infected with the HIV virus show some signs of MCI (Treisman et al., 2009). Moreover, for reasons that are not yet clear, women may be at especially high risk of HIV-related cognitive impairment.

Treatment with antiretroviral therapy does not fully prevent the HIV virus from damaging the brain (Kaul et al., 2005). This may be because HIV penetrates into the nervous system soon after a person becomes infected. What this means is that even though the new therapies have made HIV/AIDS a chronic but manageable condition (at least for those who have access to the necessary medications), prevention of infection remains the only certain strategy for avoiding the cognitive impairments associated with this disease.

## Neurocognitive Disorder Associated with Vascular Disease

Neurocognitive disorder associated with vascular disease (**vascular dementia**) is frequently confused with Alzheimer's disease because of its similar clinical picture of progressive dementia and its increasing incidence and prevalence rates with advancing age.

However, it is an entirely different disease in terms of its underlying neuropathology. In this disorder, a series of circumscribed cerebral infarcts—interruptions of the blood supply to minute areas of the brain because of arterial disease, commonly known as “small strokes”—cumulatively destroy neurons over expanding brain regions. The affected regions become soft and may degenerate over time, leaving only cavities. Although vascular cognitive impairment tends to have a more varied early clinical picture than Alzheimer's disease (Wallin & Blennow, 1993), the progressive loss of cells leads to brain atrophy and behavioral impairments that ultimately mimic those of Alzheimer's disease (Bowler et al., 1997).

Vascular cognitive impairment tends to occur after the age of 50 and affects more men than women (Askin-Edgar et al., 2002). Abnormalities of gait (e.g., being unsteady on one's feet) may be an early predictor of this condition (Vergheze et al., 2002). Vascular cognitive impairment is less common than Alzheimer's disease, accounting for only 19 percent of dementia cases in a community sample aged 65 years or older (Lyketsos et al., 2000). One reason for this is that these patients have a much shorter course of illness because they are vulnerable to sudden death from stroke or cardiovascular disease (Askin-Edgar et al., 2002). Accompanying mood disorders are also more common in vascular dementia than in Alzheimer's disease, perhaps because subcortical areas of the brain are more affected (Lyketsos et al., 2000).

The medical treatment of vascular dementia, though complicated, offers slightly more hope than that of Alzheimer's disease. Unlike Alzheimer's disease, the basic problem of cerebral arteriosclerosis (decreased elasticity of brain arteries) can be medically managed to some extent, perhaps decreasing the likelihood of further strokes. The daunting problems that caregivers face, however, are much the same in the two conditions, indicating the appropriateness of support groups, stress reduction techniques, and the like.

## Amnestic Disorder

“Amnestic” is just another way of saying “amnesia,” and the characteristic feature of **amnestic disorder** is strikingly disturbed memory. Immediate recall (i.e., the ability to repeat what has

just been heard) is not usually affected. Memory for remote past events is also usually relatively preserved. However, short-term memory is typically so impaired that the person is unable to recall events that took place only a few minutes previously. To compensate, patients sometimes confabulate, making up events to fill in the void that they have in their memories.

In contrast to patients with other forms of neurocognitive disorders, overall cognitive functioning in an amnestic disorder patient is often quite good. The affected person may be able to execute a complex task if it provides its own distinctive cues for each stage of the sequence.

Brain damage is the root cause of amnestic disorder. This damage might be caused by strokes, injury, tumors, or infections (Andreascu & Aizenstein, 2009). However, not all brain damage is permanent. **Korsakoff's syndrome** is an amnestic disorder that is caused by deficiency in vitamin B1 (thiamine). Because of this, the memory problems associated with Korsakoff's syndrome can sometimes be reversed if it is detected early enough and vitamin B1 is given. Korsakoff's syndrome is often found in chronic alcoholics or in other people who do not eat healthily. It was the cause of the memory loss of the patient in the next case study.

→ **He Forgot the Name of His Daughter** A powerfully built six-footer, Charles Jackson still showed traces of a military bearing. Before he left the army a year before, he had been demoted to buck private; this was the culmination of a string of disciplinary actions for drunkenness.

For over a year he had had monthly consultations with the current interviewer. On this occasion, the interviewer asked when they had last met. Charles replied, "Well, I just don't know. What do you think?" To the follow-up question, he said he guessed he had seen the interviewer before. "Maybe it was last week."

Asking him to remain seated, the interviewer went into the waiting room to ask Mrs. Jackson how she thought her husband was doing. She said, "Oh, he's about the same as before. He sketches some. But mostly he just sits around the house and watches TV. I come home and ask him what he's watching, but he can't even tell me."

At any rate, Charles was no longer drinking, not since they had moved to the country. It was at least 2 miles to the nearest convenience store, and he didn't walk very well anymore. "But he still talks about drinking. Sometimes he seems to think he's still in the army. He orders me to go buy him a quart of gin."

Charles remembered quite a few things, if they happened long enough ago—the gin, for example, and getting drunk with his father when he was a boy. But he couldn't remember the name of his daughter, who was two and a half. Most of the time, he just called her "the girl."

The interviewer walked back into the inner office. Charles looked up and smiled.

"Have I seen you before?" asked the interviewer.  
"Well, I'm pretty sure."  
"When was it?"  
"It might have been last week."

Source: Adapted from Morrison, 1995, pp. 50–51.

.....

In *DSM-IV* amnestic disorder was a specific and distinct diagnosis. In *DSM-5*, patients who would have been given this diagnosis will now be diagnosed as having a major neurocognitive disorder. The cause of the disorder will also be listed (e.g., major neurocognitive disorder due to substance use). Unlike other forms of neurocognitive disorder, however, the substantial decline in functioning occurs in a single cognitive domain (memory).

Another common cause is head trauma. Stroke, surgery in the temporal lobe area of the brain, hypoxia (oxygen deprivation), and some forms of brain infections (such as encephalitis) can also lead to amnestic disorder. In these cases, depending on the nature and extent of damage to the affected neural structures and on the treatment undertaken, the disorder may remit with time. A wide range of techniques have been developed to assist the good-prognosis amnestic patient in remembering recent events (e.g., Gouvier et al., 1997). Moreover, because procedural memory (i.e., the ability to learn routines, skills, and actions) is often preserved in patients with amnesia, even patients without memory for specific personal experiences can still be taught to perform tasks that might help them reenter the workforce (Cavaco et al., 2004).

## Disorders Involving Head Injury

**Traumatic brain injury (TBI)** occurs frequently, affecting just under 2 million people each year in the United States. The most common cause of TBI are falls, followed by motor vehicle accidents. Other causes include assaults and sports injuries (although the vast majority of these are probably never even reported). Children aged 0 to 4, adolescents aged 15 to 19, and adults aged 65 years and older are most likely to experience a TBI. In every age group rates of TBI are higher for males than they are for females (Faul et al., 2010). In *DSM-5* diagnostic terms such as major (or mild) neurocognitive disorder associated with head trauma are used to refer to the cognitive compromises that result from head injury.

Former Arizona Congresswoman Gabrielle Giffords is recovering from a traumatic brain injury sustained after an assailant shot her in the head. She is receiving extensive therapy and is making considerable progress.

We are also now experiencing an escalation of cases of TBI caused by explosive blasts (Champion et al., 2009). Blasts seem to damage the brain in ways that are different from the brain damage seen in civilian cases of TBI. So many veterans have been injured by improvised explosive devices that TBI has been referred to as the signature injury of the Iraq War. Research suggests that around 15 percent of soldiers who have served in Iraq have experienced a TBI (Hoge et al., 2008). The military is now making efforts to improve screening and to increase rehabilitation service for veterans (see Munsey, 2007). However, for many, a full recovery may never be possible.

### Clinical Picture

Clinicians categorize brain injuries as resulting from either a closed-head injury (where the cranium remains intact) or a penetrating head injury (where some object such as a bullet enters the brain). In closed-head injury, the damage to the brain is indirect—caused by inertial forces that cause the brain to come into violent contact with the interior skull wall or by rotational forces that twist the brain mass relative to the brain stem. Not uncommonly, closed-head injury also causes diffuse neuron damage because of the inertial force. In other words, the rapid movement of the rigid cranium is stopped on contact with an unyielding object. However, the softer brain tissue within keeps moving, and this has a shearing effect on nerve fibers and their synaptic interconnections.

Severe head injuries usually cause unconsciousness and disruption of circulatory, metabolic, and neurotransmitter regulation. Normally, if a head injury is severe enough to result in

unconsciousness, the person experiences **retrograde amnesia**, or inability to recall events immediately preceding the injury. Apparently, the trauma interferes with the brain's capacity to consolidate into long-term storage the events that were still being processed at the time of the trauma. **Anterograde amnesia** (also called posttraumatic amnesia) is the inability to store effectively in memory events that happen during variable periods of time *after* the trauma. It is also frequently observed and is regarded by many as a negative prognostic sign.

A person rendered unconscious by a head injury usually passes through stages of stupor and confusion on the way to recovering clear consciousness. This recovery of consciousness may be complete in the course of minutes, or it may take hours or days. Following a severe injury and loss of consciousness, a person's pulse, temperature, blood pressure, and important aspects of brain metabolism are all affected, and survival may be uncertain. In rare cases, an individual may live for extended periods

of time without regaining consciousness, a condition known as *coma*. The duration of the coma is generally related to the severity of the injury. If the patient survives, coma may be followed by delirium, marked by acute excitement and disorientation and hallucinations. Gradually the confusion may clear up and the individual may regain contact with reality. Individual courses of recovery are highly variable and difficult to predict (Waters & Nicoll, 2005).

Large numbers of relatively minor closed-head brain concussions and contusions (bruises) occur every year as a result of car accidents, athletic injuries, falls, and other mishaps. Even riding roller coasters that generate high G-forces may cause brain injury

Exposure to high G-forces, such as those experienced on some theme park rides, can cause neurological injury in some individuals by creating small tears in delicate blood vessels in the brain.

**TABLE 14.5**  
**Signs of a Concussion**

Temporary loss of consciousness
Confusion or foggy feeling in the brain
Amnesia for the period surrounding the event/injury
Headache that gets worse and doesn't go away
Nausea or vomiting
Excessive drowsiness
Slurred or incoherent speech
Difficulty remembering new information
Dizziness
These symptoms may not be immediately apparent.
Some symptoms may develop several days after the injury.

in some people (see Fukutake et al., 2000). It is estimated that two deaths per year can be attributed to brain hemorrhages that result from roller coaster rides (Pelletier & Gilchrist, 2005). Although these statistics are unlikely to dissuade you from heading to a theme park the next time you want to have some fun, they have prompted some calls for greater oversight of the industry.

People who play certain sports are at high risk of experiencing concussions and brain injuries. For males, the greatest risk comes from playing football; for females, the greatest risk comes from playing soccer (Lincoln et al., 2011). Signs of concussion are listed in Table 14.5. However, the majority of concussions do not involve a loss of consciousness. It is important to know that, after a concussion, the brain is four or five times more vulnerable to a second impact and that this increased vulnerability lasts for several weeks. As described in The World Around Us box on page 504, and as illustrated in the following case study, athletes at every level sometimes want to get back into the game without adequate recovery time, often with devastating consequences. In an effort to deal with this problem, many States now require that young people who have sustained a sports-related brain injury must see a doctor before they can be allowed to play again. Return to play protocols are also being established (Sahler & Greenwald, 2012).

→ **Zack's Story** Zack, a gifted athlete who played both offense and defense on his junior high school football team, was injured at 13 when his head struck the ground after tackling an opponent. The official called a time out, and Zack was sidelined for just three plays before half-time. Despite the blow, Zack shook it off

and by the start of the third quarter he was back in the game. "He always wanted to be part of the play" his father recalls.

After a hard-played second half, Zack collapsed on the field. He was airlifted to a medical facility where he underwent emergency life-saving surgery to remove the left and right side of his skull to relieve pressure from his injured and swelling brain. He experienced numerous strokes, spent 7 days on a ventilator, and was in a coma for 3 months before he awoke to a new reality. It was 9 months before Zack spoke his first word, 13 months before he could move a leg or an arm, and he spent 20 months on a feeding tube. Confined to a wheelchair, it was nearly 3 years until Zack was able to stand, with assistance, on his own two feet.

In 2009 the state of Washington passed a new law named after Zack. It requires that any young athlete who shows signs of a concussion be examined and cleared for play by a licensed health care provider. The law protects young athletes from the kind of life-threatening and potentially life-long consequences that can be caused by shaking off an injury and returning to play. Source: Adapted from CDC, 2010.

We are also learning something about the factors that may increase a person's susceptibility to having problems after a brain injury. One important risk factor appears to be the presence of the APOE-E4 allele that we discussed earlier (Waters & Nicoll, 2005). In one study of boxers, the presence of the APOE-E4 genetic risk factor was associated with more chronic neurological deficits (Jordan et al., 1997). A study of patients being treated in a neurosurgical unit found that APOE-E4 predicted patients doing more poorly at a 6-month follow-up. This was true even after controlling for such factors as severity of the initial injury (Teasdale et al., 1997).

Perhaps the most famous historical example of TBI is the case of Phineas Gage (Harlow, 1868). Gage, 25 years old, was

Though Phineas Gage survived when a tamping iron entered his face and shot through his head, his personality was altered such that his friends found that he was "no longer Gage."

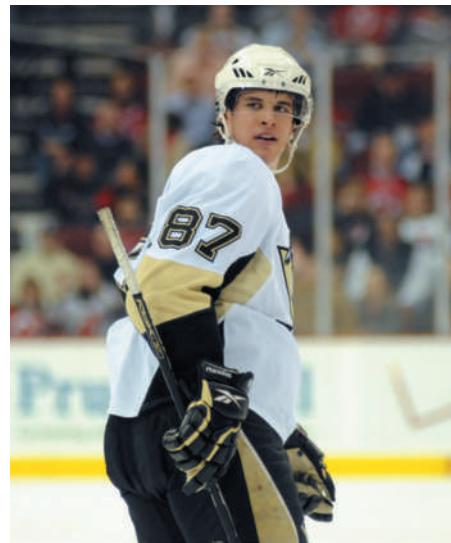

## Brain Damage in Professional Athletes

For athletes, collisions are often part of the game. But new evidence is forcing many in collegiate and professional sports to consider the potential for long-term brain damage that may come from heading the ball or tackling another player. This issue came to the attention of sports fans when Ted Johnson, a former Super Bowl champion and linebacker for the New England Patriots, went public about the crippling depressions and headaches he now experiences (MacMullan, 2007). Johnson, who has been diagnosed with a chronic postconcussion syndrome (involving fatigue, irritability, memory loss, and depression), is also showing signs of early brain damage. He believes that his problems are a direct result of the multiple hits to the head he sustained during his playing career.

Repeat concussions are very serious. After a blow to the head, the brain remains in a vulnerable state for several weeks. A second injury during this time will cause an exponential amount of damage. Johnson's cognitive functioning declined dramatically after he was involved in a serious collision during an exhibition game and had to be pulled off the field. Four days later, he was expected to engage in full contact during practice. Although he knew this was a bad idea, his pride, combined with the pressure not to appear weak, kept him from asking to be excused from the physical drills. During the practice he took a minor hit and experienced the warm and hazy sensation that signals a concussion. For Johnson, it was the beginning of the end.

Johnson decided to go public with his story after the suicide of former NFL defensive back Andre Waters. Waters, who was known to be a tough and hard-hitting player, suffered many repeat concussions during the course of his career. After his death at age 44, a neurologist examined his brain and reported that the tissue resembled that of an 85-year-old; Waters also had some signs of Alzheimer's disease. Repeat concussions were suspected to be the cause of his brain damage.

Research supports this speculation. A study of 2,552 retired professional football players showed that the majority (61 percent) had experienced at least one concussion during their playing careers. Moreover, those players who had a history of three or

Sidney Crosby, captain of the Pittsburgh Penguins hockey team, experienced concussion-like symptoms for more than a year after being injured. He wisely took time to recover before returning to the ice.

more concussions were five times more likely to be diagnosed with cognitive problems and had three times more memory impairment than players with no concussion history (Guskiewicz et al., 2005). Players who had had repeat concussions were also more likely to later be diagnosed with depression (Guskiewicz et al., 2005).

The risks associated with concussions are now being taken very seriously in the NFL and also in the NHL. Several hockey players have had their careers cut short by concussions. In 2011, Sidney Crosby, captain of the Pittsburgh Penguins waited 10 months to return to the ice after experiencing two concussions only to be sidelined again shortly afterwards. He is now playing again. After taking a hit, staying out of future games until the brain has had enough time to heal is of critical importance.

the foreman of a gang of men who were building a railroad in Cavendish, Vermont. On September 13, 1848, there was an accident, and an iron rod (3 feet 7 inches in length, about an inch in diameter, and weighing just over 13 pounds) was blown through Gage's skull, entering through his lower cheek. Gage was thrown back by the force of the explosion but started to speak a few minutes later. His men put him in an ox cart and took him to his hotel, whereupon he walked, with a little assistance, to his room, bleeding profusely. Miraculously, Gage survived the accident and eventually made a full physical recovery. However, in other respects he was a different man. What was most striking was

the change in his personality. As his doctor noted, "He is fitful, irreverent, indulging at times in the grossest profanity (which was not previously his custom), manifesting but little deference for his fellows, impatient of restraint or advice when it conflicts with his desires, at times pertinaciously obstinate, yet capricious and vacillating, devising many plans of future operations, which are no sooner arranged than they are abandoned in turn for others" (Harlow, 1868, p. 327). As others have noted, changes such as this (emotional dyscontrol, personality alterations, and impairment of self-awareness) are fairly characteristic of severe damage to the frontal lobes (Stuss et al., 1992).

## Treatments and Outcomes

As illustrated in the case of Zack, prompt medical treatment of a brain injury may be necessary to save the person's life and remove the pressure on the brain caused by intense swelling. Immediate medical treatment may also have to be supplemented by a long-range program of reeducation and rehabilitation involving many different professionals.

Although many TBI patients show few residual effects from their injury, particularly if they have experienced only a brief loss of consciousness, other patients sustain definite and long-lasting impairment. Common symptoms of minor TBI include headaches, memory problems, sensitivity to light and sound, dizziness, anxiety, irritability, fatigue, and impaired concentration (Miller, 2011). When the brain damage is extensive, a patient's general intellectual level may be considerably reduced, especially if there is damage to the temporal lobe or parietal lobes. Most people have significant delays in returning to their occupations, and many are unable to return at all (Dikmen et al., 1994). Other losses of adult social role functioning are also common (Hallett et al., 1994). Some 24 percent of TBI cases, overall, develop posttraumatic epilepsy, presumably because of the growth of scar tissue in the brain. Seizures usually develop within 2 years of the head injury. For decades after a head injury, there is also an elevated risk of depression as well as other disorders such as substance abuse, anxiety disorders, and personality disorders (Holsinger et al., 2002; Koponen et al., 2002).

In a minority of brain injury cases, dramatic personality changes occur such as those described in the case of Phineas Gage. Other kinds of personality changes include passivity, loss

Video games are now being used in the treatment of traumatic brain injury.

of drive and spontaneity, agitation, anxiety, depression, and paranoid suspiciousness. Like cognitive changes, the kinds of personality changes that emerge in severely damaged people depend, in large measure, on the site and extent of their injury (Prigatano, 1992). However, even though more than half the people who sustain TBI develop psychological symptoms, and even though alleviation of such symptoms can improve rehabilitation outcome, there are currently few studies of risk factors, pathogenesis, and treatment of these disturbances (Rao & Lyketsos, 2002).

Children who undergo significant TBI are more likely to be adversely affected the younger they are at the time of injury and the less language, fine-motor, and other competencies they have. This is because brain damage makes it harder to learn new skills and because young children have fewer developed skills to begin with. The severity of their injury and the degree to which their environment is accommodating also affect children's recovery (Anderson et al., 1997; Taylor & Alden, 1997; Yeates et al., 1997). When the injury is minor, most children emerge without lasting negative effects (Satz et al., 1997).

Treatment of TBI beyond the purely medical phase is often long, difficult, and expensive. It requires careful and continuing assessment of neuropsychological functioning and the design of interventions intended to overcome the deficits that remain. Many different treatment approaches are used including medication, rehabilitative interventions (such as occupational, physical, and speech/language therapy, cognitive therapy, behavior therapy, social skills training, vocational and recreational therapy) as well as individual, group, and family therapy (Hampton, 2011). Often, a treatment goal is to provide patients with new techniques to compensate for losses that may be permanent (Bennett et al., 1997). Research is also showing that patients with TBI may sometimes benefit from treatment with donepezil, an acetylcholinesterase inhibitor widely used in the treatment of Alzheimer's disease (Zhang et al., 2004). Table 14.6 shows some

**TABLE 14.6**  
**Predictors of Clinical Outcome After Traumatic Brain Injury**

Outcome is more favorable when there is:

- only a short period of unconsciousness or posttraumatic anterograde amnesia
- minimal cognitive impairment
- a well-functioning preinjury personality
- higher educational attainment
- a stable preinjury work history
- motivation to recover or make the most of residual capacities
- a favorable life situation to which to return
- early intervention
- an appropriate program of rehabilitation and retraining

of the variables that are associated with patients having a more favorable outcome after a TBI.

### in review

- Why is it so important to take concussions very seriously?
- What is the link between the APOE-E4 allele and problems after head injury?

- What kinds of clinical problems are associated with head injury in the short and longer term?
- What factors are associated with the degree of disability after head injury?

## UNRESOLVED issues

### Should Healthy People Use Cognitive Enhancers?

In the search for a cognitive advantage, many healthy people, young and old, are now turning to drugs that may provide cognitive benefits. Many of us routinely use caffeine, which improves vigilance, working memory, and incidental learning. Others use nicotine, which, although clearly detrimental to health when smoked, may enhance attention, working memory, and attention in the short term (Husain & Mehta, 2011; Lanni et al., 2008).

A more recent trend, however, involves the use of prescription stimulants. These include methylphenidate (Ritalin), which is used in the treatment of attention deficit disorder, and modafinil (Provigil), which is used as a wake-promoting agent for people with excessive daytime sleepiness. These compounds (which are not always legally prescribed) are now being used by students seeking better grades as well as by military personnel who need to remain awake during long missions.

Studies suggest that physicians are disinclined to prescribe these medications to young, cognitively healthy people (Banjo

et al., 2010). In part, this reluctance stems from concerns about the safety of these compounds and beliefs that the benefits they provide are very small. Certainly, evidence suggests that the benefits of cognitive enhancers in healthy individuals are indeed very modest. But there are ethical issues, too (Hyman, 2011; Lanni et al., 2008). Should drugs developed as treatments be used as cognitive enhancers in people who do not have the disorders the drugs were designed to help? What do you think? Would you take a drug approved for Alzheimer's disease if you thought it would help you do better on a test? Who is most likely to have access to these cognitive enhancers? And will their use lead to a "cognitive arms race" rather like that in some professional sports where athletes who do not take steroids are highly disadvantaged? Is it possible that students of the future might be required to provide a urine sample before taking a high-stakes exam?

# 14

## summary

### 14.1 What forms of neurocognitive disorders are recognized in DSM-5? What is presumed to be the cause of these disorders?

- The *DSM-5* recognizes major and mild forms of neurocognitive disorders as well as delirium. These disorders are thought to result from transient or permanent damage to the brain. Chronic neurocognitive disorders involve the permanent loss of neural cells.

### 14.2 What are the clinical features of neurocognitive disorders?

- Major neurocognitive disorders involve a loss of function and of previously acquired skills. Depending on the cause, the onset can be slow or gradual with a deteriorating course. The most common cause of major neurocognitive disorders is Alzheimer's disease.
- There is no simple relationship between the extent of brain damage and degree of impaired functioning. Some people who have severe damage develop no severe symptoms, whereas some with slight damage have extreme reactions.

### 14.3 What is delirium and how is it treated?

- Delirium has a sudden onset. Common among the elderly, it is characterized by a state of awareness that fluctuates between wakefulness and stupor or coma. Delirium is treated with neuroleptic medications and also with benzodiazepines.

#### **14.4 What are the risk factors for Alzheimer's disease? What changes in the brain are found in patients with Alzheimer's disease?**

- Age is a major risk factor for Alzheimer's disease as well as for other forms of dementia such as vascular dementia.
- Genes play a major role in susceptibility to and risk for Alzheimer's disease. Genetic mutations of the *APP*, *PS1*, and *PS2* genes are implicated in early-onset Alzheimer's disease. The *APOE-E4* allele of the *APOE* gene is also a risk factor for Alzheimer's disease.
- The characteristic neuropathology of Alzheimer's disease involves cell loss, plaques, and neurofibrillary tangles. Plaques contain a sticky protein called beta amyloid. Neurofibrillary tangles contain abnormal tau protein.

#### **14.5 How is Alzheimer's disease treated?**

- Alzheimer's disease causes the destruction of cells that make acetylcholine, a neurotransmitter important for memory. Drug treatments for Alzheimer's disease include cholinesterase inhibitors such as donepezil (Aricept). These drugs help stop ACh from being broken down and so make more of it available to the brain.
- Any comprehensive treatment approach for neurocognitive disorders should also involve caregivers, who are often under a great

deal of stress and have difficulty coping. They may benefit from medications as well as from support groups.

#### **14.6 What is an amnestic disorder? What causes amnestic disorders?**

- Amnestic disorders involve severe memory loss. The most common cause of amnestic disorders is chronic alcohol abuse.
- Other causes include head trauma, stroke, surgery, infections, and hypoxia.

#### **14.7 What are some of the clinical consequences of head trauma? What factors are related to the degree of impairment that results?**

- Head injuries can cause amnesia as well as other cognitive impairments. Retrograde amnesia is inability to recall events that preceded the trauma. Anterograde amnesia is inability to remember things that follow it.
- Although such inconsistencies are not completely understood, it appears that an individual's premorbid personality and life situation are important in determining his or her reactions to brain damage. The *APOE-E4* genetic allele is also important. The severity of the trauma, age of the person who is injured, and site of the injury are also important.

### → A Case of Adolescent Depression and Attempted Suicide

**Emily** is 15-year-old girl from a middle-class Caucasian background who had a history of depression during her childhood. She had periods of low mood, poor self-esteem, and social withdrawal. She also had symptoms of anxiety and was very reluctant to leave her home. During her year in the seventh grade, she became so fearful of going to school that she missed so many days she had to repeat the grade. She currently is in the eighth grade and has, to this point, missed a great deal of school. Her family became very concerned over Emily's low mood and isolation, so they enrolled her in an outpatient treatment program for depression, anxiety episodes, and eating disorders. Her depression continued, and she became more isolated, lonely, and depressed and would not leave her room even for meals. One day her grandmother found her in their car in the garage with the engine running in an effort to end her life. Emily was admitted into an inpatient treatment program following her serious suicide attempt.

There is a history of psychiatric problems, particularly mood disorders, in her family. Her mother has been hospitalized on three occasions for depression. Her maternal grandfather, now deceased, was hospitalized at one time following a manic depressive episode.

In the early phases of her hospitalization, Emily underwent an extensive psychological and psychiatric evaluation. She was administered a battery of tests, including the Minnesota

Multiphasic Personality Inventory for Adolescents (MMPI-A). She was cooperative with the evaluation and provided the assessment staff with sufficient information regarding her mood and attitudes to assist in developing a treatment program.

Emily showed many symptoms of a mood disorder in which both depression and anxiety were prominent features. The psychological evaluation indicated that she was depressed, anxious, and felt unable to deal with the school stress that her condition prompted. Moreover, her physical appearance and eating behavior suggested the strong likelihood of anorexia nervosa. Emily showed an extreme degree of social introversion on several measures and acknowledged her reticence at engaging in social interactions. The assessment psychologist concluded that her personality characteristics of social withdrawal, isolation, and difficult interpersonal relationships would likely result in her having problems in establishing a therapeutic relationship. Her treatment program involved supportive cognitive therapy along with antidepressant medication.

Although she endorsed a broad range of anxiety symptoms, in her testing and in the intake interview she endorsed few items regarding suicidal ideation. This was not sufficient evidence to support a conclusion that she was at less risk for suicide; however, it could simply reflect her unwillingness to openly discuss her recent attempt. Her past behavior and low mood indicated a need to consider the possibility of further suicide attempts.

She remained in inpatient treatment for 3 weeks and was discharged with the summary that she had shown substantial improvement. She was, however, referred for further psychological treatment on an outpatient basis.

Source: Adapted from Williams & Butcher, 2011, pp. 151–63.

Until the twentieth century, little account was taken of the special characteristics of psychopathology in children; maladaptive patterns considered relatively specific to childhood, such as autism, received virtually no attention at all. Only since the advent of the mental health movement and the availability of child guidance facilities at the beginning of the twentieth century have marked strides been made in assessing, treating, and understanding the maladaptive behavior patterns of children and adolescents.

The problems of childhood were initially seen simply as downward extensions of adult-oriented diagnoses. The prevailing view was one of children as "miniature adults." But this view failed to recognize special problems, such as those associated with the developmental changes that normally take place in childhood or adolescence. Only relatively recently have clinicians come to realize that they cannot fully understand childhood disorders without taking these developmental processes into account. Today, even though great progress has been made in providing treatment for disturbed children, facilities are still inadequate to the task, and most children with mental health problems do not receive psychological attention.

The number of children affected by psychological problems is considerable. Research studies in several countries have provided estimates of childhood disorders. Roberts, Roberts, et al. (2007)

found that 17.1 percent of adolescents in large metropolitan areas of the United States meet the criteria for one or more *DSM* diagnoses. Verhulst (1995) conducted an evaluation of the overall prevalence of childhood disorder based on 49 studies involving over 240,000 children across many countries and found the average rate to be 12.3 percent. In most studies, maladjustment is found more commonly among boys than among girls; however, for some diagnostic problems, such as eating disorders (see Chapter 8), rates are higher for girls than for boys. The most prevalent disorders are attention-deficit/hyperactivity disorder (ADHD) (Ryan-Krause et al., 2010) and separation anxiety disorders (Cartwright-Hatton et al., 2006). Some subgroups of the population—for example, Native Americans—tend to have higher rates of mental disorders. One study reported that 23 percent of the Native American children rated in the sample met criteria for 1 of the 11 mental disorders in the survey and 9 percent met criteria for 2 or more of the disorders (Whitbeck et al., 2006).

## Maladaptive Behavior in Different Life Periods

Several behaviors that characterize maladjustment or emotional disturbance are relatively common in childhood. Because of the manner in which personality develops, the various steps in growth and development, and the differing stressors people face in childhood, adolescence, and adulthood, we would expect to find some differences in maladaptive behavior in these periods. The fields of developmental science (Hetherington, 1998) and, more specifically, **developmental psychopathology** (Kim-Cohen, 2007) are devoted to studying the origins and course of individual maladaptation in the context of normal growth processes.

It is important to view a child's behavior in the context of normal childhood development (Silk et al., 2000). We cannot consider a child's behavior abnormal without determining whether the behavior in question is appropriate for the child's age. For example, temper tantrums and eating inedible objects might be viewed as abnormal behavior at age 10 but not at age 2. Despite the somewhat distinctive characteristics of childhood disturbances at different ages, there is no sharp line of demarcation between the maladaptive behavior patterns of childhood and those of adolescence, or between those of adolescence and those of adulthood. Thus, although our focus in this chapter will be on the behavior disorders of children and adolescents, we will find some inevitable carryover into later life periods.

### Varying Clinical Pictures

The clinical picture of childhood disorders tends to be distinct from the clinical picture of disorders in other life periods. Some of the emotional disturbances of childhood may be relatively short lived and less specific than those occurring in adulthood. However, some childhood disorders severely affect future development. One study found that individuals who had been

hospitalized as child psychiatric patients (between the ages of 5 and 17) died early in life due to unnatural causes (about twice the rate of the general population) when followed up from 4 to 15 years later (Kuperman et al., 1988). The suicide risk among some disturbed adolescents is long-lasting and requires careful follow-up and attention (Fortune et al., 2007). Suicidal thoughts are not uncommon in children. Riesch and colleagues (2008) report that 18 percent of sixth graders have thoughts of killing themselves. Two other recent studies have reported rates for children under age 15. Dervic, Brent, and Oquendo (2008) report that international suicide rates are 3.1 per million. Hawton and Harriss (2008) report that the long-term risk of suicide is 1.1 percent, with girls more likely than boys to commit suicide. Both studies report that difficult family relationships are the leading cause of suicidal behavior. Being bullied by another child is another factor that has been found to be associated with risk of suicide (Rivers & Noret, 2010).

## Special Psychological Vulnerabilities of Young Children

Young children are especially vulnerable to psychological problems (Ingram & Price, 2001). In evaluating the presence or extent of mental health problems in children and adolescents, one needs to consider the following:

- They do not have as complex and realistic a view of themselves and their world as they will have later; they have less self-understanding; and they have not yet developed a stable sense of identity or a clear understanding of what is expected of them and what resources they might have to deal with problems.
- Immediately perceived threats are tempered less by considerations of the past or future and thus tend to be seen as disproportionately important. As a result, children often have more difficulty than adults in coping with stressful events (Mash & Barkley, 2006). For example, children are at risk for posttraumatic stress disorder after a disaster, especially if the family atmosphere is troubled—a circumstance that adds additional stress to the problems resulting from the natural disaster (Menaghan, 2010).
- Children's limited perspectives, as might be expected, lead them to use unrealistic concepts to explain events. For young children, suicide or violence against another person may be undertaken without any real understanding of the finality of death.
- Children also are more dependent on other people than are adults. Although in some ways this dependency serves as a buffer against other dangers because the adults around him or her might "protect" a child against stressors in the environment, it also makes the child highly vulnerable to experiences of rejection, disappointment, and failure if these adults, because of their own problems, ignore the child (Lengua, 2006).
- Children's lack of experience in dealing with adversity can make manageable problems seem insurmountable (Scott

et al., 2010). On the other hand, although their inexperience and lack of self-sufficiency make them easily upset by problems that seem minor to the average adult, children typically recover more rapidly from their hurts.

## The Classification of Childhood and Adolescent Disorders

Until the 1950s no formal, specific system was available for classifying the emotional or behavioral problems of children and adolescents. Kraepelin's (1883) classic textbook on the classification of mental disorders did not include childhood disorders. In 1952, the first formal psychiatric nomenclature (*DSM-I*) was published, and childhood disorders were included. This system was quite limited and included only two childhood emotional disorders: childhood schizophrenia and adjustment reaction of childhood. In 1966, the Group for the Advancement of Psychiatry provided a classification system for children that was detailed and comprehensive. Thus, in the 1968 revision of the *DSM* (*DSM-II*), several additional categories were added. However, growing concern remained—both among clinicians attempting to diagnose and treat childhood problems and among researchers attempting to broaden our understanding of childhood psychopathology—that the then-current ways of viewing psychological disorders in children and adolescents were inappropriate and inaccurate for several reasons. The greatest problem was that the same classification system that had been developed for adults was used for childhood problems even though many childhood disorders, such as autism, learning disabilities, and school phobias, have no counterpart in adult psychopathology. The early systems also ignored the fact that in childhood disorders, environmental factors play an important part in the expression of symptoms—that is, symptoms are highly influenced by a family's acceptance or rejection of the behavior. In addition, symptoms were not considered with respect to a child's developmental level. Some of the problem behaviors might be considered age appropriate, and troubling behaviors might simply be behaviors that the child will eventually outgrow. In the most recent revision of the diagnostic and statistical manual (*DSM-5*), efforts were made to provide diagnostic classification that is consistent with current research and contemporary clinical practice.

### in review

- Define developmental psychopathology.
- Discuss the special psychological vulnerabilities of children.

## Common Disorders of Childhood

At present the *DSM-5* provides diagnoses for a large number of childhood and adolescent disorders or Neurodevelopmental Disorders. In addition, several disorders, involving intellectual disability (formerly referred to as mental retardation) are included. Space limitations do not allow us to explore fully the mental

disorders of childhood and adolescence included in the *DSM* system, so we have selected several disorders to illustrate the broad range of problems that can occur in childhood and adolescence. Some of these disorders are more transient than many of the abnormal behavior patterns of adulthood discussed in earlier chapters—and also perhaps more amenable to treatment while others have a likelihood of persistence.

## Attention-Deficit/Hyperactivity Disorder

**Attention-deficit/hyperactivity disorder (ADHD)**, often referred to as hyperactivity, is characterized by difficulties that interfere with effective task-oriented behavior in children—particularly impulsivity, excessive or exaggerated motor activity, such as aimless or haphazard running or fidgeting, and difficulties in sustaining attention (Nigg et al., 2005; see *DSM-5* Criteria for Attention-Deficit/Hyperactivity Disorder). The diagnostic criteria for ADHD remained relatively unchanged for children and adolescents in *DSM-5*.

Children with ADHD are highly distractible and often fail to follow instructions or respond to demands placed on them (Wender, 2000). Perhaps as a result of their behavioral problems, children with ADHD are often lower in intelligence, usually about 7 to 15 IQ points below average (Barkley, 1997). Children with ADHD also tend to talk incessantly and to be socially intrusive and immature. Recent research has shown that many children with ADHD show deficits on neuropsychological testing that are related to poor academic functioning (Biederman et al., 2004)

 Watch the **Video** *Jimmy: Attention-Deficit/Hyperactivity Disorder* on **MyPsychLab**.

Children with ADHD generally have many social problems because of their impulsivity and overactivity. Hyperactive children usually have great difficulty in getting along with their parents because they do not obey rules. Their behavior problems also result in their being viewed negatively by their peers (Hoza et al., 2005). In general, however, hyperactive children are not anxious, even though their overactivity, restlessness, and distractibility are frequently interpreted as indications of anxiety. They usually do poorly in school and often show specific learning disabilities such as difficulties in reading or in learning other basic school subjects. Hyperactive children also pose behavior problems in the elementary grades. The case study on page 513 reveals a typical clinical picture.

The symptoms of ADHD are relatively common among children seen at mental health facilities in the United States, with from 3 to 7 percent reported in the *DSM* and 8 percent reported in a recent study in the United Kingdom (Alloway et al., 2010). In fact, hyperactivity is the most frequently diagnosed mental health condition in children in the United States (Ryan-Krause et al., 2010). The disorder occurs most frequently among preadolescent boys—it is six to nine times more prevalent

**A.** A persistent pattern of inattention and/or hyperactivity-impulsivity that interferes with functioning or development, as characterized by (1) and/or (2):

- 1. Inattention:** Six (or more) of the following symptoms have persisted for at least 6 months to a degree that is inconsistent with developmental level and that negatively impacts directly on social and academic/occupational activities:
- Note:** The symptoms are not solely a manifestation of oppositional behavior, defiance, hostility, or failure to understand tasks or instructions. For older adolescents and adults (age 17 and older), at least five symptoms are required.
- a. Often fails to give close attention to details or makes careless mistakes in schoolwork, at work, or during other activities (e.g., overlooks or misses details, work is inaccurate).
  - b. Often has difficulty sustaining attention in tasks or play activities (e.g., has difficulty remaining focused during lectures, conversations, or lengthy reading).
  - c. Often does not seem to listen when spoken to directly (e.g., mind seems elsewhere, even in the absence of any obvious distraction).
  - d. Often does not follow through on instructions and fails to finish schoolwork, chores, or duties in the workplace (e.g., starts tasks but quickly loses focus and is easily sidetracked).
  - e. Often has difficulty organizing tasks and activities (e.g., difficulty managing sequential tasks; difficulty keeping materials and belongings in order; messy, disorganized work; has poor time management; fails to meet deadlines).
  - f. Often avoids, dislikes, or is reluctant to engage in tasks that require sustained mental effort (e.g., schoolwork or homework; for older adolescents and adults, preparing reports, completing forms, reviewing lengthy papers).
  - g. Often loses things necessary for tasks or activities (e.g., school materials, pencils, books, tools, wallets, keys, paperwork, eyeglasses, mobile telephones).
  - h. Is often easily distracted by extraneous stimuli (for older adolescents and adults, may include unrelated thoughts).
  - i. Is often forgetful in daily activities (e.g., doing chores, running errands; for older adolescents and adults, returning calls, paying bills, keeping appointments).
- 2 Hyperactivity and impulsivity:** Six (or more) of the following symptoms have persisted for at least 6 months to a degree that is inconsistent with developmental level and

that negatively impacts directly on social and academic/occupational activities:

**Note:** The symptoms are not solely a manifestation of oppositional behavior, defiance, hostility, or a failure to understand tasks or instructions. For older adolescents and adults (age 17 and older), at least five symptoms are required.

- a. Often fidgets with or taps hands or feet or squirms in seat.
  - b. Often leaves seat in situations when remaining seated is expected (e.g., leaves his or her place in the classroom, in the office or other workplace, or in other situations that require remaining in place).
  - c. Often runs about or climbs in situations where it is inappropriate. (**Note:** In adolescents or adults, may be limited to feeling restless.)
  - d. Often unable to play or engage in leisure activities quietly.
  - e. Is often "on the go," acting as if "driven by a motor" (e.g., is unable to be or uncomfortable being still for extended time, as in restaurants, meetings; may be experienced by others as being restless or difficult to keep up with).
  - f. Often talks excessively.
  - g. Often blurts out an answer before a question has been completed (e.g., completes people's sentences; cannot wait for turn in conversation).
  - h. Often has difficulty waiting his or her turn (e.g., while waiting in line).
  - i. Often interrupts or intrudes on others (e.g., butts into conversations, games, or activities; may start using other people's things without asking or receiving permission; for adolescents and adults, may intrude into or take over what others are doing).
- B. Several inattentive or hyperactive-impulsive symptoms were present prior to age 12 years.
- C. Several inattentive or hyperactive-impulsive symptoms are present in two or more settings (e.g., at home, school, or work; with friends or relatives; in other activities).
- D. There is clear evidence that the symptoms interfere with, or reduce the quality of, social, academic, or occupational functioning.
- E. The symptoms do not occur exclusively during the course of schizophrenia or another psychotic disorder and are not better explained by another mental disorder (e.g., mood disorder, anxiety disorder, dissociative disorder, personality disorder, substance intoxication or withdrawal).

among boys than among girls. ADHD occurs with the greatest frequency before age 8 and tends to become less frequent and to involve briefer episodes thereafter. ADHD has also been found to be comorbid with other disorders such as oppositional defiant disorder (ODD) (Staller, 2006), which we discuss later. Some

residual effects, such as attention difficulties, may persist into adolescence or adulthood (Odell et al., 1997). ADHD is found in other cultures (Bauermeister et al., 2010)—for example, one study of 1,573 children from 10 European countries reported that ADHD symptoms are similarly recognized across all

countries studied and that the children are significantly impaired across a wide range of domains.

**CAUSAL FACTORS IN ATTENTION-DEFICIT/HYPERACTIVITY DISORDER** The cause or causes of ADHD in children have been much debated. It still remains unclear to what extent the disorder results from environmental or biological factors (Carr et al., 2006; Hinshaw et al., 2007), and recent research points to both genetic (Sharp et al., 2009; Ilott et al., 2010) and social environmental precursors (Hechtman, 1996). Many researchers believe that biological factors such as genetic inheritance will turn out to be important precursors to the development of ADHD (Durston, 2003). But firm conclusions about any biological basis for ADHD must await further research.

→ **Gina, a Student with Hyperactivity** Gina was referred to a community clinic because of overactive, inattentive, and disruptive behavior. Her hyperactivity and uninhibited behavior caused problems for her teacher and for other students. She would impulsively hit other children, knock things off their desks, erase material on the blackboard, and damage books and other school property. She seemed to be in perpetual motion, talking, moving about, and darting from one area of the classroom to another. She demanded an inordinate amount of attention from her parents and her teacher, and she was intensely jealous of other children, including her own brother and sister. Despite her hyperactive behavior, inferior school performance, and other problems, she was considerably above average in intelligence. Nevertheless, she felt stupid and had a seriously devaluated self-image. Neurological tests revealed no significant organic brain disorder.

The search for psychological causes of ADHD has yielded similarly inconclusive results, although temperament and learning appear likely to be factors. One study suggested that family pathology, particularly parental personality, can be transmitted to children (Goos et al., 2007), and another recent study found that prenatal alcohol exposure can increase the severity of problems in children with ADHD (Ware et al., 2012). Currently, ADHD is considered to have multiple causes and effects (Hinshaw et al., 1997). Whatever cause or causes are ultimately determined to be influential in ADHD, the mechanisms underlying the disorder need to be more clearly understood and explored. There is general agreement that processes operating in the brain are disinhibiting the child's behavior (Nigg, 2001), and some research has found different EEG patterns occurring in children with ADHD than in children without ADHD (Barry et al., 2003). At this time, however, theorists do not agree what those central nervous system processes are.

**TREATMENTS AND OUTCOMES** Although the hyperactive syndrome was first described more than 100 years ago, disagreement over the most effective methods of treatment continues,

especially regarding the use of drugs to calm a child with ADHD. Yet this approach to treating children with ADHD has great appeal in the medical community; one survey (Runnheim et al., 1996) found that 40 percent of junior high school children and 15 percent of high school children with emotional and behavioral problems and ADHD are prescribed medication, mostly **Ritalin** (methylphenidate), an amphetamine. In fact, school nurses administer more daily medication for ADHD than for any other chronic health problem.

Interestingly, research has shown that amphetamines have a quieting effect on children—just the opposite of what we would expect from their effects on adults. For children with ADHD, such stimulant medication decreases overactivity and distractibility and, at the same time, increases their alertness (Konrad et al., 2004). As a result, they are often able to function much better at school (Hazell, 2007; Pelham et al., 2002).

Fava (1997) concludes that Ritalin can often lower the amount of aggressiveness in children with ADHD. In fact, many children whose behavior has not been acceptable in regular classes can function and progress in a relatively normal manner when they use such a drug. In a 5-year follow-up study, Charach, Ickowicz, and Schachar (2004) reported that children with ADHD on medication showed greater improvement in teacher-reported symptoms than nontreated children. The possible side effects of Ritalin, however, are numerous: decreased blood flow to the brain, which can result in impaired thinking ability and memory loss; disruption of growth hormone, leading to suppression of growth in the body and brain of the child; insomnia; psychotic symptoms; and others. Although amphetamines do not cure ADHD, they have reduced the behavioral symptoms in about one-half to two-thirds of the cases in which medication appears warranted.

Ritalin has been shown to be effective in the short-term treatment of ADHD (Goldstein, 2009; Spencer, 2004a). There are newer variants of the drug, referred to as extended-release methylphenidate (Concerta), that have similar benefits but with available doses that may better suit an adolescent's lifestyle (Mott & Leach, 2004; Spencer, 2004b).

Three other medications for treating ADHD have received attention in recent years. **Pemoline** is chemically very different from Ritalin (Faigel & Heiligenstein, 1996); it exerts beneficial effects on classroom behavior by enhancing cognitive processing but has less adverse side effects (Bostic et al., 2000; Pelham et al., 2005). **Strattera** (atomoxetine), a noncontrolled treatment option that can be obtained readily, is an FDA-approved non-stimulant medication (FDA, 2002). This medication reduces the symptoms of ADHD (Friemoth, 2005), but its mode of operation is not well understood. The side effects for the drug are decreased appetite, nausea, vomiting, and fatigue. The development of jaundice has been reported, and the FDA (2004) has warned of the possibility of liver damage from using Strattera. Although Strattera has been shown to reduce some symptoms of ADHD, further research is needed to evaluate its effectiveness and potential side effects (Barton et al., 2005). Another drug

that reduces symptoms of impulsivity and hyperactivity in children with attention deficit/hyperactivity disorder is **Adderall**. This medication is a combination of amphetamine and dextroamphetamine; however, research has suggested that Adderall has no advantage or improvement in results over Ritalin or Strattera (Miller-Horn et al., 2008).

Although the short-term pharmacological effect of stimulants on the symptoms of hyperactive children is well established, their long-term effects are not well known (Safer, 1997a). Carlson and Bunner (1993) reported that studies of achievement over long periods of time failed to show that the medication has beneficial effects. The pharmacological similarity of Ritalin and cocaine, for example, has caused some investigators to be concerned about its use in the treatment of ADHD (Volkow et al., 1995). There have also been some reported recreational uses of Ritalin, particularly among college students. Kapner (2003) described several surveys in which Ritalin was reportedly abused on college campuses. In one survey, 16 percent of students at one university reported using Ritalin, and in another study 1.5 percent of the population surveyed reported using Ritalin for recreational purposes within the past 30 days. Some college students share the prescription medications of friends as a means of obtaining a "high" (Chutko et al., 2010).

Some authorities prefer using psychological interventions in conjunction with medications (Mariani & Levin, 2007). The behavioral intervention techniques that have been developed for ADHD include selective reinforcement in the classroom (DuPaul et al., 1998) and family therapy (Everett & Everett, 2001). Another effective approach to treating children with ADHD involves the use of behavior therapy techniques featuring positive reinforcement and the structuring of learning materials and tasks in a way that minimizes error and maximizes immediate feedback and success (Frazier & Merrill, 1998). An example is providing a boy with ADHD immediate praise for stopping to think through a task he has been assigned before he starts to do it. The use of behavioral treatment methods for ADHD has reportedly been quite successful, at least for short-term gains.

The use of psychosocial treatment of ADHD has also shown positive results (Pelham & Fabiano, 2008; Corcoran, 2011). Van Lier and colleagues (2004) conducted a school-based behavioral intervention program using positive reinforcement aimed at preventing disruptive behavior in elementary school children. They found this program to be effective with children with ADHD with different levels of disorder but most effective with children at lower or intermediate levels.

It is important to recognize that gender differences, as noted above, are found in ADHD, with the disorder being more prominent among boys than girls and the symptoms appraised differently. Recent concerns have been expressed over the possibility that treatment of females with symptoms of ADHD might not be provided because they are more often diagnosed as "predominantly inattentive" than boys. Rucklidge (2010) points out that females are less likely to be referred to treatment than males with

ADHD although treatments appear to be equally effective for both genders. She points out that future research should be attentive to gender differences in the disorder and further examine potential differences that might occur in treatment and outcomes.

**ADHD BEYOND ADOLESCENCE** A number of changes were made to the diagnostic criteria of ADHD in the development of *DSM-5* in order to expand the diagnoses "across the life span." Although the diagnostic criteria were not substantially changed for ADHD in *DSM-5*, some adjustments as to age level of the appearance of symptoms were modified to allow the diagnosis in adult years.

Some researchers have reported that many children with ADHD retain symptoms and behavior into early adulthood. Kessler, Adler, and colleagues (2006) reported a prevalence rate of 4.4 percent in adult patients. Many children with ADHD go on to have other psychological problems such as overly aggressive behavior or substance abuse in their late teens and early adulthood (Barkley et al., 2004). For example, Carroll and Rounsville (1993) found that 34.6 percent of treatment-seeking cocaine abusers in their study had met the criteria for ADHD when they were children. In a 30-year follow-up study of hyperactive boys with conduct problems, Satterfield and colleagues (2007) reported that such boys are at substantial increased risk for adult criminality. Biederman and colleagues (2010) conducted an 11-year follow-up study of girls with ADHD and found that girls with ADHD were at high risk for antisocial, addictive, mood, anxiety, and eating disorders. In another recent study, college students with ADHD have been shown to exhibit more on-the-job difficulties than peers without ADHD (Shifrin et al., 2010). In a recent follow-up study of children with ADHD, Klein and colleagues (2012) reported that compared with peers without ADHD, those with ADHD displayed dysfunction in multiple domains as adults. Educational and occupational attainment was significantly compromised, leading to a relative economic disadvantage.

More *longitudinal research* is clearly needed before we can conclude that children with ADHD go on to develop similar or other problems in adulthood. Mannuzza, Klein, and Moulton (2003) reported that estimates of the numbers of children with

## research CLOSE-UP

### Longitudinal Research

Longitudinal research involves studying and collecting baseline information on a specific group of interest (patients with a given disorder, high-risk children, etc.) and then following up with them at a future date (e.g., 1, 5, or even 20 years later) to determine the changes that have occurred over the intervening period.

ADHD who will experience symptoms of ADHD in adulthood are likely to vary considerably. However, some of the research cited suggests that a significant percentage of adolescents continue to have problems in later life, and many continue to obtain treatment for ADHD (Doyle, 2006) or for other disorders such as major depression or bipolar disorder in their adult years (Klassen et al., 2010).

## Disruptive, Impulse-control, and Conduct Disorder

The next group of disorders involves a child's or an adolescent's relationship to social norms and rules of conduct. In both oppositional defiant disorder and conduct disorder, aggressive or anti-social behavior is the focus. As we will see, oppositional defiant disorder is usually apparent by about age 8, and conduct disorder tends to be seen by age 9. These disorders are closely linked (Thomas, 2010). However, it is important to distinguish between persistent antisocial acts—such as setting fires, where the rights of others are violated—and the less serious pranks often carried out by normal children and adolescents. Also, oppositional defiant disorder and conduct disorder involve misdeeds that may or may not be against the law; **juvenile delinquency** is the legal term used to refer to violations of the law committed by minors. (See the Unresolved Issues section at the end of this chapter.)

## THE CLINICAL PICTURE IN OPPOSITIONAL DEFIANT DISORDER

An important precursor of the antisocial behavior seen in children who develop conduct disorder is often what is now called **oppositional defiant disorder (ODD)** and categorized under Disruptive, Impulse-Control, and Conduct Disorders in *DSM-5*. The criteria for ODD were changed in *DSM-5* somewhat from the *DSM-IV* disorder. The ODD disorder is now grouped into three subtypes: angry/irritable mood, argumentative/defiant behavior and vindictiveness. Moreover, a severity rating has been included as an indicator of severity. The essential feature is a recurrent pattern of negativistic, defiant, disobedient, and hostile behavior toward authority figures that persists for at least 6 months. This disorder usually begins by the age of 8, whereas full-blown conduct disorders typically begin from middle childhood through adolescence. The lifetime prevalence of ODD as reported in a national sample of adult respondents was relatively high: 11.2 percent for boys and 9.2 percent for girls (Nock et al., 2007). Prospective studies have found a developmental sequence from oppositional defiant disorder to conduct disorder, with common risk factors for both conditions (Hinshaw, 1994). That is, virtually all cases of conduct disorder are preceded developmentally by oppositional defiant disorder, but not all children with oppositional defiant disorder go on to develop conduct

### criteria for Conduct Disorder

DSM-5

- A. A repetitive and persistent pattern of behavior in which the basic rights of others or major age-appropriate societal norms or rules are violated, as manifested by the presence of at least three of the following 15 criteria in the past 12 months from any of the categories below, with at least one criterion present in the past 6 months:

#### Aggression to People and Animals

1. Often bullies, threatens, or intimidates others.
2. Often initiates physical fights.
3. Has used a weapon that can cause serious physical harm to others (e.g., a bat, brick, broken bottle, knife, gun).
4. Has been physically cruel to people.
5. Has been physically cruel to animals.
6. Has stolen while confronting a victim (e.g., mugging, purse snatching, extortion, armed robbery).
7. Has forced someone into sexual activity.

#### Destruction of Property

8. Has deliberately engaged in fire setting with the intention of causing serious damage.
9. Has deliberately destroyed others' property (other than by fire setting).

#### Deceitfulness or Theft

10. Has broken into someone else's house, building, or car.
11. Often lies to obtain goods or favors or to avoid obligations (i.e., "cons" others).
12. Has stolen items of nontrivial value without confronting a victim (e.g., shoplifting, but without breaking and entering; forgery).

#### Serious Violations of Rules

13. Often stays out at night despite parental prohibitions, beginning before age 13 years.
  14. Has run away from home overnight at least twice while living in the parental or parental surrogate home, or once without returning for a lengthy period.
  15. Is often truant from school, beginning before age 13 years.
- B. The disturbance in behavior causes clinically significant impairment in social, academic, or occupational functioning.
- C. If the individual is age 18 years or older, criteria are not met for antisocial personality disorder.

disorder within a 3-year period (Lahey et al., 2000). The risk factors for both include family discord, socioeconomic disadvantage, and antisocial behavior in the parents.

**THE CLINICAL PICTURE IN CONDUCT DISORDER** The essential symptomatic behavior in **conduct disorder** and ODD involves a persistent, repetitive violation of rules and a disregard for the rights of others and is essentially the same as in *DSM-IV*. Children with conduct disorder show a deficit in social behavior (Happe & Frith, 1996; see *DSM* Criteria for Conduct Disorder). In general, they manifest such characteristics as overt or covert hostility, disobedience, physical and verbal aggressiveness, quarrelsomeness, vengefulness, and destructiveness. Lying, solitary stealing, and temper tantrums are common. Such children tend to be sexually uninhibited and inclined toward sexual aggressiveness. Some may engage in cruelty to animals (Becker et al., 2004), bullying (Coolidge et al., 2004), firesetting (Becker et al., 2004; Slavkin & Fineman, 2000; Stickle & Blechman, 2002), vandalism, robbery, and even homicidal acts. Children and adolescents with conduct disorder are also frequently comorbid for other disorders such as substance-abuse disorder (Goldstein et al., 2006) or depressive symptoms (O'Connor et al., 1998). Zoccolillo, Meyers, and Assiter (1997) found that conduct disorder is a risk factor for unwed pregnancy and substance abuse in teenage girls. Goldstein and colleagues (2006) report that early-onset conduct disorder is highly associated with later development of antisocial personality disorder (see Chapter 8); Fergusson, Horwood, and Ridder (2007) and Yang and colleagues (2007) found that conduct disorder in childhood and adolescence is generally related to later substance use, abuse, and dependence.

**CAUSAL FACTORS IN OPPOSITIONAL DISORDER AND CONDUCT DISORDER** Understanding of the factors associated with the development of conduct problems in childhood has increased tremendously in the past 20 years. Several factors will be covered in the sections that follow.

**A Self-Perpetuating Cycle** Evidence has accumulated that a genetic predisposition (Simonoff, 2001) leading to low verbal intelligence, mild neuropsychological problems, and difficult temperament can set the stage for early-onset conduct disorder. Baker and colleagues (2007) reported strong heritable effects of conduct problems and antisocial behavior across ethnically and economically diverse samples. The child's difficult temperament may lead to an insecure attachment because parents find it hard to engage in the good parenting that would promote a secure attachment. In addition, the low verbal intelligence and mild neuropsychological deficits that have been documented in many of these children—some of which may involve deficiencies in self-control functions such as sustaining attention, planning, self-monitoring, and inhibiting unsuccessful or impulsive behaviors—may help set the stage for a lifelong course of difficulties. In attempting to explain why the relatively

Hostility and aggressive behavior have been found to play a role in the development of conduct disorder. Children who develop this disorder early in childhood are at special risk for problems later in life.

mild neuropsychological deficits typically seen can have such pervasive effects, Moffitt and Lynam (1994) provided the following scenario: A preschooler has problems understanding language and tends to resist his mother's efforts to read to him. This deficit then delays the child's readiness for school. When he does enter school, the typically busy curriculum does not allow teachers to focus their attention on students at his low readiness level. Over time, and after a few years of school failure, the child will be chronologically older than his classmates, setting the stage for social rejection. At some point, the child might be placed into remedial programs that contain other pupils who have similar behavioral disorders as well as learning disabilities. This involvement with conduct-disordered peers exposes him to delinquent behaviors that he adopts in order to gain acceptance.

#### Age of Onset and Links to Antisocial Personality

**Disorder** Children who develop conduct disorder at an earlier age are much more likely to develop psychopathy or antisocial personality disorder as adults than are adolescents who develop conduct disorder suddenly in adolescence (Copeland et al., 2007). The link between conduct disorder and antisocial personality is stronger among lower-socioeconomic-class children (Lahey et al., 2005). It is the pervasiveness of the problems first associated with oppositional defiant disorder and then with conduct disorder that forms the pattern associated with an adult diagnosis of psychopathy or antisocial personality. Although only about 25 to 40 percent of cases of early-onset conduct disorder go on to develop adult antisocial personality disorder, over 80 percent of boys with early-onset conduct disorder do continue to have multiple problems of social dysfunction (in friendships, intimate relationships, and vocational activities) even if they do not meet all the criteria for antisocial personality disorder.

By contrast, most individuals who develop conduct disorder in adolescence do not go on to become adult psychopaths or anti-social personalities but instead have problems limited to the adolescent years. These adolescent-onset cases also do not share the same set of risk factors that the child-onset cases have, including low verbal intelligence, neuropsychological deficits, and impulsivity and attentional problems.

**Psychosocial Factors** In addition to the genetic or constitutional liabilities that may predispose a person to develop conduct disorder and adult psychopathy and antisocial personality, Kazdin (1995) underscored the importance of family and social context factors as causal variables. Children who are aggressive and socially unskilled are often rejected by their peers, and such rejection can lead to a spiraling sequence of social interactions with peers that exacerbates the tendency toward antisocial behavior (Freidenfelt & Klintenberg, 2007). Severe conduct problems can lead to other mental health problems as well. Mason and colleagues (2004) found that children who report higher levels of conduct problems are nearly four times more likely to experience a depressive episode in early adulthood.

This socially rejected subgroup of aggressive children is also at the highest risk for adolescent delinquency and probably for adult antisocial personality. In addition, parents and teachers may react to aggressive children with strong negative affect such as anger (Capaldi & Patterson, 1994), and they may in turn reject these aggressive children. The combination of rejection by parents, peers, and teachers leads these children to become isolated and alienated. Not surprisingly, they often turn to deviant peer groups for companionship, at which point a good deal of imitation of the antisocial behavior of their deviant peer models may occur.

Investigators generally seem to agree that the family setting of a child with conduct disorder is typically characterized by ineffective parenting, rejection, harsh and inconsistent discipline, and parental neglect (Frick, 1998). Frequently, the parents have an unstable marital relationship, are emotionally disturbed or sociopathic, and do not provide the child with consistent guidance, acceptance, or affection. Even if the family is intact, a child in a conflict-charged home feels overtly rejected. For example, Rutter and Quinton (1984) concluded that family discord and hostility are the primary factors defining the relationship between disturbed parents and disturbed children; this is particularly true with respect to the development of conduct disorders in children and adolescents. Such discord and hostility contribute to poor and ineffective parenting skills, especially ineffective discipline and supervision. These children are “trained” in anti-social behavior by the family—directly via coercive interchanges and indirectly via lack of monitoring and consistent discipline (Capaldi & Patterson, 1994). This all too often leads to association with deviant peers and the opportunity for further learning of antisocial behavior.

Ineffective parenting, harsh and inconsistent discipline, parental neglect, and marital discord can all contribute to oppositional defiant disorder (ODD) and conduct disorders. So can poverty and parental stress and depression.

In addition to these familial factors, a number of broader psychosocial and sociocultural variables increase the probability that a child will develop conduct disorder and, later, adult psychopathy or antisocial personality disorder (Granic & Patterson, 2006) or depressive disorder (Boylan et al., 2010). Low socioeconomic status, poor neighborhoods, parental stress, and depression all appear to increase the likelihood that a child will become enmeshed in this cycle (Schonberg & Shaw, 2007).

**TREATMENTS AND OUTCOMES** By and large, our society tends to take a punitive, rather than a rehabilitative, attitude toward an antisocial, aggressive youth. Thus the emphasis is on punishment and on “teaching the child a lesson.” Such treatment, however, seems to intensify rather than correct the behavior. Treatment for oppositional defiant disorder and conduct disorder tends to focus on the dysfunctional family patterns described above and on finding ways to alter the child’s aggressive or otherwise maladaptive behaviors (Behan & Carr, 2000; Milne et al., 2001).

**The Cohesive Family Model** Therapy for a child with conduct disorder is likely to be ineffective unless some way can be found to modify the child’s environment. One interesting and often effective treatment strategy with conduct disorder is the cohesive family model (Granic & Patterson, 2006; Patterson et al., 1998). In this family-group-oriented approach, parents of children with conduct disorder are viewed as lacking in parenting skills and as behaving in inconsistent ways, thereby reinforcing inappropriate behavior and failing to socialize their children. Children learn to escape or avoid parental criticism by escalating their negative behavior. This tactic, in turn, increases their parents’ aversive interactions and criticism. The child

observes the increased anger in his or her parents and models this aggressive pattern. The parental attention to the child's negative, aggressive behavior actually serves to reinforce that behavior instead of suppressing it. Viewing conduct problems as emerging from such interactions places the treatment focus squarely on the interaction between the child and the parents (Patterson et al., 1991).

Obtaining treatment cooperation from parents who are themselves in conflict with each other is difficult. Often, an overburdened parent who is separated or divorced and working simply does not have the resources, the time, or the inclination to learn and practice a more adequate parental role (Clarke-Stewart et al., 2000). In more extreme cases, the circumstances may call for a child to be removed from the home and placed in a foster home or institution, with the expectation of a later return to the home if intervening therapy with the parent or parents appears to justify it (Hahn et al., 2005).

Unfortunately, children who are removed to new environments often interpret this removal as further rejection not only by their parents but by society as well. Unless the changed environment offers a warm, kindly, and accepting yet consistent and firm setting, such children are likely to make little progress (see Pumariega, 2007).

**Behavioral and Biologically Based Treatments** The effectiveness of behavior therapy techniques and biologically based treatments has made the outlook brighter for children with conduct disorder (Kazdin & Weisz, 2003). A recent study of treating depression and oppositional defiant behavior with the antidepressant medication, fluoxetine (Prozac), and cognitive behavior therapy found a reduction in oppositionality over those not receiving the medication (Jacobs et al., 2010).

Teaching control techniques to the parents of such children is particularly important so that they can function as therapists in reinforcing desirable behavior and modifying the environmental conditions that have been reinforcing maladaptive behavior in their children. The changes brought about when parents consistently accept and reward their child's positive behavior and stop focusing on the negative behavior may finally change their perception of and feelings toward the child, leading to the basic acceptance that the child has so badly needed.

Although effective tactics for behavioral management can be taught to parents, they often have difficulty carrying out treatment plans. If this is the case, other techniques, such as family therapy or parental counseling, are used to ensure that the parent or person responsible for the child's discipline is sufficiently assertive to follow through on the program.

### in review

- Describe two common anxiety disorders found in children and adolescents.
- Distinguish among conduct disorder, oppositional defiant disorder, and juvenile delinquency.

## Anxiety and Depression in Children and Adolescents

### Anxiety Disorders of Childhood and Adolescence

In modern society, no one is totally insulated from anxiety-producing events or situations, and the experience of traumatic events can predispose children to develop anxiety disorders (Shevlin et al., 2007). Most children are vulnerable to fears and uncertainties as a normal part of growing up, and children can get generalized panic disorder just as adults do. Children with anxiety disorders, however, are more extreme in their behavior than those experiencing "normal" anxiety. These children appear to share many of the following characteristics: oversensitivity, unrealistic fears, shyness and timidity, pervasive feelings of inadequacy, sleep disturbances, and fear of school (Goodyer, 2000). Children diagnosed as suffering from an anxiety disorder typically attempt to cope with their fears by becoming overly dependent on others for support and help. In the *DSM-5*, anxiety disorders of childhood and adolescence are classified similarly to anxiety disorders in adults (Albano et al., 1996). Research has shown that anxiety disorders are often comorbid with depressive disorders (Kendall et al., 2010; O'Neil et al., 2010) or may be influential in later depression (Silberg et al., 2001); children who have these comorbid conditions often have significantly more symptoms than children who have anxiety disorders without depression (Masi et al., 2000).

Anxiety disorders are common among children. In a recent review of the epidemiological studies of anxiety in children, Pine and Klein (2010) conclude that the prevalence for any anxiety disorder accompanied by impairment appears to be about 5 to 10 percent. For example, 9.7 percent of children in one community-based school sample clearly met diagnostic criteria for an anxiety-based disorder (Dadds et al., 1997). There is a greater preponderance of anxiety-based disorder in girls than in boys (Lewinsohn et al., 1998). And, among adolescents, Goodwin and Gotlib (2004b) reported that panic attacks occurred in 3.3 percent of a large community-based epidemiological study.

### SEPARATION ANXIETY DISORDER **Separation anxiety disorder**

**disorder**, classified under Anxiety Disorders in *DSM-5*, is the most common of the childhood anxiety disorders, reportedly occurring in 2 to 41 percent of children in past population health studies (Cartwright-Hatton et al., 2006). Children with separation anxiety disorder exhibit unrealistic fears, oversensitivity, self-consciousness, nightmares, and chronic anxiety. They lack self-confidence, are apprehensive in new situations, and tend to be immature for their age. Such children are described by their parents as shy, sensitive, nervous, submissive, easily discouraged, worried, and frequently moved to tears. Typically, they are overly dependent, particularly on their parents. The essential feature in the clinical picture of this disorder is excessive anxiety

- A. Developmentally inappropriate and excessive fear or anxiety concerning separation from those to whom the individual is attached, as evidenced by at least three of the following:
  - 1. Recurrent excessive distress when anticipating or experiencing separation from home or from major attachment figures.
  - 2. Persistent and excessive worry about losing major attachment figures or about possible harm to them, such as illness, injury, disasters, or death.
  - 3. Persistent and excessive worry about experiencing an untoward event (e.g., getting lost, being kidnapped, having an accident, becoming ill) that causes separation from a major attachment figure.
  - 4. Persistent reluctance or refusal to go out, away from home, to school, to work, or elsewhere because of fear of separation.
  - 5. Persistent and excessive fear of or reluctance about being alone or without major attachment figures at home or in other settings.
  - 6. Persistent reluctance or refusal to sleep away from home or to go to sleep without being near a major attachment figure.
  - 7. Repeated nightmares involving the theme of separation.
  - 8. Repeated complaints of physical symptoms (e.g., headaches, stomachaches, nausea, vomiting) when separation from major attachment figures occurs or is anticipated.
- B. The fear, anxiety, or avoidance is persistent, lasting at least 4 weeks in children and adolescents and typically 6 months or more in adults.
- C. The disturbance causes clinically significant distress or impairment in social, academic, occupational, or other important areas of functioning.
- D. The disturbance is not better explained by another mental disorder, such as refusing to leave home because of excessive resistance to change in autism spectrum disorder; delusions or hallucinations concerning separation in psychotic disorders; refusal to go outside without a trusted companion in agoraphobia; worries about ill health or other harm befalling significant others in generalized anxiety disorder; or concerns about having an illness in illness anxiety disorder.

about separation from major attachment figures, such as their mother, and from familiar home surroundings (Bernstein & Layne, 2006). In many cases, a clear psychosocial stressor can be identified, such as the death of a relative or a pet. The case study below illustrates the clinical picture in this disorder.

→ **Johnny's Severe Separation Anxiety** Johnny was a highly sensitive 6-year-old who suffered from numerous fears, nightmares, and chronic anxiety. He was terrified of being separated from his mother, even for a brief period. When his mother tried to enroll him in kindergarten, he became so upset when she left the room that the principal arranged for her to remain in the classroom. After 2 weeks, however, this arrangement had to be discontinued, and Johnny had to be withdrawn from kindergarten because his mother could not leave him even for a few minutes. Later, when his mother attempted to enroll him in the first grade, Johnny manifested the same intense anxiety and unwillingness to be separated from her. At the suggestion of the school counselor, Johnny's mother brought him to a community clinic for assistance with the problem. The therapist who initially saw Johnny and his mother was wearing a white clinic jacket, which led to a severe panic reaction on Johnny's part. His mother had to hold him to

When children with separation anxiety disorder are actually separated from their attachment figures, they typically become preoccupied with morbid fears, such as the worry that their parents are going to become ill or die.

keep him from running away, and he did not settle down until the therapist removed his jacket. Johnny's mother explained that he was terrified of doctors and that it was almost impossible to get him to a physician even when he was sick.

.....

When children with separation anxiety disorder are actually separated from their attachment figures, they typically become preoccupied with morbid fears, such as the worry that their parents are going to become ill or die. They cling helplessly to adults, have difficulty sleeping, and become intensely demanding. Separation anxiety is more common in girls (Bernstein & Layne, 2006), and the disorder is not very stable over time (Poulton et al., 2001). One study, for example, reported that 44 percent of youngsters showed recovery at a 4-year follow-up (Cantwell & Baker, 1989). However, some children go on to exhibit school refusal problems (a fear of leaving home and parents to attend school) and continue to have subsequent adjustment difficulties. A disproportionate number of children with separation anxiety disorder also experience a high number of other anxiety-based disorders such as phobia and obsessive-compulsive disorder (Egger et al., 2003; Kearney et al., 2003).

**CAUSAL FACTORS IN ANXIETY DISORDERS** A number of causal factors have been emphasized in explanations of the childhood anxiety disorders. Although genetic factors have been thought to contribute to the development of anxiety disorders, particularly obsessive-compulsive disorder, in children (Nestadt et al., 2010), social and cultural factors are likely to be influential in resulting in anxiety disorders in children. For example, Potocznick and Perreira (2010) found an increased risk of anxiety and depression among immigrant Latino youth. Parental behavior and family stress in minority families have been particularly noted as potential influential factors in the origin of anxiety disorders in children; however, broader cultural factors are also important considerations.

Anxious children often manifest an unusual constitutional sensitivity that makes them easily conditionable by aversive stimuli. For example, they may be readily upset by even small disappointments—a lost toy or an encounter with an overeager dog. They then have a harder time calming down, a fact that can result in a build-up and generalization of surplus fear reactions.

The child can become anxious because of early illnesses, accidents, or losses that involved pain and discomfort. The traumatic effect of experiences such as hospitalizations makes such children feel insecure and inadequate. The traumatic nature of certain life changes such as moving away from friends and into a new situation can also have an intensely negative effect on a child's adjustment.

Overanxious children often have the modeling effect of an overanxious and protective parent who sensitizes a child to the dangers and threats of the outside world. Often, the parent's overprotectiveness communicates a lack of confidence in the child's ability to cope, thus reinforcing the child's feelings of inadequacy (Woodruff-Borden et al., 2002).

Indifferent or detached parents (Chartier et al., 2001) or rejecting parents (Hudson & Rapee, 2001) also foster anxiety in their children. The child may not feel adequately supported in mastering essential competencies and in gaining a positive self-concept. Repeated experiences of failure stemming from poor learning skills may lead to subsequent patterns of anxiety or withdrawal in the face of "threatening" situations. Other children may perform adequately but may be overcritical of themselves and feel intensely anxious and devalued when they perceive themselves as failing to do well enough to earn their parents' love and respect.

The role that social-environmental factors might play in the development of anxiety-based disorders, though important, is not clearly understood. A cross-cultural study of fears (Ollendick et al., 1996) found significant differences among American, Australian, Nigerian, and Chinese children and adolescents. These authors suggest that cultures that favor inhibition, compliance, and obedience appear to increase the levels of fear reported. In another study in the United States, Last and Perrin (1993) reported that there are some differences between African American and white children with respect to types of anxiety disorders. White children are more likely to present with school refusal than are African American children, who show more PTSD symptoms. This difference might result from differing patterns of referral for African American and white families, or it might reflect differing environmental stressors placed on the children. Several studies have also reported a strong association between exposure to violence and a reduced sense of security and psychological well-being (Cooley-Quille et al., 2001). Children who experience a sense of diminished control over negative environmental factors may become more vulnerable to the development of anxiety than those children who achieve a sense of efficacy in managing stressful circumstances.

**TREATMENTS AND OUTCOMES** The anxiety disorders of childhood occasionally continue into adolescence and young adulthood, leading first to maladaptive avoidance behavior and later to increasingly idiosyncratic thinking and behavior or an inability to "fit in" with a peer group. Typically, however, this is not the case. As affected children grow and have wider interactions in school and in activities with peers, they often benefit from experiences such as making friends and succeeding at given tasks. Teachers who are aware of the needs of both overanxious and shy, withdrawn children are often able to ensure that they will have successful experiences that help alleviate their anxiety.

**Biologically Based Treatments** Psychopharmacological treatment of anxiety disorders in children and adolescents is becoming more common today (Vitiello & Waslick, 2010). Birmaher and colleagues (2003) evaluated the efficacy of using fluoxetine in the treatment of a variety of anxiety-based disorders and found the medication useful. However, the cautious use of medications with anxiety-based disorders involves obtaining diagnostic clarity since these conditions often coexist with other disorders.

**Psychological Treatment** Behavior therapy procedures, sometimes used in school settings, often help anxious children (Mash & Barkley, 2006). Such procedures include assertiveness training to provide help with mastering essential competencies and desensitization to reduce anxious behavior. Kendall and colleagues have reported the successful use of manual-based cognitive-behavioral treatment (well-defined procedures using positive reinforcement to enhance coping strategies to deal with fears) for children with anxiety disorders (Chu & Kendall, 2004). Behavioral treatment approaches such as desensitization must be explicitly tailored to a child's particular problem, and *in vivo* methods (using real-life situations graded in terms of the anxiety they arouse) tend to be more effective than having the child "imagine" situations. Svensson, Larsson, and Oest (2002) reported successful treatment of phobic children using brief exposure.

Cognitive behavioral therapy has been shown to be highly effective at reducing anxiety symptoms in young children (Legerstee et al., 2010; Hirshfeld-Becker et al., 2010). An interesting and effective cognitive-behavioral anxiety prevention and treatment study was implemented in Australia. In an effort to identify and reduce anxiousness in young adolescents, Dadds and colleagues (1997) identified 314 children who met the criteria for an anxiety disorder out of a sample of 1,786 children 7 to 14 years old in a school system in Brisbane, Australia. They contacted the parents of these anxious children to engage them in the treatment intervention, and the parents of 128 of the children agreed to participate. The treatment intervention involved holding group sessions with the children in which they were taught to recognize their anxious feelings and deal with them more effectively than they otherwise would have. In addition, the parents were taught behavioral management procedures to deal more effectively with their child's behavior. Six months after therapy was completed, significant anxiety reduction was shown for the treatment group compared with an untreated control sample.

## Childhood Depression and Bipolar Disorder

Childhood depression includes behaviors such as withdrawal, crying, avoidance of eye contact, physical complaints, poor appetite, and even aggressive behavior and in some cases suicide (Pfeffer, 1996a, 1996b). One epidemiological study (Cohen et al., 1998) reported an association between somatic illness and childhood depressive illness, suggesting that there may be some common etiologic factors.

In the past, childhood depression has been classified according to essentially the same *DSM* diagnostic criteria used for adults. However, research on the neurobiological correlates and treatment responses of children, adolescents, and adults has shown clear differences in hormonal levels and in the response to treatment (Kaufman et al., 2001). Gaffrey and colleagues (2011) recently reported an fMRI study indicating that depressed preschoolers exhibit a significant positive relationship

Childhood depression includes behaviors such as withdrawal, crying, avoiding eye contact, physical complaints, poor appetite, and in some extreme cases, aggressive behavior and suicide.

between depression severity and right amygdala activity when viewing facial expressions of negative affect.

Future neuroimaging studies are needed to explore these differences further. One modification used for diagnosing depression in children is that irritability is often found as a major symptom and can be substituted for depressed mood, as seen in the following case.

→ **The Unhappy Child** Joey is a 10-year-old boy whose mother and teacher have shared their concerns about his irritability and temper tantrums displayed both at home and at school. With little provocation, he bursts into tears and yells and throws objects. In class he seems to have difficulty concentrating and seems easily distracted. Increasingly shunned by his peers, he plays by himself at recess, and at home he spends most of his time in his room watching TV. His mother notes that he has been sleeping poorly and has gained 10 pounds over the past couple of months from constant snacking. A consultation with the school psychologist has ruled out learning disabilities and attention-deficit disorder; instead, she says, he is a deeply unhappy child who expresses feelings of worthlessness and hopelessness—and even a wish that he would die. These experiences probably began about 6 months ago when his father, divorced from Joey's mother for several years, remarried and moved to another town, with the result that he spends far less time with Joey.

Source: Adapted from Hammen & Rudolph, 1996, pp. 153–54.

Depression in children and adolescents occurs with high frequency. The overall prevalence rates are as follows: under age 13, 2.8 percent; ages 13 to 18, 5.6 percent (girls, 5.9 percent; boys, 4.6 percent). These rates have been generally consistent over the past 30 years (Costello et al., 2006). Lewinsohn and colleagues (1993) report that 7.1 percent of the adolescents surveyed reported having attempted suicide in the past; in another

epidemiological study, Lewinsohn, Rohde, and Seeley (1994) point out that 1.7 percent of adolescents between 14 and 18 had made a suicide attempt.

There is an increased use of bipolar diagnosis among children and adolescents in the United States (see *Developments in Research*, p. 523). Moreno and colleagues (2007) reported that the estimated annual number of youth office-based visits with a diagnosis of bipolar disorder increased from 25 (1994–1995) to 1,003 (2002–2003) visits per 100,000 population, as did adult visits, with the majority of visits by males (66.5). A high percentage of these adolescents received a comorbid diagnosis, frequently ADHD.

**CAUSAL FACTORS IN CHILDHOOD DEPRESSION** The causal factors implicated in the childhood anxiety disorders are pertinent to the depressive disorders as well.

**Biological Factors** There appears to be an association between parental depression and behavioral and mood problems in children (Halligan et al., 2007; Hammen et al., 2004). Children of parents with major depression are more impaired, receive more psychological treatment, and have more psychological diagnoses than children of parents with no psychological disorders (Kramer et al., 1998). This is particularly the case when the parent's depression affects the child through less-than-optimal interactions (Carter et al., 2001). A controlled study of family history and onset of depression found that children from mood-disordered families had significantly higher rates of depression than those from nondisordered families (Kovacs et al., 1997). The suicide attempt rate has also been shown to be higher for children of depressed parents (7.8 percent) than for the offspring of control parents (Weissman et al., 1992).

Other biological factors might also make children vulnerable to psychological problems like depression. These factors include biological changes in the neonate as a result of alcohol intake by the mother during pregnancy, as prenatal exposure to alcohol is related to depression in children. M. J. O'Connor's (2001) study of children exposed to alcohol in utero reveals a continuity between alcohol use by the mother and infant negative affect and early childhood depression symptoms. (See *Developments in Research*, p. 373 for a discussion of fetal alcohol syndrome.)

**Learning Factors** Learning maladaptive behaviors appears to be important in childhood depressive disorders, and there are likely to be learning or cultural factors in the expression of depression. Stewart, Kennard and colleagues (2004) reported that depression symptoms and hopelessness are higher in Hong Kong than in the United States. In addition, a number of studies have indicated that children's exposure to early traumatic events can increase their risk for the development of depression. Children who have experienced past stressful events are susceptible to states of depression that make them vulnerable to suicidal thinking under stress (Silberg et al., 1999). Intense or persistent sensitiza-

Mothers who are depressed may transmit their depression to their children by their lack of responsiveness to the children as a result of their own depression (Bagner et al., 2010). Unfortunately, depression among mothers is all too common. Exhaustion, marital distress as a result of the arrival of children in a couple's lives, delivery complications, and the difficulties of particular babies may all play a part.

tion of the central nervous system in response to severe stress might induce hyperreactivity and alteration of the neurotransmitter system, leaving these children vulnerable to later depression (Heim & Nemeroff, 2001). A recent study by Olino and colleagues (2010) found that temperamental emotionality was associated with having a depressed parent. Children who are exposed to negative parental behavior or negative emotional states may develop depressed affect themselves (Herman-Stahl & Peterson, 1999). For example, childhood depression has been found to be more common in divorced families (Palosaari & Laippala, 1996).

One important area of research is focusing on the role of the mother-child interaction in the transmission of depressed affect. Specifically, investigators have been evaluating the possibility that mothers who are depressed transfer their low mood to their infants through their interactions with them (Jackson & Huang, 2000). Depression among mothers is not uncommon and can result from several sources, such as financial or marital problems. One study found that parenting problems and depressed mood in mothers are associated with depression in children (Oldehinkel et al., 2007).

Depressed mothers do not respond effectively to their children (Goldsmith & Rogoff, 1997), and they tend to be less sensitively attuned to, and more negative toward, their infants than nondepressed mothers. Other research has shown that negative (depressed) affect and constricted mood on the part of a mother, which shows up as unresponsive facial expressions and irritable behavior, can produce similar responses in her infant (Tronick & Cohn, 1989). Interestingly, the negative impact of depressed mothers' interaction style has also been studied at the physiological level. Infants have been reported to exhibit greater frontal brain electrical activity during the expression of negative emotionality by their mothers (Dawson et al., 1997). Although many of these studies have implicated the mother-child relationship in

## Bipolar Disorder in Children and Adolescents: Is There an Epidemic?

**B**ipolar disorder is often characterized by extreme mood swings and aggressive, irritable behavior (Braaten, 2011). Until recent years it was thought to largely be a disorder occurring in adulthood. But in the late 1990s, many psychiatrists began applying the diagnosis to children and adolescents and prescribing bipolar medication for their treatment (see Geller & DelBello, 2008). In DSM-5, the diagnosis of childhood depression has been modified as a means of preventing the over-diagnosis of bipolar disorder in children. A new diagnosis, disruptive mood regulation disorder, has been included for children at or under age 18 who exhibit persistent irritability and frequent lack of behavioral control. Bipolar disorder is often comorbid with other disorders such as ADHD (Klassen et al., 2010). Is there an epidemic of depression and bipolar disorder among children and adolescents?

As described in Chapter 7, bipolar disorders differ from unipolar mood disorders by the presence of manic or hypomanic symptoms. A person who experiences a manic episode has a markedly elevated, euphoric, and expansive mood that is often interrupted by occasional outbursts of intense irritability or even violence. In order to meet *DSM-5* diagnostic criteria, these extreme moods must persist for at least a week. In addition, three or more additional symptoms must occur in the same time period. There must also be significant impairment of life or social functioning. Hospitalization is often necessary during manic episodes. In about two-thirds of cases, the manic episodes either immediately precede or immediately follow a depressive episode; in other cases, the manic and depressive episodes are separated by intervals of relatively normal functioning. Bipolar disorder occurs equally in males and females and usually starts in adolescence and young adulthood. The likelihood of a full recovery from bipolar disorder is low even with the use of mood-stabilizing medications such as lithium because bipolar disorder is typically a recurrent condition that continues into adulthood.

The *DSM-5* provides criteria to define bipolar disorder in children that are based on how the disorder typically appears in adults; however, there is not a specific childhood or adolescent bipolar condition in the present *DSM* manual. The diagnostic criteria for bipolar disorder have not changed over the past decade (McClellan et al., 2007), even though there is an increased use of the diagnosis among children and adolescents in the United States, as noted by recent news media reports (Carey, 2007) as well as recent research surveys.

The question of overdiagnosis of bipolar disorder in children has emerged, in part, because of the increased use of antidepressant prescriptions for children and adolescents. For example, Harris (2005) points out that during a recent 3-month period in the child assessment unit at Cambridge Hospital in Massachusetts, a quarter of the children ages 3 to 13 years who were in

her care had been given a diagnosis of bipolar disorder by their outpatient clinicians and were receiving mood stabilizers or antipsychotics. Another quarter were believed to have bipolar disorder by their parents, who requested that appropriate medications be started. A number of authorities, however, have questioned the extreme increase in the use of bipolar diagnoses for children and adolescents and the more extensive use of medications for treating bipolar disorder among young people.

Does the increased rate of bipolar diagnosis for young people result from changes in practice in which clinicians are using the diagnosis more? Or, are younger people acquiring the disorder more commonly? Or, are practitioners now recognizing more patients with the disorder that they had "missed" in the past? Many experts theorize that the increase reflects the fact that doctors are more aggressively applying the diagnosis to children, not an indication that the incidence of the disorder has increased. Blader and Carlson (2007) point out that the growth in the rate of bipolar disorder-diagnosed discharges might reflect a "progressive rebranding" of the same clinical phenomena for which hospitalized children previously received different diagnoses such as ADHD. Basing their conclusions on data from the National Hospital Discharge Survey, Blader and Carlson reported that the rate of bipolar diagnoses jumped from 10.0 percent to 34.1 percent for all pediatric psychiatric discharges during the study period, and it rose from 10.2 percent to 25.9 percent in adolescents. They concluded that the rate for discharge diagnosis of bipolar disorder in children has increased by 25 percent annually.

The reported increase in depression and bipolar disorder among children and adolescents has, however, been questioned by some studies. For example, using published rates of admission in epidemiological research in the United Kingdom, Costello, Erkanli, and Angold (2006) report different results. They conducted a meta-analysis of 26 epidemiological studies on children born between 1965 and 1996 that included nearly 60,000 interviews that allowed for a diagnosis of depression and concluded that there is not an increased prevalence of adolescent depression over the past 30 years.

Several authorities have advised caution in the use of bipolar diagnoses in children and adolescents. Harris (2005) points out that child and adolescent psychiatrists must demand tighter criteria and higher quality of evidence in regard to juvenile bipolar disorder in order to ensure diagnostic accuracy and also integrate these criteria into case formulations that lead to an effective treatment plan. One concern resulting from possible inaccurate diagnoses of bipolar disorder is that psychiatrists might overprescribe medications used in the treatment of bipolar disorder (NIMH, 2007).

development of the disorder, depression in fathers has also been related to depression in children (Jacob & Johnson, 2001).

Considerable evidence has accumulated that depressive symptoms are positively correlated with the tendency to attribute positive events to external, specific, and unstable causes and negative events to internal, global, and stable causes (Klein et al., 2008); with fatalistic thinking (Roberts et al., 2000); and with feelings of helplessness (Kistner et al., 2001). For example, the child may respond to peer rejection or teasing by concluding that he or she has some internal flaw.

**TREATMENTS AND OUTCOMES** The view that childhood and adolescent depression is like adult depression has prompted researchers to treat children displaying mood disorders—particularly adolescents who are viewed as suicidal (Greenhill & Waslick, 1997)—with medications that have worked with adults. Research on the effectiveness of antidepressant medications with children is both limited (Emslie & Mayes, 2001) and contradictory at best, and some studies have found antidepressants to be only moderately helpful (Wagner & Ambrosini, 2001). Some studies using fluoxetine (Prozac) with depressed adolescents have shown the drug to be more effective than a placebo (DeVane & Sallee, 1996; Emslie et al., 1997), and other research has shown fluoxetine to be effective in the treatment of depression when administered as part of cognitive-behavioral therapy (Treatment for Adolescents with Depression Study [TADS] Team, U.S., 2004), although complete remission of symptoms was seldom obtained. Antidepressant medications may also have some undesirable side effects (nausea, headaches, nervousness, insomnia, and even seizures) in children and adolescents. Four accidental deaths from a drug called desipramine have been reported (Campbell & Cueva, 1995).

Emslie, Croarkin, and Mayes (2010) recently pointed out that antidepressants are among the most widely used drugs in treating children and adolescents for a variety of disorders, with significant increases over the past 20 years. Primarily, antidepressants are used for the same disorders as in adults (i.e., depression, anxiety).

Depressed mood has come to be viewed as an important risk factor in suicide among children and adolescents. About 7 to 10 percent of adolescents report having made at least one suicide attempt (Safer, 1997b). Children who attempt suicide are at greater risk for subsequent suicidal episodes than are non-attempters, particularly within the first 2 years after their initial attempt (Pfeffer et al., 1994), and some research has suggested that antidepressant medication treatment in children and adolescents is associated with an increased risk of suicide (Olfson et al., 2006). Among the childhood disorders, depression especially merits aggressive treatment. Recent attention is being paid to the increased potential of suicidal ideation and behavior in children and adolescents who are taking SSRIs for their depression (Whittington et al., 2004), and some risk of suicide for those taking the medication has been noted (Couzin, 2004). The

extent to which these medications represent an additional threat of suicide is being investigated.

An important facet of psychological therapy with children, whether for depression or anxiety or other disorders, is providing a supportive emotional environment in which they can learn more adaptive coping strategies and more effective emotional expression (see Gillham et al., 2006). Older children and adolescents often benefit from a positive therapeutic relationship in which they can discuss their feelings openly (Harvey & Taylor, 2010). Younger children and those with less developed verbal skills may benefit from play therapy. Play therapy has been found to be an effective psychological treatment with children (Schafer, 2010; Steele et al., 2007), particularly using a developmentally appropriate and skill-based approach (Reddy & Atamanoff, 2006). As a treatment technique, play therapy emerged out of efforts to apply psychodynamic therapy to children. Through their play, children often express their feelings, fears, and emotions in a direct and uncensored fashion, providing a clinician with a clearer picture of problems and feelings (Perry & Landreth, 2001). Research has shown that play therapy is as effective as other types of treatment such as behavior therapy at engaging children in expressing problems. In one study, in which play therapy was integrated into an 8-week intervention program to treat children with conduct disorder, the subjects showed significant gains at a 2-year follow-up (McDonald et al., 1997).

The predominant approach for treating depression in children and adolescents over the past few years has been the combined use of medication and psychotherapy (Skaer et al., 2000). Controlled studies of psychological treatment with depressed adolescents have shown significantly reduced symptoms with cognitive-behavioral therapy (Horowitz et al., 2007; Mash & Barkley, 2006). Short-term residential treatment can also be effective with depressed children (Leichtman, 2006). A recent longitudinal follow-up study of adolescents who had been treated for depression showed that effective treatment can reduce the recurrence of depression (Beavers et al., 2007).

### in review

- How do the symptoms of childhood depression compare to those seen in adult depression?
- Describe the symptoms of ADHD.
- Identify four common symptom disorders that can arise in childhood.

## Elimination Disorders (Enuresis, Encopresis), Sleepwalking, and Tics

The childhood disorders we will deal with in this section—“elimination disorders” (enuresis and encopresis), sleepwalking, and tics—typically involve a single outstanding symptom rather

than a pervasive maladaptive pattern. These disorders are essentially the same in DSM-5 as in DM-IV-TR.

## Enuresis

The term **enuresis** refers to the habitual involuntary discharge of urine, usually at night, after the age of expected continence (age 5). In *DSM-5*, functional enuresis is described as bed-wetting that is not organically caused and classified under elimination disorders. Children who have primary functional enuresis have never been continent; children who have secondary functional enuresis have been continent for at least a year but have regressed.

Enuresis may vary in frequency, from nightly occurrence to occasional instances when a child is under considerable stress or is unduly tired. It has been estimated that some 4 to 5 million children and adolescents in the United States suffer from the inconvenience and embarrassment of this disorder. Estimates of the prevalence of enuresis reported in *DSM IV* are 5 to 10 percent among 5-year-olds, 3 to 5 percent among 10-year-olds, and 1.1 percent among children age 15 or older. An epidemiological study in China reported a 4.3 percent prevalence, with a significantly higher percentage of boys than girls (Liu et al., 2000).

Enuresis may result from a variety of organic conditions, such as disturbed cerebral control of the bladder (Goin, 1998), neurological dysfunction, other medical factors such as medication side effects (Took & Buck, 1996), or having a small functional bladder capacity and a weak urethral sphincter (Dahl, 1992). One group of researchers reported that 11 percent of their enuretic patients had disorders of the urinary tract (Watanabe et al., 1994). However, most investigators have pointed to a number of other possible causal factors: (1) faulty learning, resulting in the failure to acquire inhibition of reflexive bladder emptying; (2) personal immaturity, associated with or stemming from emotional problems; (3) disturbed family interactions, particularly those that lead to sustained anxiety, hostility, or both; and (4) stressful events (Haug Schnabel, 1992). For example, a child may regress to bed-wetting when a new baby enters the family and becomes the center of attention.

Medical treatment of enuresis typically centers on using medications such as the antidepressant drug imipramine. The mechanism underlying the action of the drug is unclear, but it may simply lessen the deepest stages of sleep to light sleep, enabling the child to recognize bodily needs more effectively (Dahl, 1992). An intranasal desmopressin (DDAVP) has also been used to help children manage urine more effectively (Rahm et al., 2010). This medication, a hormone replacement, apparently increases urine concentration, decreases urine volume, and therefore reduces the need to urinate. The use of this medication to treat enuretic children is no panacea, however. Disadvantages of its use include its high cost and the fact that it is effective only with a small subset of enuretic children, and then only temporarily. Bath and colleagues (1996) reported that treatment with desmopressin was disappointing but conclude that this treatment has some utility as a way to enable children to stay dry for brief periods of time—for example, at a camp or on a holiday. Moffatt (1997) suggested that DDAVP

When combined with medication such as desmopressin, a urine alarm (shown here) can be very effective in treating enuresis. The child sleeps with a wetness detector, which is wired to a battery-operated alarm in his or her undergarment. Through conditioning, the child comes to associate bladder tension with awakening.

has an important place in treating nocturnal enuresis in youngsters who have not responded well to behavioral treatment methods. It is good to remember that medications by themselves do not cure enuresis and that there is frequent relapse when the drug is discontinued or the child habituates to the medication (Dahl, 1992).

Conditioning procedures have proved to be highly effective treatment for enuresis (Friman et al., 2008). Mowrer and Mowrer (1938), in their classic research that is still relevant today, introduced a procedure in which a child sleeps on a pad that is wired to a battery-operated bell. At the first few drops of urine, the bell is set off, thus awakening the child. Through conditioning, the child comes to associate bladder tension with awakening. Some evidence suggests that a biobehavioral approach—that is, using the urine alarm along with desmopressin—is most effective (Mellon & McGrath, 2000).

With or without treatment, the incidence of enuresis tends to decrease significantly with age, but many experts still believe that enuresis should be treated in childhood because there is presently no way to identify which children will remain enuretic into adulthood (Goin, 1998). In an evaluation of research on the treatment of bed-wetting, Houts, Berman, and Abramson (1994) concluded that treated children are more improved at follow-up than nontreated children. They also found that learning-based procedures are more effective than medications.

## Encopresis

The term **encopresis** describes a symptom disorder of children who have not learned appropriate toileting for bowel movements after age 4. This condition, classified under elimination disorders, in *DSM-5*, is less common than enuresis; however, *DSM*-based estimates are that about 1 percent of 5-year-olds have encopresis. A study of 102 cases of encopretic children yielded the following list of characteristics: The average age of children with encopresis was 7, with a range of ages 4 to 13. About one-third of encopretic children were also enuretic, and a large sex difference was found, with about six times more boys than girls

in the sample. Many of the children soiled their clothing when they were under stress. A common time was in the late afternoon after school; few children actually had this problem at school. Most of the children reported that they did not know when they needed to have a bowel movement or were too shy to use the bathrooms at school.

Many encopretic children suffer from constipation, so an important element in the diagnosis is a physical examination to determine whether physiological factors are contributing to the disorder. The treatment of encopresis usually involves both medical and psychological aspects. Several studies of the use of conditioning procedures with encopretic children have reported moderate treatment success; that is, no additional incidents occurred within 6 months following treatment (Friman et al., 2008). However, research has shown that a minority of children (11 to 20 percent) do not respond to learning-based treatment approaches (Keeley et al., 2009).

## Sleepwalking

The onset of **sleepwalking disorder** is usually between the ages of 6 and 12. The disorder is classified in parasomnias in *DSM-5*. The symptoms of sleepwalking disorder involve repeated episodes in which a person leaves his or her bed and walks around without being conscious of the experience or remembering it later.

The incidence of sleepwalking reported for children in the *DSM* is high for one episode—between 10 and 30 percent is relatively common—and girls are more likely to experience sleep-walking than boys (Mahendran et al., 2006). The incidence for repeated episodes is usually low—from 1 to 5 percent. Children subject to this problem usually go to sleep in a normal manner but arise during the second or third hour of sleep. They may walk to another room of the house or even outside, and they may engage in complex activities. Finally, they return to bed and in the morning remember nothing that had taken place. While moving about, sleepwalkers' eyes are partially or fully open; they avoid obstacles, listen when spoken to, and ordinarily respond to commands, such as to return to bed. Shaking them will usually awaken sleepwalkers, and they will be surprised and perplexed at finding themselves in an unexpected place. Sleepwalking takes place during NREM (non-rapid eye movement) sleep, and sleepwalking episodes usually last only a few minutes (Plazzi et al., 2005). The causes of sleepwalking—a condition of arousal in which the subject arises from deep sleep, even displaying long, complex behavior including leaving the bed and walking, with memory impairment of the event—are not fully understood.

Little attention has been devoted to the treatment of sleep-walking. Clement (1970), however, reported on the treatment of a 7-year-old boy through behavior therapy. During treatment, the therapist learned that just before each sleepwalking episode, the boy had a nightmare about being chased by “a big black bug.” After his nightmare began, he perspired freely, moaned and talked in his sleep, tossed and turned, and finally got up

and walked through the house. He did not remember the sleep-walking episode when he awoke the next morning. Assessment data revealed no neurological or other medical problems and indicated that he was of normal intelligence. He was, however, found to be a very anxious, guilt-ridden little boy who avoided performing assertive and aggressive behaviors appropriate to his age and sex (p. 23). The therapist focused treatment on having the boy's mother awaken him each time he showed signs of an impending episode. After washing his face with cold water and making sure he was fully awake, the mother would return him to bed, where he was to hit and tear up a picture of the big black bug. (At the start of the treatment program, he had made several of these drawings.)

Eventually, the nightmare was associated with awakening, and he learned to wake up on most occasions when he was having a bad dream. Thus the basic behavior therapy followed in this case was the same as that used in the conditioning treatment for enuresis, where a waking response is elicited by an intense stimulus just as urination is beginning and becomes associated with, and eventually prevents, nocturnal bed-wetting.

## Tic Disorders

A **tic** is a persistent, intermittent muscle twitch or spasm, usually limited to a localized muscle group. The term is used broadly to include blinking the eye, twitching the mouth, licking the lips, shrugging the shoulders, twisting the neck, clearing the throat, blowing the nose, and grimacing, among other actions. Tic disorders are classified under motor disorders in *DSM-5*. Tics occur most frequently between the ages of 2 and 14 (Evans et al., 1996). In some instances, as in clearing the throat, an individual may be aware of the tic when it occurs, but usually he or she performs the act habitually and does not notice it. In fact, many individuals do not even realize they have a tic unless someone brings it to their attention. A cross-cultural examination of tics found a similar pattern in research and clinical case reports from other countries (Staley et al., 1997). Moreover, the age of onset (average 7 to 8 years) and predominant gender (male) of cases were reported to be similar across cultures (Turan & Senol, 2000). A recent study on the prevalence of tic disorder in children and adolescents conducted by Stefanoff and colleagues (2008) reported that tic disorders are common among schoolchildren. They found that the lifetime prevalence of tic disorders (TD) is 2.6 percent for transient tic disorder (TTD), 3.7 percent for chronic tic disorder (CTD), and 0.6 percent for Tourette disorder (TD).

The psychological impact that tics can have on an adolescent is illustrated in the following case.

### → The Adolescent Who Wanted to Be a Teacher

An adolescent who had wanted very much to be a teacher told the school counselor that he was thinking of giving up his plans. When asked why, he explained that several friends had told him that he had a persistent twitching of the mouth

muscles when he answered questions in class. He had been unaware of this muscle twitch and, even after being told about it, could not tell when it took place. However, he became acutely self-conscious and was reluctant to answer questions or enter into class discussions. As a result, his general level of tension increased, and so did the frequency of the tic, which now became apparent even when he was talking to his friends. Thus a vicious circle had been established. Fortunately, the tic proved amenable to treatment by conditioning and assertiveness training.

.....

**Tourette's disorder**, classified as a motor disorder in *DSM-5*, is an extreme tic disorder involving multiple motor and vocal patterns. This disorder typically involves uncontrollable head movements with accompanying sounds such as grunts, clicks, yelps, sniffs, or words. Some, possibly most, tics are preceded by an urge or sensation that seems to be relieved by execution of the tic. Tics are thus often difficult to differentiate from compulsions, and they are sometimes referred to as "compulsive tics" (Jankovic, 1997). An epidemiological study in Sweden reported the prevalence of Tourette's disorder in children and adolescents to be about 0.56 percent (Khalifa & von Knorring, 2004). About one-third of individuals with Tourette's disorder manifest coprolalia, which is a complex vocal tic that involves the uttering of obscenities. Some people with Tourette's disorder also experience explosive outbursts (Budman et al., 2000). The average age of onset for Tourette's disorder is 7, and most cases have an onset before age 14. The disorder frequently persists into adulthood, and it is about three times more frequent among males than among females. Although the exact cause of Tourette's disorder is undetermined, evidence suggests an organic basis (Margolis et al., 2006). There are many types of tics, and many of them appear to be associated with the presence of other psychological disorders (Cardona et al., 1997), particularly obsessive-compulsive disorder (OCD). Most tics, however, do not have an organic basis but stem from psychological causes such as self-consciousness or tension in social situations, and they are usually associated with severe behavioral problems (Rosenberg et al., 1995). As in the case of the adolescent boy previously described, an individual's awareness of the tic often increases tension and the occurrence of the tic.

Among medications, neuroleptics are the most predictably effective tic-suppressing drugs (Kurlan, 1997). Clonazepam, clonidine, and tiapride have all shown effectiveness in reducing motor tics; however, tiapride has shown the greatest decrease in the intensity and frequency of tics (Drtikova et al., 1996). Campbell and Cueva (1995) reported that both haloperidol and pimozide reduced the severity of tics by about 65 percent but that haloperidol seemed the more effective of the two medications. Gilbert and colleagues (2004) reported that risperidone outperformed pimozide in tic suppression.

Most people suffering from tic disorders do not receive treatment for their symptoms (Cook & Blacher, 2007); however,

behavioral intervention techniques have been used successfully in treating tics (Woods & Miltenberger, 2001). One successful program, habit reversal treatment or HRT, involves several sequential elements, beginning with awareness training, relaxation training, and the development of incompatible responses, and then progressing to cognitive therapy and modification of the individual's overall style of action (Chang, Piacentina, & Walkup, 2007). Finally, perfectionist expectations about self-image (which are often found in children and adolescents with tics) are addressed through cognitive restructuring. Because children with Tourette's disorder can have substantial family adjustment (Wilkinson et al., 2001) and school adjustment problems (Nolan & Gadow, 1997), interventions should be designed to aid their adjustment and to modify the reactions of peers to them. School psychologists can play an effective part in the social adjustment of the child with Tourette's disorder (Walter & Carter, 1997) by applying behavioral intervention strategies that help arrange the child's environment to be more accepting of such unusual behaviors.

## Neurodevelopmental Disorders

The **neurodevelopmental disorders** are a group of severely disabling conditions that are among the most difficult to understand and treat. They make up about 3.2 percent of cases seen in inpatient settings (Sverd et al., 1995). They are considered to be the result of some structural differences in the brain that are usually evident at birth or become apparent as the child begins to develop (Siegel, 1996). There is fairly good diagnostic agreement in the determination of neuro developmental disorders in children whether one follows the *DSM-5* or the ICD-10 (the International Classification of Disease, published by the World Health Organization), which have slightly different criteria for some disorders. Several Neurodevelopmental disorders are covered in *DSM-5*—for example, **autism spectrum disorder**, one of the most severe and puzzling disorders occurring in early childhood. (See Goldstein et al., 2009, for a comprehensive discussion of the assessment of developmental disorders.)

## Autism Spectrum Disorder

One of the most disabling of the childhood disorders is autistic disorder, which is often referred to as autism, childhood autism (Schopler et al., 2001), or, in the *DSM-5*, autism spectrum disorder. It is a developmental disorder that involves a wide range of problematic behaviors including deficits in language and perceptual and motor development; defective reality testing; and an inability

to function in social situations. The following case illustrates some of the behaviors that may be seen in a child with autism.

→ **The Need for Routine** Mathew is 5 years old. When spoken to, he turns his head away. Sometimes he mumbles unintelligibly. He is neither toilet trained nor able to feed himself. He actively resists being touched. He dislikes sounds and is uncommunicative. He cannot relate to others and avoids looking anyone in the eye. He often engages in routine manipulative activities such as dropping an object, picking it up, and dropping it again. He shows a pathological need for sameness. While seated, he often rocks back and forth in a rhythmic motion for hours. Any change in routine is highly upsetting to him.

Autism in infancy and childhood was first described by Kanner (1943). It afflicts tens of thousands of American children from all socioeconomic levels and is seemingly on the increase—estimates

range between 30 and 60 people in 10,000 (Fombonne, 2005). A recent study by the Centers for Disease Control and Prevention (CDC, 2013) reported that the rate of autism among children is about 1 in 50. This reported increase in autism in recent years is likely due to methodological differences between studies and changes in diagnostic practice and public and professional awareness in recent years rather than an increase in prevalence (Williams et al., 2005). Autism is usually identified before a child is 30 months of age and may be suspected in the early weeks of life. Diagnostic stability over the childhood years is quite high for autism. Lord and colleagues (2006) report that children diagnosed with autism by age 2 tend to be similarly diagnosed at age 9. One study found that autistic behavior such as lack of empathy, inattention to others, and inability to imitate is shown as early as 20 months (Charman et al., 1997).

#### THE CLINICAL PICTURE IN AUTISTIC SPECTRUM DISORDER

Children with autism show varying degrees of impairments and

### criteria for Autism Spectrum Disorder

DSM-5

- A. Persistent deficits in social communication and social interaction across multiple contexts, as manifested by the following, currently or by history (examples are illustrative, not exhaustive; see text):
  - 1. Deficits in social-emotional reciprocity, ranging, for example, from abnormal social approach and failure of normal back-and-forth conversation; to reduced sharing of interests, emotions, or affect; to failure to initiate or respond to social interactions.
  - 2. Deficits in nonverbal communicative behaviors used for social interaction, ranging, for example, from poorly integrated verbal and nonverbal communication; to abnormalities in eye contact and body language or deficits in understanding and use of gestures; to a total lack of facial expressions and nonverbal communication.
  - 3. Deficits in developing, maintaining, and understanding relationships, ranging, for example, from difficulties adjusting behavior to suit various social contexts; to difficulties in sharing imaginative play or in making friends; to absence of interest in peers.
- B. Restricted, repetitive patterns of behavior, interests, or activities, as manifested by at least two of the following, currently or by history (examples are illustrative, not exhaustive; see text):
  - 1. Stereotyped or repetitive motor movements, use of objects, or speech (e.g., simple motor stereotypies, lining up toys or flipping objects, echolalia, idiosyncratic phrases).
  - 2. Insistence on sameness, inflexible adherence to routines, or ritualized patterns of verbal or nonverbal behavior (e.g., extreme distress at small changes, difficulties with transitions, rigid thinking patterns, greeting rituals, need to take same route or eat same food every day).
  - 3. Highly restricted, fixated interests that are abnormal in intensity or focus (e.g., strong attachment to or preoccupation with unusual objects, excessively circumscribed or perseverative interests).
  - 4. Hyper- or hyporeactivity to sensory input or unusual interest in sensory aspects of the environment (e.g., apparent indifference to pain/temperature, adverse response to specific sounds or textures, excessive smelling or touching of objects, visual fascination with lights or movement).
- C. Symptoms must be present in the early developmental period (but may not become fully manifest until social demands exceed limited capacities, or may be masked by learned strategies in later life).
- D. Symptoms cause clinically significant impairment in social, occupational, or other important areas of current functioning.
- E. These disturbances are not better explained by intellectual disability (intellectual developmental disorder) or global developmental delay. Intellectual disability and autism spectrum disorder frequently co-occur; to make comorbid diagnoses of autism spectrum disorder and intellectual disability, social communication should be below that expected for general developmental level.

**Note:** Individuals with a well-established DSM-IV diagnosis of autistic disorder, Asperger's disorder, or pervasive developmental disorder not otherwise specified should be given the diagnosis of autism spectrum disorder. Individuals who have marked deficits in social communication, but whose symptoms do not otherwise meet criteria for autism spectrum disorder, should be evaluated for social (pragmatic) communication disorder.

capabilities. In this section, we will discuss some of the behaviors that may be evident in autism. A cardinal and typical sign is that a child seems apart or aloof from others, even in the earliest stages of life (Hillman & Snyder, 2007). Mothers often remember such babies as never being cuddly, never reaching out when being picked up, never smiling or looking at them while being fed, and never appearing to notice the comings and goings of other people.

**A Social Deficit** Typically, children with autism do not show any need for affection or contact with anyone, and they usually do not even seem to know or care who their parents are. Several studies, however, have questioned the traditional view that autistic children are emotionally flat. These studies (Capps et al., 1993) have shown that children with autism do express emotions and should not be considered as lacking emotional reactions (Jones et al., 2001). Instead, Sigman (1996) has characterized the seeming inability of children with autism to respond to others as a lack of social understanding—a deficit in the ability to attend to social cues from others. The child with autism is thought to have a “mind blindness,” an inability to take the attitude of others or to “see” things as others do. For example, a child with autism appears limited in the ability to understand where another person is pointing. Additionally, children with autism show deficits in attention and in locating and orienting to sounds in their environment (Hillman & Snyder, 2007).

The lack of social interaction among children with autism has been well described. A behavioral observation study by Lord and Magill-Evans (1995) noted that the youngsters with autism engaged in fewer social interactions than other children; however, this study also made the important observation that the children with autism did not play—particularly, did not show spontaneous play. In fact, much of the time, nothing was going on.

Encopresis is common (Siegel, 2003) among children with autism. Radford and Anderson (2003) point out that relatively little of the clinical descriptive literature on children with autism addresses the problem of toilet training. They note that failing to cooperate in toilet training is a common problem and one that creates added difficulty for parents of children with autism, and they provide practical advice and training guidelines for dealing with this problem behavior. In addition, a high prevalence of sleep problems has been reported for children with autism (Williams et al., 2004).

**An Absence of Speech** Children with autism do not effectively learn by imitation (Smith & Bryson, 1994). This dysfunction might explain their characteristic absence or severely limited use of speech. If speech is present, it is almost never used to communicate except in the most rudimentary fashion, such as by saying “yes” in answer to a question or by the use of **echolalia**—the parrot-like repetition of a few words. Whereas the echoing of parents’ verbal behavior is found to a small degree in normal children as they experiment with their ability to produce articulate speech, persistent echolalia is found in about 75 percent of autistic children (Prizant, 1983).

**Self-Stimulation** Self-stimulation is often characteristic of children with autism. It usually takes the form of such repetitive movements as head banging, spinning, and rocking, which may continue by the hour. Other bizarre repetitive behaviors are typical.

Children with autism seem to actively arrange the environment on their own terms in an effort to exclude or limit variety and intervention from other people, preferring instead a limited and solitary routine. These children often show an active aversion to auditory stimuli, crying even at the sound of a parent’s voice. The pattern is not always consistent, however; children with autism may at one moment be severely agitated or panicked by a very soft sound and at another time be totally oblivious to a loud noise.

**Intellectual Ability** Compared with the performance of other groups of children on cognitive or intellectual tasks, children with autism often show marked impairment. For example, children with autism are significantly impaired on memory tasks when compared with both normal children and children with intellectual disability. They show a particular deficit in representing mental states—that is, they appear to have deficits in social reasoning but can manipulate objects. Carpentieri and Morgan (1996) found that the cognitive impairment in children with autism is reflected in their greater impairment in adaptive behaviors than is seen in mentally retarded children without autism.

Some children with autism are quite skilled at fitting objects together; thus their performance on puzzles or form boards may be average or above. Even in the manipulation of objects, however, difficulty with meaning is apparent. For example, when pictures are to be arranged in an order that tells a story, children with autism show a marked deficiency in performance. Moreover, adolescents with autism, even those who are functioning well, have difficulty with symbolic tasks such as pantomime—in which they are asked to recall motor actions to imitate tasks (e.g., ironing) with imagined objects—in spite of the fact that they might perform the task well with real objects (Hillman & Snyder, 2007).

**Maintaining Sameness** Many children with autism become preoccupied with and form strong attachments to unusual objects such as rocks, light switches, or keys. In some instances, the object is so large or bizarre that merely carrying it around interferes with other activities. When their preoccupation with the object is disturbed—for example, by its removal or by attempts to substitute something in its place—or when anything familiar in the environment is altered even slightly, these children may have a violent temper tantrum or a crying spell that continues until the familiar situation is restored. Thus children with autism are often said to be “obsessed with the maintenance of sameness.”  Watch the Video Xavier: Autism on MyPsychLab.

**CAUSAL FACTORS IN AUTISM** The precise cause or causes of autism are unknown, although most investigators agree that a fundamental disturbance of the central nervous system is

involved (Girgis et al., 2007; Volker & Lopata, 2008). Many investigators believe that autism begins with some type of inborn defect that impairs an infant's perceptual-cognitive functioning—the ability to process incoming stimuli and to relate to the world. Recent MRI research suggests that abnormalities in the brain anatomy may contribute to the brain metabolic differences and behavioral phenotype in autism (McAlonan et al., 2005). Whatever the physiological mechanisms or brain structures involved, evidence has accumulated that defective genes or damage from radiation or other conditions during prenatal development may play a significant role in the etiologic picture (Nicolson & Szatmari, 2003; Waterhouse & Fein, 1997). Evidence for a genetic contribution to autism comes from examining the risk for autism in the siblings of autistic children (Levy et al., 2009; Mazefsky et al., 2008). The best estimates are that in families with one child with autism there is a 3 to 5 percent risk of a sibling having autism as well. Although this figure may seem low in an absolute sense, it is in fact extremely high, given the frequency of autism in the population. The most extensive autism genetics research project recently reported that tiny, rare variations in genes increase the risk of autism spectrum disorder (Autism Genome Project, 2007). These results suggest that components of the brain's glutamate neurotransmitter system are involved in autism. Thus, autism seemingly results from faulty wiring in the early stages of development. That is, glutamate increases neuronal activity and plays an important role in wiring the brain during early development. Smoller and colleagues (2013) recently conducted a study analyzing genetic factors in mental disorders in 33,332 cases and 27,888 controls of European ancestry. They concluded that five disorders: autism spectrum disorders, schizophrenia, ADHD, bipolar disorder, and recurrent major depressive disorder shared a genetic basis.

Nevertheless, the exact mode of genetic transmission is not yet understood, but it seems likely that relatives may also show an increased risk for other cognitive and social deficits that are milder in form than true autism (Smalley, 1991).

**TREATMENTS AND OUTCOMES OF AUTISM** The treatment prognosis for autistic disorder is poor, and because of the severity of their problems, those diagnosed with autism are often insufficiently treated (Moldin & Rubenstein, 2006). Moreover, because of the typically poor response to treatment, children with autism are often subjected to a range of fads and "novel" approaches that turn out to be equally ineffective.

**Medical Treatment** In the past, the use of medications to treat children with autism has not proved effective. The drugs most often used in the treatment of autism are antidepressants (21.7 percent), antipsychotic medication (16.8 percent), and stimulants (13.9 percent; Handen & Lubetsky, 2005); but the data on their effectiveness do not support their use unless a child's behavior is unmanageable by other means (Sloman, 1991). If irritability and aggressiveness are present, the medical

management of a case might involve the use of medications to lower the level of aggression (Fava, 1997). Although there are no sure-fire medications approved for this purpose, the drug clomipramine has had some beneficial effects (see the discussion by Erickson et al., 2007). However, no currently available medication reduces the symptoms of autism enough to encourage its general use. We will thus direct our attention to a variety of psychological procedures that have been more successful in treating children with autism.

**Behavioral Treatment** Behavior therapy in an institutional setting has been used successfully in the elimination of self-injurious behavior, the mastery of the fundamentals of social behavior, and the development of some language skills (Charlop-Christie et al., 1998). The late Ivar Lovaas (1987), a pioneer in behavioral treatment of children with autism, reported highly positive results from a long-term experimental treatment program. The intervention developed by Lovaas and colleagues is very intensive and is usually conducted in the children's homes rather than in a clinical setting. The children are usually immersed in a one-to-one teaching situation for most of their waking hours over several years. The intervention is based on both discrimination-training strategies (reinforcement) and contingent aversive techniques (punishment). The treatment plan typically enlists parents in the process and emphasizes teaching children to learn from and interact with "normal" peers in real-world situations. Of the treated children in the study by Lovaas and colleagues, 47 percent achieved normal intellectual functioning, and another 40 percent attained the mildly retarded level. In comparison, only 2 percent of the untreated control children achieved normal functioning, and 45 percent attained mildly retarded functioning. These remarkable results did, however, require a considerable staffing effort, with well-qualified therapists working with each child at least 40 hours per week for 2 years.

Some studies show that intensive behavioral treatment of children with autism, requiring a significant investment of time and energy on the part of therapist and parents, can bring about improvement, particularly if this treatment continues at home rather than in an institution.

Some of the other impressive results with children with autism have also been obtained in projects that involve parents, with treatment in the home (Siegel, 2003). Treatment contracts with parents specify the desired behavior changes in their child and spell out the explicit techniques for bringing about these changes. Such “contracting” acknowledges the value of the parents as potential agents of change (Huynen et al., 1996). See Developments in Practice below for an example of the use of technology to improve autistic behavior.

**The Effectiveness of Treatment** It is too early to draw conclusions about the effectiveness of newer treatment methods or the degree of improvement they actually accomplish, although reports of effective behavioral intervention in some areas, such as attention skills, have been noted (Martins & Harris, 2006). The prognosis for children with autism, particularly for children showing symptoms before the age of 2, is poor. Commonly, the

long-term results of autism treatments have been unfavorable. A great deal of attention has thus been given to high-functioning children with autism (children who meet the criteria for autism yet develop functional speech).

One important factor limiting treatment success is the difficulty that children with autism have in generalizing behavior outside the treatment context. Children with severe developmental disabilities do not transfer skills across situations very well. Consequently, learning behavior in one situation does not appear to help them meet challenges in others.

In spite of a few remarkable cases of dramatic success, the overall prognosis for children with autism remains guarded. Less than one-fourth of the children who receive treatment attain even marginal adjustment in later life. Even with intensive, long-term care in a clinical facility, where gratifying improvements in specific behaviors may be brought about, children with autism are a long way from becoming normal.

## developments in PRACTICE

### Can Virtual Reality Video Games Improve Treatment of Children with Neurodevelopmental Disorders?

Many children and adolescents with learning disabilities or neurodevelopmental disorders, like other children today, are readily drawn to computer video games and will spend long hours at machines. The potential value of video media and virtual reality games at engaging and training young people appears to be great. These approaches have shown considerable promise in interesting and motivating children who might have cognitive processing impairments (Ecale et al., 2010). Even though many of these children have problems in social relationships, deficits in attention, and often volatile and disruptive behaviors they can readily become engrossed in the world of virtual reality (see informative discussion by Durkin, 2010). Recent projects in developmental psychology in Japan have incorporated the use of computer-based media technology for influencing young people, including those with disabilities, to learn and experience new ways of functioning (Shwab et al., 2005). For example, Nakamura, Iwabuchi, and Sakai (2005) report an intervention using cell phone calls to promote a qualitative change in communication behavior in a boy with autism.

Although video games as a medium for teaching life skills are recognized as having potential for the development of effective treatments (Cartreine et al., 2010), a successful treatment requires more than its value as entertainment or time consumption. It is not necessarily a productive goal for a child with autism to just sit and stare in front of a TV screen and watch the same program all day as often happens. The treatment benefit needs to be more carefully considered. Programs for treatment or education require specifically tailored strategies to obtain the most effective results. Machines can only perform as they are

programmed to do. Thus appropriate behavioral change strategies need to be developed and studied for particular applications. The effectiveness of behavior modification approaches using computer technology for children with developmental disorders has not been widely demonstrated or even explored for many problem areas. It takes considerable research and development, along with extensive programming skills, to address particular problems that can change behavior. At this time, the psychological knowledge and research base lingers behind the expanding developments in technical equipment.

The video and virtual reality game phenomena that have attracted many young people's interest have also prompted some unanswered questions. This approach to education and treatment has come under criticism and raised potential concerns over its use. For example, there is concern that this approach has a strong potential for “addiction” to virtual reality games that could potentially adversely influence a child's development (Pies, 2009). Questions have also been raised about the need for further considerations as to possible ethical issues, involving such factors as identity, equity, and confidentiality, that face instructors and therapists who use online teaching or therapy (Anderson & Simpson, 2007).

Although the available and acceptable use of computer-based learning methods show promise, there are professional issues and program research limitations that need to be more fully explored before the full potential of this methodology is reached.

Parenting children with autism can be trying and stressful (Dunn et al., 2001) and can be very financially stressful for families. Parents of children with autism often find themselves in the extremely frustrating situation of trying to understand their child, providing day-to-day care, and searching for possible educational resources for their child in the present health and educational environment. An informative book on the topic of autism is *The World of the Autistic Child* (Siegel, 1996, 2007). Siegel discusses the impact that having a child with autism can have on the family—both parents and siblings—and describes ways of dealing with the problems that can arise, including the possible need of psychological treatment for other family members. The book is a particularly valuable guide to accessing the resources available for educating and treating children with autism and negotiating the confusing educational environment. Whether to seek residential placement, clearly a necessity in some situations and families, is also an important decision that parents of many children with autism must address.

- What is known about the causes and treatments of autistic disorder?

## Specific Learning Disorders

The inadequate development found in **learning disorders**, a term that refers to delayed development, may be manifested in language, speech, mathematical, or motor skills, and it is not necessarily due to any demonstrable physical or neurological defect. Of these types of problems, the best known and most widely researched are a variety of reading/writing difficulties known collectively as **dyslexia**. In dyslexia, the individual manifests problems in word recognition and reading comprehension; often he or she is markedly deficient in spelling and memory (Smith-Spark & Fisk, 2007) as well. On assessments of reading skill, these persons routinely omit, add, and distort words, and their reading is typically painfully slow.

The diagnosis of learning disorders is restricted to those cases in which there is clear impairment in school performance or (if the person is not a student) in daily living activities—impairment not due to intellectual disability or to a pervasive developmental disorder such as autism. Skill deficits due to attention-deficit/hyperactivity disorder are coded under that diagnosis. This coding presents another diagnostic dilemma, however, because some investigators hold that an attention deficit is basic to many learning disorders; evidence for the latter view is equivocal (see Faraone et al., 1993). Children (and adults) with these disorders are more generally said to be learning disordered. Significantly more boys than girls are diagnosed as learning disabled, but estimates of the extent of this gender discrepancy have varied widely from study to study. Prevalence estimates have shown that approximately 1 in 59, or 4.6 million people, in the United States (National Institutes of Mental Health, 2007) are learning disabled.

Children with learning disorders can experience deep emotional tension under normal learning circumstances.

Children with learning disorder are initially identified as such because of an apparent disparity between their expected academic achievement level and their actual academic performance in one or more school subjects such as math, spelling, writing, or reading. Typically, these children have overall IQs, family backgrounds, and exposure to cultural norms and symbols that are consistent with at least average achievement in school. They do not have obvious, crippling emotional problems, nor do they seem to be lacking in motivation, cooperativeness, or eagerness to please their teachers and parents—at least not at the outset of their formal education. Nevertheless, they fail, often abysmally and usually with a stubborn, puzzling persistence.

The consequences of these encounters between children with learning disabilities and rigid school systems can be disastrous to these children's self-esteem and general psychological well-being, and research indicates that these effects do not necessarily dissipate after secondary schooling ends but impact their career adjustment (Morris & Turnbull, 2007). Thus even when learning disorder difficulties are no longer a significant impediment, an individual may bear, into maturity and beyond, the scars of many painful school-related episodes of failure.

But there is also a brighter side to this picture. High levels of general talent and of motivation to overcome the obstacle of a learning disorder sometimes produce a life of extraordinary

achievement. Sir Winston Churchill, British statesman, author, and inspiring World War II leader, is said to have been dyslexic as a child. The same attribution is made to Woodrow Wilson, former university professor and president of the United States, and to Nelson Rockefeller, former governor of New York and vice president of the United States. Such examples remind us that the “bad luck” and personal adversity of having a learning disorder need not be uniformly limiting; quite the contrary.

### Causal Factors in Learning Disorder

Probably the most widely held view of the causes of specific learning disorders is that they are the products of subtle central nervous system impairments. In particular, these disabilities are thought to result from some sort of immaturity, deficiency, or dysregulation limited to those brain functions that supposedly mediate, for normal children, the cognitive skills that learning disorder children cannot efficiently acquire. For example, many researchers believe that language-related learning disorders such as dyslexia are associated with a failure of the brain to develop in a normally asymmetrical manner with respect to the right and left hemispheres. Specifically, portions of the left hemisphere, where language function is normally mediated, for unknown reasons appear to remain relatively underdeveloped in many dyslexic individuals (Beaton, 1997). Recent work with functional magnetic resonance imaging (see Chapter 4) has suggested that dyslexic individuals have a deficiency of physiological activation in the cerebellum (Richards et al., 2005).

Some investigators believe that the various forms of learning disorder, or the vulnerability to develop them, may be genetically transmitted. This issue seems not to have been studied with the same intensity or methodological rigor as in other disorders, but identification of a gene region for dyslexia on chromosome 6 has been reported (Schulte-Koerne, 2001). Although it would be somewhat surprising if a single gene were identified as the causal factor in all cases of reading disorder, the hypothesis of a genetic contribution to at least the dyslexic form of learning disorder seems promising. One twin study of mathematics disability has also turned up evidence of some genetic contribution to this form of learning disorder (Alarcon et al., 1997).

### Treatments and Outcomes

Because we do not yet have a confident grasp of what is “wrong” with the average learning disordered child, it is important to have a clear assessment of their problems and abilities (Mapou, 2009) so that successful treatment can be implemented. We have had limited success in treating many of these children. Many informal and single-case reports claim success with various treatment approaches, but direct instruction strategies often do not succeed in transforming these children’s abilities (Gettinger & Koscik, 2001), and there are few well-designed and well-executed outcome studies on specific treatments for learning disorders.

We have only limited data on the long-term, adult adjustments of people who grew up with the personal, academic, and social problems that learning disorder generally entails. Two

## THINKING CRITICALLY about DSM-5

### Changes to the Diagnostic System are Nominal for Some Disorders

The logo for DSM-5, featuring the text "DSM-5" in white on a blue background with a rainbow gradient bar below it.

**A**long with the addition of new diagnostic categories, such as gambling disorder and hoarding disorder, and the revision of other earlier diagnostic criteria resulting in disorders such as disruptive mood dysregulation disorder, there have been changes to some existing categories that are largely nominal in order to make the terminology more appropriate with contemporary language use and/or consistent with forthcoming *International Classification of Diseases* system (ICD-11) to be published in 2015.

Several reasons are provided for renaming of some diagnostic categories. For example, the term mental retardation was used in describing individuals with intellectual impairment in previous editions of the *DSM*. However, the term “Mental Retardation” has come to be unacceptable in contemporary use and is considered to be derogatory by many. The new term, “intellectual disability” to replace the term mental retardation has come into more common use in the last decades by

professionals, by the lay public and various advocacy groups. As noted by the *DSM-5* committee, a U.S. legal statute (Public Law 111-256 or Rosa’s Law) has replaced the term mental retardation with intellectual disability. At the Second Session of the 111 Congress of the United States in 2010 the following resolution was passed:

- (b) INDIVIDUALS WITH DISABILITIES EDUCATION ACT—  
(1) SECTION 601(c) (12)(C) of the Individuals with Disabilities Education Act (20 U.S.C. 1400(c) (12)(C) is amended by striking “having mental retardation” and inserting “having intellectual disabilities.”

Although, some practitioners (being accustomed to prior terminology) may have “translation” difficulties as they proceed with new language in *DSM-5* the behaviors and symptoms that make up the problem areas being described are essentially familiar ones.

studies of college students with learning disorder (Gregg & Hoy, 1989) suggest that as a group they continue to have problems—academic, personal, and social—into the postsecondary education years. In a community survey of learning disorder adults, Khan, Cowan, and Roy, (1997) found that some 50 percent of them had personality abnormalities. Cato and Rice (1982) extracted from the available literature a lengthy list of problems experienced by the typical learning disorder adult. These include—in addition to expected difficulties with self-confidence—continuing problems with deficits in the ordinary skills such as math that these people had trouble with as children. The authors do note, however, that there are considerable individual differences in these outcomes and that some adults with learning disorder are able to manage very well.

## Intellectual Disability

**Intellectual disability** (intellectual developmental disorder) is characterized by deficits in general mental abilities, such as reasoning, problem solving, planning, abstract-thinking, judgment, academic learning, and learning from experience (APA 2013, p. 31). For the diagnosis to apply, these problems must begin before the age of 18. Intellectual disability is thus defined in terms of level of performance as well as intelligence. The definition says nothing about causal factors, which may be primarily biological, psychosocial, sociocultural, or a combination of these. By definition, any functional equivalent of Intellectual disability that has its onset after age 17 must be considered a dementia rather than intellectual disability. The distinction is an important one because the psychological situation of a person who acquires a pronounced impairment of intellectual functioning after attaining maturity is vastly different from that of a person whose intellectual resources were below normal throughout all or most of his or her development.

Intellectual disability occurs among children throughout the world (Fryers, 2000). In its most severe forms, it is a source of great hardship to parents as well as an economic and social burden on a community. The point prevalence rate of diagnosed intellectual disability in the United States is estimated to be about 1 percent, which would indicate a population estimate of some 2.6 million people. In fact, however, prevalence is extremely difficult to pin down because definitions of intellectual disability vary considerably (Roeleveld et al., 1997). Most states have laws providing that persons with IQs below 70 who show socially incompetent or persistently problematic behavior can be classified as “mentally retarded” and, if judged otherwise unmanageable, may be placed in an institution. Informally, IQ scores between about 70 and 90 are often referred to as “borderline” or (in the upper part of the range) as “dull-normal.”

Initial diagnoses of intellectual disability occur very frequently at ages 5 to 6 (around the time that schooling begins for most children), peak at age 15, and drop off sharply after that. For the most part, these patterns in age of first diagnosis reflect changes in life demands. During early childhood, individuals

Individuals with mild intellectual disability constitute the largest number of those categorized as mentally retarded. With help, a great majority of these individuals can adjust socially, master simple academic and occupational skills, and become self-supporting citizens.

with only a mild degree of intellectual impairment, who constitute the vast majority of the mentally retarded, often appear to be normal. Their subaverage intellectual functioning becomes apparent only when difficulties with schoolwork lead to a diagnostic evaluation. When adequate facilities are available for their education, children in this group can usually master essential school skills and achieve a satisfactory level of socially adaptive behavior. Following the school years, they usually make a more or less acceptable adjustment in the community and thus lose the identity of being mentally retarded.

### Levels of Intellectual Disability

The various levels of intellectual disability are described in greater detail in the following sections.

**MILD INTELLECTUAL DISABILITY** Individuals with mild intellectual disability constitute by far the largest number of those diagnosed with intellectual disability. Within the educational context, people in this group are considered educable, and their intellectual levels as adults are comparable to those of average 8- to 11-year-old children. Statements such as the latter, however, should not be taken too literally. An adult with mild disability with a mental age of, say, 10 (that is, his or her intelligence test performance is at the level of the average 10-year-old) may not in fact be comparable to the average 10-year-old in information-processing ability or speed (Weiss et al., 1986). On the other hand, he or she will normally have had far more experience in living, which would tend to raise the measured intelligence scores.

The social adjustment of people with mild intellectual disability often approximates that of adolescents, although they tend to lack normal adolescents' imagination, inventiveness, and judgment. Ordinarily, they do not show signs of brain pathology or other physical anomalies, but often they require some measure of supervision because of their limited abilities to foresee

**TABLE 15.1**  
**Disability Severity and IQ Ranges**

Diagnosed Level of Intellectual disability	Corresponding IQ Range
Mild disability	50–55 to approximately 70
Moderate disability	35–40 to 50–55
Severe disability	20–25 to 35–40
Profound disability	below 20–25

the consequences of their actions. With early diagnosis, parental assistance, and special educational programs, the great majority of borderline and individuals with mild intellectual disability can adjust socially, master simple academic and occupational skills, and become self-supporting citizens (Maclean, 1997).

**MODERATE INTELLECTUAL DISABILITY** Individuals with moderate intellectual disability are likely to fall in the educational category of trainable, which means that they are presumed able to master certain routine skills such as cooking or minor janitorial work if provided specialized instruction in these activities. In adult life, individuals with moderate intellectual disability attain intellectual levels similar to those of average 4- to 7-year-old children. Although some can be taught to read and write a little and may manage to achieve a fair command of spoken language, their rate of learning is slow, and their level of conceptualizing is extremely limited. They usually appear clumsy and ungainly, and they suffer from bodily deformities and poor motor coordination. Some individuals with moderate intellectual disability are hostile and aggressive; more typically, they are affable and nonthreatening. In general, with early diagnosis, parental help, and adequate opportunities for training, most individuals with moderate intellectual disability can achieve partial independence in daily self-care, acceptable behavior, and economic sustenance in a family or other sheltered environment.

**SEVERE INTELLECTUAL DISABILITY** In individuals with severe intellectual disability, motor and speech development are severely retarded and sensory defects and motor handicaps are common. They can develop limited levels of personal hygiene and self-help skills, which somewhat lessen their dependency, but they are always dependent on others for care. However, many profit to some extent from training and can perform simple occupational tasks under supervision.

**PROFOUND INTELLECTUAL DISABILITY** Most individuals with profound intellectual disability are severely deficient in adaptive behavior and unable to master any but the simplest tasks. Useful speech, if it develops at all, is rudimentary. Severe physical deformities, central nervous system pathology, and retarded growth are typical; convulsive seizures, mutism, deafness, and other physical anomalies are also common. These

individuals must remain in custodial care all their lives. They tend, however, to have poor health and low resistance to disease and thus a short life expectancy. Severe and profound cases of intellectual disability can usually be readily diagnosed in infancy because of the presence of obvious physical malformations, grossly delayed development (e.g., in taking solid food), and other obvious symptoms of abnormality. These individuals show a marked impairment of overall intellectual functioning.

### Causal Factors in Intellectual Disability

Some cases of intellectual disability occur in association with known organic brain pathology (Kaski, 2000). In these cases, retardation is virtually always at least moderate, and it is often severe. Profound retardation, which fortunately is rare, always includes obvious organic impairment. Organically caused retardation is, in essential respects, similar to dementia, except for the different history of prior functioning. In this section, we will consider five biological conditions that may lead to intellectual disability, noting some of the possible interrelationships among them. Then we will review some of the major clinical types of intellectual disability associated with these organic causes.

**GENETIC-CHROMOSOMAL FACTORS** Intellectual disability, especially mild disability, tends to run in families. Poverty and sociocultural deprivation, however, also tend to run in families, and with early and continued exposure to such conditions, even the inheritance of average intellectual potential may not prevent subaverage intellectual functioning.

Genetic-chromosomal factors play a much clearer role in the etiology of relatively infrequent but more severe types of intellectual disability such as Down syndrome and a heritable condition known as fragile X (Huber & Tamminga, 2007; Schwarte, 2008). The gene responsible for fragile X syndrome (FMR-1) was identified in 1991 (Verkerk et al., 1991). In such conditions, genetic aberrations are responsible for metabolic alterations that adversely affect the brain's development. Genetic defects leading to metabolic alterations may, of course, involve many other developmental anomalies besides intellectual disability—for example, autism (Wassink et al., 2001). In general, intellectual disability associated with known genetic-chromosomal defects is moderate to severe.

**INFECTIONS AND TOXIC AGENTS** Intellectual disability may be associated with a wide range of conditions due to infection such as viral encephalitis or genital herpes (Kaski, 2000). If a pregnant woman is infected with syphilis or HIV-1 or if she gets German measles, her child may suffer brain damage.

A number of toxic agents such as carbon monoxide and lead may cause brain damage during fetal development or after birth (Kaski, 2000). In rare instances, immunological agents such as antitetanus serum or typhoid vaccine may lead to brain damage. Similarly, if taken by a pregnant woman, certain drugs, including an excess of alcohol (West et al., 1998), may lead to

congenital malformations. And an overdose of drugs administered to an infant may result in toxicity and cause brain damage. In rare cases, brain damage results from incompatibility in blood types between mother and fetus. Fortunately, early diagnosis and blood transfusions can minimize the effects of such incompatibility.

**TRAUMA (PHYSICAL INJURY)** Physical injury at birth can result in intellectual disability (Kaski, 2000). Although the fetus is normally well protected by its fluid-filled placenta during gestation, and although its skull resists delivery stressors, accidents do happen during delivery and after birth. Difficulties in labor due to malposition of the fetus or other complications may irreparably damage the infant's brain. Bleeding within the brain is probably the most common result of such birth trauma. Hypoxia—lack of sufficient oxygen to the brain stemming from delayed breathing or other causes—is another type of birth trauma that may damage the brain.

**IONIZING RADIATION** In recent decades, a good deal of scientific attention has been focused on the damaging effects of ionizing radiation on sex cells and other bodily cells and tissues. Radiation may act directly on the fertilized ovum or may produce gene mutations in the sex cells of either or both parents, which may lead to defective offspring. Sources of harmful radiation were once limited primarily to high-energy X rays used in medicine for diagnosis and therapy, but the list has grown to include nuclear weapons testing and leakages at nuclear power plants, among others.

**MALNUTRITION AND OTHER BIOLOGICAL FACTORS** It was long thought that dietary deficiencies in protein and other essential nutrients during early development of the fetus could do irreversible physical and mental damage. However, it is currently believed that this assumption of a direct causal link may have been oversimplified. Ricciuti (1993) cited growing evidence that malnutrition may affect mental development more indirectly by altering a child's responsiveness, curiosity, and motivation to learn. According to this hypothesis, these losses would then lead to a relative retardation of intellectual facility. The implication here is that at least some malnutrition-associated intellectual deficit is a special case of psychosocial deprivation, which is also involved in retardation outcomes, as described below.

A limited number of cases of intellectual disability are clearly associated with organic brain pathology. In some instances—particularly of the severe and profound types—the specific causes are uncertain or unknown, although extensive brain pathology is evident.

### Organic Retardation Syndromes

Intellectual disability stemming primarily from biological causes can be classified into several recognizable clinical types (Murphy et al., 1998), of which Down syndrome, phenylketonuria (PKU), and cranial anomalies will be discussed here. Table 15.2 presents information on several other well-known forms.

**DOWN SYNDROME** First described by Langdon Down in 1866, **Down syndrome** is the best known of the clinical conditions

**TABLE 15.2**  
**Other Disorders Sometimes Associated with Intellectual Disability**

Clinical Type	Symptoms	Causes
No. 18 trisomy syndrome	Peculiar pattern of multiple congenital anomalies, the most common being low-set malformed ears, flexion of fingers, small jaw, and heart defects	Autosomal anomaly of chromosome 18
Tay-Sachs disease	Hypertonicity, listlessness, blindness, progressive spastic paralysis, and convulsions (death by the third year)	Disorder of lipid metabolism, carried by a single recessive gene
Turner's syndrome	In females only; webbing of neck, increased carrying angle of forearm, and sexual infantilism; intellectual disability may occur but is infrequent	Sex chromosome anomaly (XO)
Klinefelter's syndrome	In males only; features vary from case to case, the only constant finding being the presence of small testes after puberty	Sex chromosome anomaly (XXY)
Niemann-Pick's disease	Onset usually in infancy, with loss of weight, dehydration, and progressive paralysis	Disorder of lipid metabolism
Bilirubin encephalopathy	Abnormal levels of bilirubin (a toxic substance released by red cell destruction) in the blood; motor incoordination frequent	Often, Rh (ABO) blood group incompatibility between mother and fetus
Rubella, congenital	Visual difficulties most common, with cataracts and retinal problems often occurring together, and with deafness and anomalies in the valves and septa of the heart	The mother's contraction of rubella (German measles) during the first few months of her pregnancy

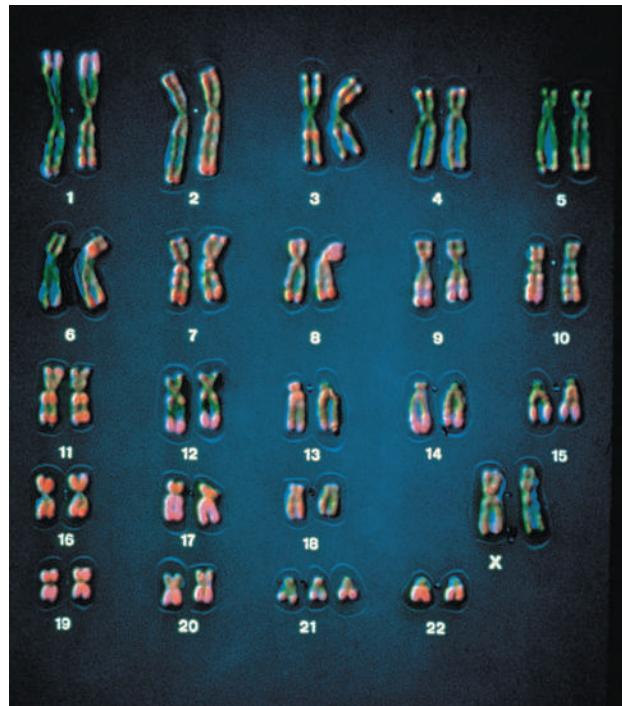

Source: Based on American Psychiatric Association (2013); Harris (2006).

Physical features found among children with Down syndrome include almond-shaped eyes, abnormally thick skin on the eyelids, and a face and nose that are often flat and broad. The tongue may seem too big for the mouth and may show deep fissures. The iris of the eye is frequently speckled. The neck is often short and broad, as are the hands. The fingers are stubby, and the little finger is often more noticeably curved than the other fingers.

associated with moderate and severe intellectual disability. The prevalence of Down syndrome has been reported to be 5.9 per 10,000 of the general population (Cooper, Smiley, et al., 2009). It is a condition that creates irreversible limitations on survivability, intellectual achievement, and competence in managing life tasks (Bittles et al., 2007; Patterson & Lott, 2008) and is associated with health problems in later life such as pneumonia and other respiratory infections. The availability of amniocentesis and chorionic villus sampling in expectant mothers has made it possible to detect *in utero* the extra genetic material involved in Down syndrome, which is most often the trisomy of chromosome 21, yielding 47 rather than the normal 46 chromosomes (see Figure 15.1).

**The Clinical Picture in Down Syndrome** A number of physical features are often found among children with Down syndrome, but few of these children have all of the characteristics commonly thought to typify this group. The eyes appear almond-shaped, and the skin of the eyelids tends to be abnormally thick. The face and nose are often flat and broad, as is the back of the head. The tongue, which seems too large for the mouth, may show deep fissures. The iris of the eye is frequently speckled. The neck is often short and broad, as are the hands.

The fingers are stubby, and the little finger is often more noticeably curved than the other fingers. Although facial surgery is sometimes tried to correct the more stigmatizing features, its success is often limited (Roizen, 2007). Also, parents' acceptance of their Down syndrome child is inversely related to their support of such surgery (Katz et al., 1997).

There are special medical problems with Down syndrome children that require careful medical attention and examinations (Tyrer et al., 2007). Death rates for children with Down syndrome have, however, decreased dramatically in the past century. In 1919 the life expectancy at birth for such children was about 9 years; most of the deaths were due to gross physical problems, and a large proportion occurred in the first year of life. Thanks to antibiotics, surgical correction of lethal anatomical defects such as holes in the walls separating the heart's chambers, and better general medical care, many more of these children now live to adulthood (Hijii et al., 1997). Nevertheless, they appear as a group to experience an accelerated aging process (Hasegawa et al., 1997) and a decline in cognitive abilities (Thompson, 2003). One recent study reported that of those with Down syndrome who were age 60 and above, a little more than 50 percent had clinical evidence of dementia (Margallo et al., 2007).

Despite their problems, children with Down syndrome are usually able to learn self-help skills, acceptable social behavior,

Today many more Down syndrome children are living to adulthood than in the past and are able to learn self-help, social, and manual skills. It is not unusual for Down syndrome children to be mainstreamed to some extent with unimpaired children, such as this boy (center, with glasses). Children with Down syndrome tend to remain relatively unimpaired in their appreciation of spatial relationships and visual-motor coordination; they show their greatest deficits in verbal and language-related skills.

and routine manual skills that enable them to be of assistance in a family or institutional setting (Brown et al., 2001). The traditional view has been that children with Down syndrome are unusually placid and affectionate. However, research has called into question the validity of this generalization (Pary, 2004). These children may indeed be very docile, but probably in no greater proportion than normal children; they may also be equally (or more) difficult in various areas. In general, the quality of a child's social relationships depends on both IQ level and a supportive home environment (Alderson, 2001). Adults with Down syndrome may manifest less maladaptive behavior than comparable persons with other types of learning disabilities (Collacott et al., 1998).

Research has also suggested that the intellectual defect in Down syndrome may not be consistent across various abilities. Children with Down syndrome tend to remain relatively unimpaired in their appreciation of spatial relationships and in visual-motor coordination, although some evidence disputes this conclusion (Uecker et al., 1993). Research data are quite consistent in showing that their greatest deficits are in verbal and language-related skills (Azari et al., 1994; Silverstein et al., 1982). Because spatial functions are known to be partially localized in the right cerebral hemisphere, and language-related functions localized in the left cerebral hemisphere, some investigators speculate that the syndrome is especially crippling to the left hemisphere.

Chromosomal abnormalities other than the trisomy of chromosome 21 may occasionally be involved in the etiology of Down syndrome. However, the extra version of chromosome 21 is present in at least 94 percent of cases. As we noted earlier, it may be significant that this is the same chromosome that has been implicated in research on Alzheimer's disease, especially given that persons with Down syndrome are at extremely high risk for Alzheimer's as they get into and beyond their late 30s (Prasher & Kirshnan, 1993).

The reason for the trisomy of chromosome 21 is not clear, and research continues to address the potential causes (Korbel et al., 2009), but the defect seems definitely related to cognitive deficit (Kahlem, 2006) and to parental age at conception. It has been known for many years that the incidence of Down syndrome increases on an accelerating slope (from the 20s on) with increasing age of the mother. A woman in her 20s has about 1 chance in 2,000 of conceiving a Down syndrome baby, whereas the risk for a woman in her 40s is 1 in 50 (Holvey & Talbott, 1972). As in the case of all birth defects, the risk of having a Down syndrome baby is also high for very young mothers, whose reproductive systems have not yet fully matured. Research has also indicated that the father's age at conception is implicated in Down syndrome, particularly at higher ages (Stene et al., 1981).

Thus it seems that advancing age in either parent increases the risk of the trisomy 21 anomaly, although the effect of maternal age is greater. It is not yet clear how aging produces this effect. A reasonable guess is that aging is related to cumulative exposure to varied environmental hazards such as radiation that might have adverse effects on the processes involved in zygote formation or development.

**PHENYLKETONURIA** In **phenylketonuria (PKU)**, a baby appears normal at birth but lacks a liver enzyme needed to break down phenylalanine, an amino acid found in many foods. The genetic error results in intellectual disability only when significant quantities of phenylalanine are ingested, which is virtually certain to occur if the child's condition remains undiagnosed (Grodin & Laurie, 2000). This disorder occurs in about 1 in 12,000 births (Deb & Ahmed, 2000). This condition is reversible (Embrey et al., 2007); however, if the condition is not detected and treated, the amount of phenylalanine in the blood increases and eventually produces brain damage.

The disorder usually becomes apparent between 6 and 12 months after birth, although such symptoms as vomiting, a peculiar odor, infantile eczema, and seizures may occur during the early weeks of life. Often, the first symptoms noticed are signs of intellectual disability, which may be moderate to severe, depending on the degree to which the disease has progressed. Lack of motor coordination and other neurological problems caused by the brain damage are also common, and often the eyes, skin, and hair of untreated PKU patients are very pale (Dyer, 1999).

The early detection of PKU by examining urine for the presence of phenylpyruvic acid is routine in developed countries, and dietary treatment (such as the elimination of phenylalanine-containing foods such as diet soda or turkey) and related procedures can be used to prevent the disorder (Sullivan & Chang, 1999). With early detection and treatment—preferably before an infant is 6 months old—the deterioration process can usually be arrested so that levels of intellectual functioning may range

from borderline to normal. A few children suffer intellectual disability despite restricted phenylalanine intake and other preventive efforts, however. Dietary restriction in late-diagnosed PKU may improve the clinical picture somewhat, but there is no real substitute for early detection and prompt intervention (Pavone et al., 1993).

It appears that for a baby to inherit PKU, both parents must carry the recessive gene. Thus, when one child in a family is discovered to have PKU, it is especially critical that other children in the family be screened as well. Also, a pregnant PKU mother whose risk status has been successfully addressed by early dietary intervention may damage her at-risk fetus unless she maintains rigorous control of phenylalanine intake.

Patients with PKU are typically advised to follow a restricted diet over their life span in order to prevent cognitive impairment. Some investigators have reported mild deficits in cognitive functioning even with long-term treatment (White et al., 2002). However, other research has found little support for the hypothesis that deficits will occur even with dietary restrictions (Channon et al., 2004).

**CRANIAL ANOMALIES** Intellectual disability is associated with a number of conditions that involve alterations in head size and shape and for which the causal factors have not been definitely established (Carr et al., 2007). In the rare condition known as **macrocephaly** (large-headedness), for example, there is an increase in the size and weight of the brain, an enlargement of the skull, visual impairment, convulsions, and other neurological symptoms resulting from the abnormal growth of glial cells that form the supporting structure for brain tissue.

**Microcephaly** The term **microcephaly** means “small-headedness.” This condition is associated with a type of intellectual disability resulting from impaired development of the brain and a consequent failure of the cranium to attain normal size.

The most obvious characteristic of microcephaly is a small head, the circumference of which rarely exceeds 17 inches, compared with the normal size of approximately 22 inches. Penrose (1963) also describes children with microcephaly as being invariably short in stature but having relatively normal musculature and sex organs. Beyond these characteristics, they differ considerably from one another in appearance, although there is a tendency for the skull to be cone-shaped, with a receding chin and forehead. Children with microcephaly fall within the moderate, severe, and profound categories of intellectual disability but most show little language development and are extremely limited in mental capacity.

Microcephaly may result from a wide range of factors that impair brain development, including intrauterine infections and pelvic irradiation during the mother’s early months of pregnancy. Miller (1970) noted a number of cases of microcephaly in Hiroshima and Nagasaki that apparently resulted from the atomic bomb explosions during World War II. The role of

genetic factors is not clear, although there is speculation that a single recessive gene is involved in a primary, inherited form of the disorder (Robinson & Robinson, 1976). Treatment is ineffective once faulty development has occurred; at present, preventive measures focus on the avoidance of infection and radiation during pregnancy.

**Hydrocephaly** The condition referred to as **hydrocephaly** is a relatively rare disorder in which the accumulation of an abnormal amount of cerebrospinal fluid within the cranium causes damage to the brain tissues and enlargement of the skull (Materro et al., 2001). In congenital cases, the head either is already enlarged at birth or begins to enlarge soon thereafter, presumably as a result of a disturbance in the formation, absorption, or circulation of the cerebrospinal fluid. The disorder can also arise in infancy or early childhood following the development of a brain tumor, subdural hematoma, meningitis, or other conditions. In these cases, the condition appears to result from a blockage of the cerebrospinal pathways and an accumulation of fluid in certain brain areas.

The clinical picture in hydrocephaly depends on the extent of neural damage, which in turn depends on the age at onset and the duration and severity of the disorder. In chronic cases, the chief symptom is the gradual enlargement of the upper part of the head out of proportion to the face and the rest of the body. While the expansion of the skull helps minimize destructive pressure on the brain, serious brain damage occurs nonetheless. This damage leads to intellectual impairment and to such other effects as convulsions and impairment or loss of sight and hearing. The degree of intellectual impairment varies, being severe or profound in advanced cases.

Hydrocephaly can be treated by a procedure in which shunting devices are inserted to drain cerebrospinal fluid. With early diagnosis and treatment, this condition can usually be arrested before severe brain damage has occurred (Duinkerke et al., 2004). Even with significant brain damage, carefully planned and early interventions that take into account both strengths and weaknesses in intellectual functioning may minimize disability (Baron & Goldberger, 1993).

## Treatments, Outcomes, and Prevention

A number of programs have demonstrated that significant changes in the adaptive capacity of children with intellectual disability are possible through special education and other rehabilitative measures (Berney, 2000). The degree of change that can be expected is related, of course, to the individual’s particular situation and level of intellectual disability.

**TREATMENT FACILITIES AND METHODS** Parents of children with intellectual disability often find that childrearing is a very difficult challenge (Glidden & Schoolcraft, 2007). For example, recent research has shown that learning disability is associated with a higher incidence of mental health problems (Cooper &

van der Speck, 2009). One decision that the parents of a intellectual disabled child must make is whether to place the child in an institution (Gath, 2000). Most authorities agree that this should be considered as a last resort, in light of the unfavorable outcomes normally experienced—particularly in regard to the erosion of self-care skills (Lynch et al., 1997). In general, children who are institutionalized fall into two groups: (1) those who, in infancy and childhood, manifest severe intellectual disability and associated physical impairment and who enter an institution at an early age; and (2) those who have no physical impairments but show relatively mild intellectual disability and a failure to adjust socially in adolescence, eventually being institutionalized chiefly because of delinquency or other problem behavior (see Stattin & Klackenberg-Larsson, 1993). In these cases, social incompetence is the main factor in the decision. The families of patients in the first group come from all socioeconomic levels, whereas a significantly higher percentage of the families of those in the second group come from lower educational and occupational strata.

Long-term institutional care is linked with behavioral and emotional problems (Yang et al., 2007). The effect of being institutionalized in adolescence depends heavily on the institution's facilities as well as on individual factors because great care must be taken in assessing the residents' needs and in the recruitment of staff personnel (Petronko et al., 1994). For the many teenagers with intellectual disability whose families are not in a position to help them achieve a satisfactory adjustment, community-oriented residential care seems a particularly effective alternative (Alexander et al., 1985). Unfortunately, many neighborhoods resist the location of such facilities within their confines and reject integration of residents into the local society (Short & Johnston, 1997).

For individuals with intellectual disability who do not require institutionalization, educational and training facilities have historically been woefully inadequate. It still appears that a very substantial proportion of individuals with intellectual disability in the United States never get access to services appropriate to their specific needs (Luckasson et al., 1992).

This neglect is especially tragic in view of the ways that exist to help these people. For example, classes for individuals with mild intellectual disability, which usually emphasize reading and other basic school subjects, budgeting and money matters, and developing of occupational skills, have succeeded in helping many people become independent, productive community members. Classes for those with moderate and severe intellectual disability usually have more limited objectives, but they emphasize the development of self-care and other skills—e.g., toilet habits (Wilder et al., 1997)—that enable individuals to function adequately and to be of assistance in either a family (e.g., Heller et al., 1997) or an institutional setting. Just mastering toilet training and learning to eat and dress properly may mean the difference between remaining at home or in a community residence and being institutionalized.

Today, there are approximately 129,000 people with intellectual disability and other related conditions who receive intermediate care although many are not institutionalized. This is considerably less than the number of residents in treatment 40 years ago. These developments reflect both the new optimism that has come to prevail and, in many instances, new laws and judicial decisions upholding the rights of retarded people and their families. A notable example is Public Law 94–142, passed by Congress in 1975 and since modified several times (see Hayden, 1998). This statute, termed the Education for All Handicapped Children Act, asserts the right of intellectually disabled people to be educated at public expense in the least restrictive environment possible.

During the 1970s, there was a rapid increase in alternative forms of care for individuals with intellectual disability (Tyor & Bell, 1984). These included the use of decentralized regional facilities for short-term evaluation and training, small private hospitals specializing in rehabilitative techniques, group homes or halfway houses integrated into the local community, nursing homes for the elderly with intellectual disability, the placement of children with severe intellectual disability in more enriched foster-home environments, varied forms of support to the family for own-home care, and employment services (Conley, 2003). The past 25 years have seen a marked enhancement in alternative modes of life for individuals with intellectual disability, rendering obsolete (and often leading to the closing of) many public institutions formerly devoted exclusively to this type of care.

**EDUCATION AND INCLUSION PROGRAMMING** Typically, educational and training procedures involve mapping out target areas of improvement such as personal grooming, social behavior, basic academic skills, and (for retarded adults) simple occupational skills (see Shif, 2006). Within each area, specific skills are divided into simple components that can be learned and reinforced before more complex behaviors are required. Behavior modification that builds on a step-by-step progression can bring retarded individuals repeated experiences of success and lead to substantial progress even in severely impaired individuals (Mash & Barkley, 2006).

For children with mild intellectual disability, the question of what schooling is best is likely to challenge both parents and school officials. Many such children fare better when they attend regular classes for much of the day. Of course, this type of approach—often called **mainstreaming** or “inclusion programming”—requires careful planning, a high level of teacher skill, and facilitative teacher attitudes (Wehman, 2003).

### in review

- Compare and contrast mild, moderate, severe, and profound intellectual disability.
- Describe five biological conditions that may lead to intellectual disability.

- Describe some of the physical characteristics of children born with Down syndrome. What is its cause?
- What is the cause of and the preventive treatment for phenylketonuria (PKU)?
- Describe rehabilitation approaches to intellectual disability.

## Planning Better Programs to Help Children and Adolescents

In our earlier discussion of several disorders of childhood and adolescence, we noted the wide range of treatment procedures available as well as the marked differences in outcomes. In concluding this chapter, we will discuss certain special factors associated with the treatment of children and adolescents that can affect the success of an intervention.

### Special Factors Associated with Treatment of Children and Adolescents

Mental health treatment, psychotherapy, and behavior therapy have been found to be as effective with children and adolescents as with adults (Kazdin & Weisz, 2003), but treatments conducted in laboratory-controlled studies are more effective than “real-world” treatment situations (Weisz et al., 1995). There are a number of special factors to consider in relation to treatment for children and adolescents, as follows:

**THE CHILD'S INABILITY TO SEEK ASSISTANCE** Most emotionally disturbed children who need assistance are not in a position to ask for help themselves or to transport themselves to and from child-treatment clinics. Thus, unlike an adult, who can usually seek help, a child is dependent, primarily on his or her parents. Adults should realize when a child needs professional help and take the initiative in obtaining it. Often, however, adults are unaware of the problems or neglect this responsibility.

The law identifies four areas in which treatment without parental consent is permitted: (1) in the case of mature minors (those considered capable of making decisions about themselves); (2) in the case of emancipated minors (those living independently, away from their parents); (3) in emergency situations; and (4) in situations in which a court orders treatment. Many children, of course, come to the attention of treatment agencies as a consequence of school referrals, delinquent acts, abuse by parents, or as a result of family custody court cases.

**VULNERABILITIES THAT PLACE CHILDREN AT RISK FOR DEVELOPING EMOTIONAL PROBLEMS** Children and youth who experience or are exposed to violence are at increased risk for developing psychological disorders (Seifert, 2003). In addition, many families provide an undesirable environment for their growing children (Ammerman et al., 1998). Studies have shown that up to a fourth of American children may be living in inadequate homes and that 7.6 percent of American youth have

reported spending at least one night in a shelter, public place, or abandoned building (Ringwalt et al., 1998). Another epidemiological study (Susser et al., 1993) reveals that 23 percent of newly homeless men in New York City reported a history of out-of-home care as children. Parental substance abuse has also been found to be associated with the vulnerability of children to develop psychological disorders (Bijttebier & Goethals, 2006).

High-risk behaviors or difficult life conditions need to be recognized and taken into consideration (Harrington & Clark, 1998). For example, there are a number of behaviors such as engaging in sexual acts or delinquency and using alcohol or drugs that might place young people at great risk for developing later emotional problems. Moreover, physical or sexual abuse, parental divorce, family turbulence, and homelessness (Cauce et al., 2000; Spataro et al., 2004) can place young people at great risk for emotional distress and subsequent maladaptive behavior (see *The World Around Us* on p. 542). Dodge and colleagues (1997) found that children from homes with harsh discipline and physical abuse, for example, were more likely to be aggressive and conduct disordered than those from homes with less harsh discipline and from nonabusing families.

### NEED FOR TREATING PARENTS AS WELL AS CHILDREN

Because many of the behavior disorders specific to childhood appear to grow out of pathogenic family interactions and result from having parents with psychiatric problems themselves (Johnson et al., 2000), it is often important for the parents, as well as their child, to receive treatment (Dishion & Stormshak, 2007). In some instances, in fact, the treatment program may focus on the parents entirely, as in the case of child abuse.

Increasingly, then, the treatment of children has come to mean family therapy in which one or both parents, along with the child and siblings, may participate in all phases of the program. This is particularly important when the family situation has been identified as involving violence (Chaffin et al., 2004). Many therapists have discovered that fathers are particularly difficult to engage in the treatment process. For working parents and for parents who basically reject the affected child, such treatment may be hard to arrange (Gaudin, 1993), especially in the case of poorer families who lack transportation and money. Thus both parental and economic factors help determine which emotionally disturbed children will receive assistance.

**POSSIBILITY OF USING PARENTS AS CHANGE AGENTS** In essence, parents can be used as change agents by training them in techniques that enable them to help their child. Typically, such training focuses on helping the parents understand their child's behavior disorder and teaching them to reinforce adaptive behavior while withholding reinforcement for undesirable behavior. Encouraging results have been obtained with parents who care about their children and want to help them (Garza et al., 2007). Kazdin, Holland, and Crowley (1997) described a number of barriers to parental involvement in treatment that result

## The Impact of Child Abuse on Psychological Adjustment

Children who are physically or sexually abused show problems in social adjustment (Macmillan, 2010) and are particularly likely to feel that the outcomes of events are determined by external factors beyond their own control (Kinzl & Biebl, 1992; Toth et al., 1992). They are also more likely to experience depressive symptoms (Bushnell et al., 1992; Emery & Laumann-Billings, 1998). As a result, abused children are dramatically less likely to assume personal responsibility for themselves, and they generally demonstrate less interpersonal sensitivity than control children. Children who have been abused have been shown to have long-term adjustment problems, for example, in adjustment to college (Elliott, 2009) and adjustment in intimate relationships later in life (Friesen et al., 2010). Moreover, child abuse and neglect may initiate a chain of violence. Child abuse is also associated with delinquent and criminal behavior when the victim grows up. Maxfield and Widom (1996), in a follow-up study of 908 people who were abused as children, found that their arrest rate for nontraffic offenses was significantly higher than that of a control sample of people who had not been abused as children.

Child abuse is an increasing concern in the United States (Crosson-Tower, 2002). A survey of reported incidents of child abuse in this country found that such reports increased 1.7 percent in 1995, the total number of incidents exceeding 3.1 million; an estimated 1,215 children were killed in 1995 in child abuse incidents (National Committee to Prevent Child Abuse, 1996). The excessive use of alcohol or drugs in a family appears to increase the risk of violent death in the home (Rivera et al., 1997). Some evidence suggests that boys are more often physically abused than girls. It is clear that many children brought to the attention of legal agencies for abuse

have been abused before. Moreover, the significantly higher rates among psychiatric inpatients of having been abused as children suggest that such maltreatment plays a causal role in the development of severe psychopathology (Read, 1997).

When the abuse involves a sexual component such as incest or rape, the long-range consequences can be profound (Paolucci et al., 2001). Adults who were sexually abused as children often show serious psychological symptoms such as a tendency to use dissociative defense mechanisms to excess, excessive preoccupation with bodily functions, lowered self-esteem (Nash et al., 1993), or a tendency to disengage as a means of handling stress (Coffey et al., 1996).

The role of sexual abuse in causing psychological problems has been the subject of several longitudinal studies. A large percentage of sexually abused children experience intense psychological symptoms following the incident (for example, the 74 percent reported by Bentovim et al., 1987). At follow-up, however, the improvement often seems dramatic (Bentovim et al., 1987; Conte et al., 1986). Several investigators have conceptualized the residual symptoms of sexual abuse as a type of posttraumatic stress disorder (PTSD) because the symptoms experienced are similar—for example, nightmares, flashbacks, sleep problems, and feelings of estrangement (Donaldson & Gardner, 1985; Koltek et al., 1998).

Child abuse all too frequently produces maladaptive social behavior in its victims (Winton & Mara, 2001). The treatment of abused children thus needs to address their problems of inadequate social adjustment, depression, and poor interpersonal skills. However, treatment can be effective if the therapy is targeted to specific needs of the child (Harvey & Taylor, 2010).

in dropout from therapy. For example, coming from a disadvantaged background, having parents who are antisocial, or having parents who are under great stress tends to result in premature termination of treatment. Research on parental adherence to clinical recommendations has shown that many of the treatment suggestions made during evaluations are not followed by caregivers. However, one recent study by Dreyer and colleagues (2010) found that 81 percent of the recommendations from an ADHD evaluation were followed up.

### PROBLEM OF PLACING A CHILD OUTSIDE THE FAMILY

Most communities have juvenile facilities that, day or night, will provide protective care and custody for young victims of unfit homes, abandonment, abuse, neglect, and related conditions. Depending on the home situation and the special needs of the child, he or she will later be either returned to his or her parents

or placed elsewhere. In the latter instance, four types of facilities are commonly relied on: (1) foster homes, (2) private institutions for the care of children such as group homes, (3) county or state institutions, and (4) the homes of relatives. At any one time, more than half a million children are living in foster-care facilities, many of whom have been abused or neglected (Minnis et al., 2006).

The quality of a child's new home is, of course, a crucial determinant of whether the child's problems will be alleviated or made worse, and there is evidence to suggest that foster-home placement has more positive effects than group-home placement (Buckley & Zimmermann, 2003; Groza et al., 2003). Efforts are usually made to screen the placement facilities and maintain contact with the situation through follow-up visits, but even so, there have been cases of mistreatment in the new home (Dubner & Motta, 1999; Wilson et al., 2000). In cases of child abuse,

child abandonment, or a serious childhood behavior problem that parents cannot control, it had often been assumed that the only feasible action was to take the child out of the home and find a temporary substitute. With such a child's own home so obviously inadequate, the hope was that a more stable outside placement would be better for the child. But when children are taken from their homes and placed in an institution (which promptly tries to change them) or in a series of foster homes (where they obviously do not really belong), they are likely to feel rejected by their own parents, unwanted by their new caretakers, rootless, constantly insecure, lonely, and bitter. Not surprisingly, children and adolescents in foster homes tend to require more mental health services than do other children (dos Reis et al., 2001).

Accordingly, the trend today is toward permanent planning. First, every effort is made to hold a family together and to give the parents the support and guidance they need for adequate childrearing. If this is impossible, then efforts are made to free the child legally for adoption and to find an adoptive home as soon as possible. This, of course, means that the public agencies need specially trained staffs with reasonable caseloads and access to resources that they and their clients may need.

**VALUE OF INTERVENING BEFORE PROBLEMS BECOME ACUTE** Over the last 25 years, a primary concern of many researchers and clinicians has been to identify and provide early help for children who are at special risk (Athey et al., 1997). Rather than waiting until these children develop acute psychological problems that may require therapy or major changes in living arrangements, psychologists are attempting to identify conditions in the children's lives that seem likely to bring about or maintain behavior problems and, where such conditions exist, to intervene before development has been seriously distorted (Schroeder & Gordon, 2002). An example of this approach is provided in the work of Steele and Forehand (1997). These investigators found that children of parents who had a chronic medical condition (the fathers were diagnosed as having hemophilia, and many were HIV positive) were vulnerable to developing internalizing problems and avoidant behavior, particularly when the parent-child relationship was weak. These symptoms in the child were associated with depression in the parent. The investigators concluded that clinicians may be able to reduce the impact of parental chronic illness by strengthening the parent-child relationship and decreasing the child's use of avoidant strategies.

As described in Chapter 5, another type of early intervention has been developed in response to the special vulnerability children experience in the wake of a disaster or trauma such as a hurricane, accident, hostage-taking, or shooting (Shaw, 2003). Children and adolescents often require considerable support and attention to deal with such traumatic events, which are all too frequent in today's world. Individual and small-group psychological therapy might be implemented for victims of trauma (Cohen et al., 2006);

support programs might operate through school-based interventions (Klingman, 1993); or community-based programs might be implemented to reduce the posttraumatic symptoms.

Early intervention has the double goal of reducing the stressors in a child's life and strengthening the child's coping mechanisms. It can often reduce the incidence and intensity of later maladjustment, thus averting problems for both the individuals concerned and the broader society. It is apparent that children's needs can be met only if adequate preventive and treatment facilities exist and are available to the children who need assistance.

## Family Therapy as a Means of Helping Children

To address a child's problems, it is often necessary to alter pathological family interaction patterns that produce or serve to maintain the child's behavior problems (Mash & Barkley, 2006). Several family therapy approaches have been developed (Prout & Brown, 2007) that differ in some important ways—for example, in terms of how the family is defined (whether to include extended family members); what the treatment process will focus on (whether communications between the family members or the aberrant behavior of the problem family members is the focus); and what procedures are used in treatment (analyzing and interpreting hidden messages in the family communications or altering the reward and punishment contingencies through behavioral assessment and reinforcement). But whatever their differences, all family therapies view a child's problems, at least in part, as an outgrowth of pathological interaction patterns within the family, and they attempt to bring about positive change in family members through analysis and modification of the deviant family patterns (Everett & Everett, 2001).

Treatment outcome research strongly supports the effectiveness of family therapy in improving disruptive family relationships and promoting a more positive atmosphere for children (Shadish et al., 1993).

## Child Advocacy Programs

Today there are over 74 million people under age 18 in the United States (U. S. Bureau of the Census, 2009). Children who encounter mental health problems are at substantial risk for adjustment problems in later life (Smith & Smith, 2010). Unfortunately, both treatment and preventive programs for our society's children remain inadequate for dealing with the extent of psychological problems among children and adolescents. In 1989 the United Nations General Assembly adopted the U.N. Convention on the Rights of the Child, which provides a detailed definition of the rights of children in political, economic, social, and cultural areas. This international recognition of the rights of children can potentially have a great impact in promoting the humane treatment of children. However, implementing those high ideals on a practical level is difficult at best.

In the United States, one approach that has evolved in recent years is mental health child advocacy. Advocacy programs

attempt to help children or others receive services that they need but often are unable to obtain for themselves. In some cases, advocacy seeks to better conditions for underserved populations by changing the system (Pithouse & Crowley, 2007). Federal programs offering services for children are fragmented in that different agencies serve different needs; thus no government agency is charged with considering the whole child and planning comprehensively for children who need help. Consequently, child advocacy is often frustrating and difficult to implement.

Outside the federal government, advocacy efforts for children have until recently been supported largely by legal and special-interest citizen's groups such as the Children's Defense Fund, a public interest organization based in Washington, DC. Mental health professionals were typically not involved. Today, however, there is greater interdisciplinary involvement in attempts to provide effective advocacy programs for children (Carlson, 2001; Singer & Singer, 2000).

Although such programs have made important local gains toward bettering conditions for children with mental

disabilities, a great deal of confusion, inconsistency, and uncertainty still persist in the advocacy movement as a whole (Beeman & Edleson, 2000), and there is still a need to improve the accountability of mental health services for children. In addition, the tendency at both federal and state levels has for some time been to cut back on funds for social services. Even so, some important steps have been taken toward child advocacy, and new efforts to identify and help high-risk children have been made (National Advisory Mental Health Council, 2007). If the direction and momentum of these efforts can be maintained and if sufficient financial support for them can be procured, the psychological environment for children could substantially improve.

### in review

- What special factors must be considered in providing treatment for children and adolescents?
- Why is therapeutic intervention a more complicated process with children than with adults?

## UNRESOLVED issues

### Can Society Deal with Delinquent Behavior?

One of the most troublesome and widespread problems in childhood and adolescence is delinquent behavior, especially that involving juvenile violence (Popma, 2007). This behavior includes such acts as destruction of property, violence against other people, and various behaviors contrary to the needs and rights of others and in violation of society's laws. The term *juvenile delinquency* is a legal one that refers to illegal acts committed by individuals between the ages of 8 and 18 (depending on state law). It is not recognized in the *DSM* as a disorder. The actual incidence of juvenile delinquency is difficult to determine because many delinquent acts are not reported. However, some data are available:

- Of the more than 2 million young people who go through the juvenile courts each year in the United States, about a million and a half are there for delinquent acts. About one in five adolescents entering the juvenile justice system suffers from a mental health condition (Phillippi & DePrato, 2010).
- In 2008, there were over 2.1 million juveniles arrested in the United States, which accounts for about 16 percent of all violent crime arrests; 1,740 juveniles were murder victims (about 11 percent of all murders) (Puzzanchera, 2009).
- A high prevalence of mental health problems has been found among adolescents in juvenile justice populations (Vermeiren et al., 2006). A significant research literature shows that adolescents detained in adult correctional facilities have a high rate of suicide or are likely to commit more crimes when they are released (Bath & Billick, 2010).

- Although most juvenile crime is committed by males, the rate has also risen for females. Female delinquents are commonly apprehended for drug use, sex offenses, running away from home, and incorrigibility.
- Both the incidence and the severity of delinquent behavior are disproportionately high for lower-class adolescents (Puzzanchera, 2009) with the violent crime arrest rate five times greater for African Americans than whites.

### CAUSAL FACTORS

Only a small group of "continuous" delinquents actually evolve from oppositional defiant behavior to conduct disorder and then to adult antisocial personality; most people who engage in delinquent acts as adolescents do not follow this path (Moffitt, 1993a). The individuals who show adolescence-limited delinquency are thought to do so as a result of social mimicry. As they mature, they lose their motivation for delinquency and gain rewards for more socially acceptable behavior. Several key variables seem to play a part in the genesis of delinquency. They fall into the general categories of personal pathology, pathogenic family patterns, and undesirable peer relationships.

#### Personal Pathology

**Genetic Determinants** Although the research on genetic determinants of antisocial behavior is far from conclusive,

(continued)

More than 2 million children a year go through the juvenile justice system for committing delinquent acts.

some evidence suggests possible hereditary contributions to criminality (Bailey 2000).

**Brain Damage and Learning Disability** In a distinct minority of delinquency cases (an estimated 1 percent or less), brain pathology results in lowered inhibitory controls and a tendency toward episodes of violent behavior. Such adolescents are often hyperactive, impulsive, emotionally unstable, and unable to inhibit themselves when strongly stimulated.

**Psychological Disorders** Some delinquent acts appear to be directly associated with behavior disorders such as hyperactivity (Freidenfelt & Klintenberg, 2007). One study reported that over half of delinquents show evidence of mental disorders and 14 percent are judged to have mental disorder with substantial impairment that requires a highly restrictive environment (Shelton, 2001).

**Antisocial Traits** Many habitual delinquents appear to share the traits typical of antisocial personalities (Bailey, 2000). They are impulsive, defiant, resentful, devoid of feelings of remorse or guilt, incapable of establishing and maintaining close interpersonal ties, and seemingly unable to profit from experience.

**Drug Abuse** Many delinquent acts—particularly theft, prostitution, and assault—are directly associated with alcohol or drug use (Leukefeld et al., 1998). Most adolescents who abuse hard drugs such as heroin are forced to steal to maintain their habit. In the case of female addicts, theft may be combined with or replaced by prostitution as a means of obtaining money.

**Pathogenic Family Patterns** Of the various family patterns that have been implicated in contributing to juvenile delinquency, the following appear to be the most important.

**Parental Absence or Family Conflict** Delinquency appears to be much more common among youths from homes in which parents have separated or divorced than among those from homes in which a parent has died, suggesting that parental conflict may be a key element in causing delinquency.

**Parental Rejection and Faulty Discipline** In many cases, one or both parents reject a child. When the father is the rejecting parent, it is difficult for a boy to identify with him and use him as a model for his own development. However, the detrimental effects of parental rejection and inconsistent discipline are by no means attributable only to fathers. Adolescents who experience alienation from both parents have been found to be more prone to delinquent behavior (Leas & Mellor, 2000).

#### Undesirable Peer Relationships

Delinquency tends to be an experience shared by a cultural group (O'Donnell, 2004). In a classic study, Haney and Gold (1973) found that about two-thirds of delinquent acts are committed in association with one or two other people, and most of the remainder involve three or four others. Usually the offender and the companion or companions are of the same sex. Interestingly, girls are more likely than boys to have a constant friend or companion in delinquency.

Broad social conditions may also tend to produce or support delinquency (Ward & Laughlin, 2003). An adolescent's developmental level can have a great deal of influence over how effectively he or she engages with the justice system and resolves his or her problems (Kraus & Pope, 2010). Interrelated factors that appear to be of key importance include alienation and rebellion, social rejection, and the psychological support afforded by membership in a delinquent gang. Gang activity remains a widespread problem across the United States, with prevalence rates remaining significantly elevated in 2008 compared with numbers in the early 2000s (U.S. Department of Justice, Office of Justice Programs,

2010). Every state and every large city has a gang problem, and gangs are cropping up in small rural towns across the United States as well. The problem of gang membership is most prevalent in lower-SES areas and more common among ethnic minority adolescents (48 percent are African Americans; 43 percent are Hispanic Americans) than among Caucasians. Although young people join gangs for many reasons, most members appear to feel inadequate in and rejected by the larger society. About 1 percent of youth ages 10 to 17 are gang members (Snyder & Sickmund, 2006). One study (Yoder et al., 2003) found that a significant number of homeless youth (32 percent of the sample) become gang members. Gang membership gives them a sense of belonging and a means of gaining some measure of status and approval.

### DEALING WITH DELINQUENCY

If juvenile institutions have adequate facilities and personnel, they can be of great help to youth who need to be removed from aversive environments (see Scott, 2010, for a comprehensive overview). These institutions can give adolescents a chance to learn about themselves and their world, to further their education and develop needed skills, and to find purpose and meaning in their lives. In such settings, young people may also have the opportunity to receive psychological counseling and group therapy. The use of "boot camps"

(juvenile facilities designed along the lines of army-style basic training) has received some support as a means of intervening in the delinquency process (Weis & Toolis, 2008), although some of the early programs were highly criticized as being both overly harsh and ineffective in bringing about positive change. One early study reported that youth in boot camps viewed their environment as more positive and therapeutic than did those enrolled in traditional programs and that they showed less antisocial behavior at the end of the training (MacKenzie et al., 2001). However, the harsh, punitive programs favored by many "law and order" politicians (as noted by the Washington State Institute for Public Policy, 1995, 1998) often fail because they do not bring about the necessary behavioral changes through reinforcing alternative behaviors (Huey & Henggeler, 2001). The value of the boot camp as a behavioral change approach for young delinquents remains to be determined by research.

Behavior therapy techniques based on the assumption that delinquent behavior is learned, maintained, and changed according to the same principles as other learned behavior have shown promise in the rehabilitation of juvenile offenders who require institutionalization (Ammerman & Hersen, 1997). Counseling with parents and related environmental changes are generally of vital importance in a total rehabilitation program (Farrington, 2010), but it is often difficult to get parents involved with incarcerated delinquents.

## summary

### 15.1 How does maladaptive behavior appear in different life periods?

- Children once were viewed as "miniature adults." It was not until the second half of the twentieth century that a diagnostic classification system focused clearly on the special problems of children.
- In this chapter, the *DSM-5* classification system is followed in order to provide clinical descriptions of a wide range of childhood behavior problems.

### 15.2 What are the common disorders of childhood?

- Attention-deficit/hyperactivity disorder is one of the more common behavior problems of childhood. In this disorder, the child shows impulsive, overactive behavior that interferes with his or her ability to accomplish tasks.

- The major approaches to treating children with ADHD have been medication and behavior therapy. Using medications such as amphetamines with children is somewhat controversial. Behavior therapy, particularly cognitive-behavioral methods, has shown a great deal of promise in modifying the behavior of children with hyperactivity.
- In conduct disorder, a child engages in persistent aggressive or antisocial acts. The possible causes of conduct disorder or delinquent behavior include biological factors, personal pathology, family patterns, and peer relationships.

### 15.3 Do anxiety and depression appear in children and adolescents?

- Children who suffer from anxiety or depressive disorders typically do not cause trouble for others through their aggressive conduct. Rather, they are fearful, shy, withdrawn, and insecure and have difficulty adapting to outside demands.
- The anxiety disorders may be characterized by extreme anxiety, withdrawal, or avoidance behavior. A likely cause is early family relationships that generate anxiety and prevent the child from developing more adaptive coping skills.

#### **15.4 What are some specific disorders that occur in childhood?**

- Several other disorders of childhood involve behavior problems characterized by a single outstanding symptom rather than pervasive maladaptive patterns. The symptoms may involve enuresis, encopresis, sleepwalking, or tics.

#### **15.5 What are intellectual disabilities?**

- Specific learning disorders are those in which failure of mastery is limited to circumscribed areas, chiefly involving academic skills such as reading. General cognitive ability may be normal or superior.
- Affected children are commonly described as learning disabled (LD). Some localized defect in brain development is often considered the primary cause of the disorder. Learning disorders create great turmoil and frustration in victims, their families, schools, and professional helpers.
- When serious organic brain impairment occurs before the age of 18, the cognitive and behavioral deficits experienced are referred to as intellectual disability. Relatively common forms of such intellectual disability, which in these cases is normally at least moderate in severity, include Down syndrome, phenylketonuria (PKU), and certain cranial anomalies.
- This organic type of mental deficit accounts for only some 25 percent of all cases of intellectual disability.

- In children with autism spectrum disorders, extreme maladaptive behavior occurs during the early years and prevents affected children from developing psychologically.

- It has not been possible to normalize the behavior of children with autism through treatment, but newer instructional and behavior modification techniques have been helpful in improving the functioning of less severely impaired children with autism.

#### **15.6 How can we plan better programs to help children and adolescents?**

- We reviewed a number of potential causes for the disorders of childhood and adolescence. Although genetic predisposition appears to be important in several disorders, parental psychopathology, family disruption, and stressful circumstances (such as parental death or desertion and child abuse) can also contribute.
- There are special problems, and special opportunities, involved in treating childhood disorders. The need for preventive and treatment programs for children is always growing, and in recent years child advocacy has become effective in some states. Unfortunately, the financing and resources necessary for such services are not always readily available, and the future of programs for improving psychological environments for children remains uncertain.

What biological approaches to treating abnormal behavior are available?

Most of us have experienced a time or situation when we were dramatically helped by talking things over with a relative or friend. Most therapists, like all good listeners, rely on receptiveness, warmth, and empathy and take a nonjudgmental approach to the problems their clients present.

But there is more to therapy than just giving someone an opportunity to talk. Therapists also introduce into the relationship psychological interventions that are designed to promote new understandings, behaviors, or both on the client's part. The fact that these interventions are deliberately planned and systematically guided by certain theoretical preconceptions is what distinguishes professional therapy from more informal helping relationships.

## An Overview of Treatment

The belief that people with psychological problems can change—can learn more adaptive ways of perceiving, evaluating, and behaving—is the conviction underlying all **psychotherapy**. Achieving these changes is by no means easy. Sometimes a person's view of the world and her or his self-concept are distorted because of pathological early relationships that have been reinforced by years of negative life experiences. In other

instances, environmental factors such as an unsatisfying job, an unhappy relationship, or financial stresses must be the focus of attention in addition to psychotherapy. Because change can be hard, people sometimes find it easier to bear their present problems than to challenge themselves to chart a different life course. Therapy also takes time. Even a highly skilled and experienced therapist cannot undo a person's entire past history and, within a short time, prepare him or her to cope adequately with difficult life situations. Therapy offers no magical transformations. Nevertheless, it holds promise even for the most severe mental disorders. Moreover, contrary to common opinion, psychotherapy can be less expensive in the long run than alternative modes of intervention (Dobson et al., 2008; Gabbard et al., 1997).

Numerous therapeutic approaches exist, ranging from psychoanalysis to Zen meditation. However, the era of managed care has prompted new and increasingly stringent demands that the efficacy of treatments be empirically demonstrated. This chapter will explore some of the most widely accepted psychological and biological treatment approaches in use today. Although we recognize that different groups of mental health professionals often have their own preferences with respect to the use of the terms *client* and *patient*, in this chapter we use the terms interchangeably.

### Why Do People Seek Therapy?

People who seek therapy vary widely in their problems and in their motivations to solve them. Below we explore a few such motivations.

**STRESSFUL CURRENT LIFE CIRCUMSTANCES** Perhaps the most obvious candidates for psychological treatment are people experiencing sudden and highly stressful situations such as a divorce or unemployment—people who feel so overwhelmed by a crisis that they cannot manage on their own. These people often feel quite vulnerable and tend to be open to psychological treatment because they are motivated to alter their present intolerable mental states. In such situations, clients may gain considerably—and in a brief time—from the perspective provided by their therapists.

**PEOPLE WITH LONG-STANDING PROBLEMS** Other people entering therapy have experienced long-term psychological distress and have lengthy histories of maladjustment. They may have had interpersonal problems such as an inability to be comfortable with intimacy, or they may have felt susceptible to low moods that are difficult for them to shake. Chronic unhappiness and the inability to feel confident and secure may finally prompt them to seek outside help. These people seek psychological assistance out of dissatisfaction and despair. They may enter treatment with a high degree of motivation, but as therapy proceeds, their persistent patterns of maladaptive behavior may generate

resistance with which a therapist must contend. For example, a narcissistic client who expects to be praised by his or her therapist may become disenchanted and hostile when such ego “strokes” are not forthcoming.

**RELUCTANT CLIENTS** Some people enter therapy by a more indirect route. Perhaps they had consulted a physician for their headaches or stomach pains, only to be told that nothing was physically wrong with them. After they are referred to a therapist, they may at first resist the idea that their physical symptoms are emotionally based. Motivation to enter treatment differs widely among psychotherapy clients. Reluctant clients may come from many situations—for example, a person with a substance abuse problem whose spouse threatens “either therapy or divorce,” or a suspected felon whose attorney advises that things will go better at trial if it can be announced that the suspect has “entered therapy.” A substantial number of angry parents bring their children to therapists with demands that their child’s “problematic behavior,” which they view as independent of the family context, be “fixed.” These parents may be surprised and reluctant to recognize their own roles in shaping their child’s behavior patterns.

In general, males are more reluctant to seek help of any kind when they are experiencing problems than females are. In the case of depression, far more men than women say that they would never consider seeing a therapist; when men are depressed they are even reluctant to seek informal help from their friends. Moreover, when men do seek professional help, they tend to ask fewer questions than women do (see Addis & Mahalik, 2003).

Why should this be? One answer is that men are less able than women to recognize and label feelings of distress and to identify these feelings as emotional problems. In addition, men who subscribe to masculine stereotypes emphasizing self-reliance and lack of emotionality also tend to experience more gender-role conflict when they consider traditional counseling, with its focus on emotions and emotional disclosure. For a man who prides himself on being emotionally stoic, seeking help for a problem like depression may present a major threat to his self-esteem. Seeking help also requires giving up some control and may run counter to the ideology that “a real man helps himself.”

How can men be encouraged to seek help when they have difficulties? Part of the solution may be to develop new treatment approaches that provide a better fit for men who see little value in talking about their problems. An example here might be the use of virtual reality therapy to treat soldiers with posttraumatic stress disorder (PTSD; see Chapter 5). Another strategy is to use more creative approaches to encourage men to seek help and support. For example, television commercials for erectile dysfunction use professional basketball players and football coaches to encourage men with similar problems to “step up to the plate” and talk to their doctors. Making men more aware of other “masculine men” who have been “man enough” to go for

help when they needed it may be an important step toward educating those whose adherence to masculine gender roles makes it difficult for them to acknowledge and seek help for their problems.

**PEOPLE WHO SEEK PERSONAL GROWTH** A final group of people who enter therapy have problems that would be considered relatively normal. That is, they appear to have achieved success, have financial stability, have generally accepting and loving families, and have accomplished many of their life goals. They enter therapy not out of personal despair or impossible interpersonal involvements but out of a sense that they have not lived up to their own expectations and realized their own potential. These people, partly because their problems are more manageable than the problems of others, may make substantial gains in personal growth.

Psychotherapy, however, is not just for people who have clearly defined problems, high levels of motivation, and an ability to gain insight into their behavior. Psychotherapeutic interventions have been applied to a wide variety of chronic problems. Even severely disturbed clients with psychosis may profit from a therapeutic relationship that takes into account their level of functioning and maintains therapeutic subgoals that are within their capabilities (e.g., Kendler, 1999; Valmaggia et al., 2008).

It should be clear from these brief descriptions that there is no typical client. Neither is there a model therapy. No currently used form of therapy is applicable to all types of clients, and all of the standard therapies can document some successes. Most authorities agree that client variables such as motivation to change and severity of symptoms are exceedingly important to the outcome of therapy (Clarkin & Levy, 2004). As we will see, the various therapies have relatively greater success when a therapist takes the characteristics of a particular client into account in determining treatment approaches.

## Who Provides Psychotherapeutic Services?

Members of many different professions have traditionally provided advice and counsel to individuals in emotional distress. Physicians, in addition to caring for their patients’ physical problems, often become trusted advisers in emotional matters as well. Many physicians are trained to recognize psychological problems that are beyond their expertise and to refer patients to psychological specialists or to psychiatrists.

Another professional group that deals extensively with emotional problems is the clergy. A minister, priest, or rabbi is frequently the first professional to encounter a person experiencing an emotional crisis. Although some clergy are trained mental health counselors, most limit their counseling to religious matters and spiritual support and do not attempt to provide psychotherapy. Rather, like general-practice physicians, they are trained to recognize problems that require professional management and to refer seriously disturbed people to mental health specialists.

Often the first person that someone experiencing an emotional crisis will talk to is a trusted member of his or her religious community.

The three types of mental health professionals who most often administer psychological treatment in mental health settings are clinical psychologists, psychiatrists, and psychiatric social workers. In addition to their being able to provide psychotherapy, the medical training and licensure qualifications of psychiatrists enable them to prescribe psychoactive medications and also to administer other forms of medical treatment such as electroconvulsive therapy. In some states, appropriately supervised psychologists and other clinical specialists may prescribe medications if they have received additional training. Although mental health professionals differ with respect to their training and approach to treatment, generally, psychiatrists differ from psychologists insofar as they treat mental disorders using biological approaches (e.g., medications), whereas psychologists treat patients' problems by examining and in some cases changing their patients' behaviors and thought patterns.

In a clinic or hospital (as opposed to an individual practice), a wide range of treatment approaches may be used. These range from the use of medications, to individual or group psychotherapy, to home, school, or job visits aimed at modifying adverse conditions in a client's life—for example, helping a teacher become more understanding and supportive of a child-client's needs. Often the latter is as important as treatment directed toward modifying the client's personality, behavior, or both.

This willingness to use a variety of procedures is reflected in the frequent use of a team approach to assessment and treatment, particularly in group practice and institutional settings. This approach ideally involves the coordinated efforts of medical, psychological, social work, and other mental health personnel working together as the needs of each case warrant. Also of key importance is the current practice of providing treatment facilities in the community. Instead of considering maladjustment to be an individual's private misery, which in the past often

required confinement in a distant mental hospital, this approach integrates family and community resources in a total treatment approach.

## The Therapeutic Relationship

The therapeutic relationship evolves out of what both client and therapist bring to the therapeutic situation. The outcome of psychotherapy normally depends on whether the client and therapist are successful in achieving a productive working alliance. The client's major contribution is his or her motivation. Clients who are pessimistic about their chances of recovery or who are ambivalent about dealing with their problems and symptoms respond less well to treatment (e.g., Mussell et al., 2000).

The establishment of an effective working alliance between client and therapist is seen by most investigators and practitioners as essential to psychotherapeutic gain. Our experiences as therapists affirm this basic observation, as does the research literature. In a very real sense, the relationship with the therapist is therapeutic in its own right. Studies of the therapeutic relationship show that how well patients do over the course of therapy is predicted by the ability of their therapist to form a strong alliance with them (Baldwin et al., 2007).

Although definitions of the therapeutic alliance vary, its key elements are (1) a sense of working collaboratively on the problem, (2) agreement between patient and therapist about the goals and tasks of therapy, and (3) an affective bond between patient and therapist (see Constantino et al., 2001; Martin et al., 2000). Clear communication is also important. This is no doubt facilitated by the degree of shared experience in the backgrounds of client and therapist.

Almost as important as motivation is a client's expectation of receiving help. This expectancy is often sufficient in itself to bring about substantial improvement, perhaps because patients who expect therapy to be effective engage more in the process (Meyer et al., 2002). Just as a placebo often lessens pain for someone who believes it will do so, a person who expects to be

What are some of the key elements of an effective therapeutic alliance between client and therapist?

helped by therapy is likely to be helped, almost regardless of the particular methods used by a therapist. The downside of this fact is that if a therapy or therapist fails for whatever reason to inspire client confidence, the effectiveness of treatment is likely to be compromised.

To the art of therapy, a therapist brings a variety of professional skills and methods intended to help people see themselves and their situations more objectively—that is, to gain a different perspective. Besides helping provide a new perspective, most therapy situations also offer a client a safe setting in which he or she is encouraged to practice new ways of feeling and acting, gradually developing both the courage and the ability to take responsibility for acting in more effective and satisfying ways.

To bring about such changes, an effective psychotherapist must help the client give up old and dysfunctional behavior patterns and replace them with new, functional ones. Because clients will present varying challenges in this regard, the therapist must be flexible enough to use a variety of interactive styles.

- What kinds of professionals provide help to people in psychological distress? In what kinds of settings does treatment occur?
- What factors are important in determining how well patients do in therapy?

## Measuring Success in Psychotherapy

Evaluating treatment success is not always as easy as it might seem (Hill & Lambert, 2004). Attempts at estimating clients' gains in therapy generally depend on one or more of the following sources of information: (1) a therapist's impression of changes that have occurred, (2) a client's reports of change, (3) reports from the client's family or friends, (4) comparison of pretreatment and posttreatment scores on personality tests or other instruments designed to measure relevant facets of psychological functioning, and (5) measures of change in selected overt behaviors. Unfortunately, each of these sources has its own limitations.

A therapist may not be the best judge of a client's progress because any therapist is likely to be biased in favor of seeing himself or herself as competent and successful (after all, therapists are only human). In addition, the therapist typically has only a limited observational sample (the client's in-session behavior) from which to make judgments of overall change. Furthermore, therapists can inflate improvement averages by deliberately or subtly encouraging difficult clients to discontinue therapy. The problem of how to deal with early dropouts from treatment further complicates many studies of therapy outcomes. Should these patients be excluded from analyses of outcome? (After all, they have received little or none of the therapy being evaluated.) Or should they be included and counted as treatment failures? These issues have been at the heart of much debate and discussion.

Also, a client is not necessarily a reliable source of information on therapeutic outcomes. Not only may clients want to believe for various personal reasons that they are getting better, but in an attempt to please the therapist they may report that they are being helped. In addition, because therapy often requires a considerable investment of time, money, and sometimes emotional distress, the idea that it has been useless is a dissonant one. Relatives of the client may also be inclined to "see" the improvement they had hoped for, although they often seem to be more realistic than either the therapist or the client in their evaluations of outcome.

Clinical ratings by an outside, independent observer are sometimes used in research on psychotherapy outcomes to evaluate the progress of a client; these ratings may be more objective than ratings made by those directly involved in the therapy. Another widely used objective measure of client change is performance on various psychological tests. A client evaluated in this way takes a battery of tests before and after therapy, and the differences in scores are assumed to reflect progress, or lack of progress, or occasionally even deterioration. However, some of the changes that such tests show may be artificial, as with *regression to the mean*, wherein very high (or very low) scores tend on repeated measurement to drift toward the average of their own distributions, yielding a false impression that some real change has been documented. Also, the particular tests selected are likely to focus on the theoretical predictions of the therapist or researcher. Thus they are not necessarily valid predictors of the changes, if any, that the therapy actually induces or of how the client will behave in real life. And without follow-up assessment, they provide little information on how enduring any change is likely to be.

### Objectifying and Quantifying Change

Generalized terms such as *recovery*, *marked improvement*, and *moderate improvement*, which were often used in outcome research in the past, are open to considerable differences in interpretation. Today the emphasis is on using more quantitative

### research CLOSE-UP

#### Regression to the Mean

This reflects the statistical tendency for extreme scores (e.g., very high or very low scores) on a given measure to look less extreme at a second assessment (as occurs in a repeated-measures design). Because of this statistical artifact, people whose scores are farthest away from the group mean to begin with (e.g., people who have the highest anxiety scores or the lowest scores on self-esteem) will tend to score closer to the group mean at the second assessment, even if no real clinical change has occurred.

methods of measuring change. For example, the Beck Depression Inventory (a self-report measure of depression severity) and the Hamilton Rating Scale for Depression (a set of rating scales used by clinicians to measure the same thing) both yield summary scores and have become almost standard in the pre- and post-therapy assessment of depression. Changes in preselected and specifically denoted behaviors that are systematically monitored, such as how many times a client with obsessions about contamination washes his or her hands, are often highly valid measures of outcome. Such techniques, including client self-monitoring, have been widely and effectively used, mainly by behavioral and cognitive-behavioral therapists.

In research settings, functional magnetic resonance imaging (fMRI) can be used to examine brain activity before and after treatment. For example, Nakao and colleagues (2005) studied 10 outpatients with obsessive-compulsive disorder (OCD). At the start of the study, all the patients received a brain scan while they were engaged in a task that required them to think about words (e.g., sweat, urine, feces) that triggered their obsessions and compulsions. Patients were then treated for 12 weeks either with the SSRI (selective serotonin reuptake inhibitor) fluvoxamine (Luvox) or with behavior therapy. At the end of this treatment period, the brain scanning was repeated.

The results showed that, before treatment, certain areas of the brain thought to be involved in OCD (e.g., a brain region in the frontal lobe called the orbitofrontal cortex) were activated during the symptom-provocation task. However, after therapy, these same regions showed much less activation when the patients were challenged to think about the provocative trigger words. In subsequent research these scientists have also shown that, after 12 weeks of behavior therapy, patients with OCD again show changes in several brain regions that are implicated in this disorder (Nabeyama et al., 2008). Research of this type suggests that physiological changes may indeed accompany the clinical gains that occur in psychotherapy (see Siegle et al., 2012). It is important to keep in mind, however, that changes on rating scales (or on MRI scans) do not necessarily tell us how well the patient is functioning in everyday life (Kazdin, 2008).

### Would Change Occur Anyway?

What happens to disturbed people who do not obtain formal treatment? In view of the many ways in which people can help each other, it is not surprising that improvement often occurs without professional intervention. Moreover, some forms of psychopathology such as depressive episodes or brief psychotic disorder sometimes run a fairly short course with or without treatment. In other instances, disturbed people improve over time for reasons that are not apparent.

Even if many emotionally disturbed persons tend to improve over time without psychotherapy, psychotherapy can often accelerate improvement or bring about desired behavior change that might not otherwise occur. Most researchers today would agree that psychotherapy is more effective than no

treatment (see Shadish et al., 2000), and indeed the pertinent evidence, widely cited throughout this entire text, confirms this strongly. The chances of an average client benefiting significantly from psychological treatment are, overall, impressive (Lambert & Ogles, 2004). Research suggests that about 50 percent of patients show clinically significant change after 21 therapy sessions. After 40 sessions, about 75 percent of patients have improved (Lambert et al., 2001).

But *why* do patients improve? Remarkably, we know very little about the mechanisms through which therapeutic change occurs, or about the “active ingredients” of effective therapy (Kazdin, 2008; Hayes et al., 2011). We do know that progress in therapy is not always smooth and linear, however. Sudden gains can occur between one therapy session and another (Tang & DeRubeis, 1999; Tang et al., 2002). These clinical leaps appear to be triggered by cognitive changes or by psychodynamic insights that patients experience in certain critical sessions. Researchers are now actively exploring how such factors as therapist adherence (how well a therapist delivers a particular type of therapy) and therapist competence (how skillfully the therapist administers the therapy) impact how well the patient does (see Webb et al., 2010). For patients receiving cognitive therapy for depression, therapist competence has been shown to be a predictor of better clinical outcome, as might be expected (Strunk et al., 2010).

### Can Therapy Be Harmful?

The outcomes of psychotherapy are not invariably either neutral (no effect) or positive. Some clients are actually harmed by their encounters with psychotherapists (see *The World Around Us* box). According to one estimate, somewhere between 5 and 10 percent of clients deteriorate during treatment (Lambert & Ogles, 2004). Patients suffering from borderline personality disorder and from OCD typically have higher rates of negative treatment outcomes than do patients with other problems (Mohr, 1995).

Problems in the therapeutic alliance account for some instances of treatment failure. For example, a mismatch of therapist and client personality characteristics may produce deteriorating outcomes. Our impression, supported by some evidence (see Beutler et al., 2004; Castonguay et al., 2010), is that certain therapists, probably for reasons of personality or lack of interpersonal skills, just do not do well with certain types of client problems. In light of these intangible factors, it is ethically required of all therapists (1) to monitor their work with various types of clients to discover any such deficiencies and (2) to refer to other therapists those clients with whom they may be ill-equipped to work (American Psychological Association, 2002).

Unfortunately, clinicians are often quite bad at recognizing when their clients are not doing well (Whipple & Lambert, 2011). To address this problem, research-based measures to assess clinical deterioration are now being developed. If clinicians are willing to use these in their routine clinical practice,

## When Therapy Harms

**T**here are many ways in which therapy can be detrimental. For example, a particular therapy might make certain symptoms worse, make a person more concerned about the symptoms they do have, or make the client excessively dependent on the therapist in order to function. Encounters with some therapists or forms of therapy may also make a person less willing to seek therapy in the future.

Lilienfeld (2007) has developed a list of therapies that have potentially harmful consequences. One example is “rebirthing” therapy for children with attachment problems. This approach, which involves therapists wrapping children in blankets, sitting on them, and squeezing them in an attempt to mirror the birth process, has resulted in several children dying of suffocation.

Another problematic technique is facilitated communication, which is based on the premise that children with autism can communicate if they have the assistance of a facilitator who

helps the child communicate using a computer keyboard. Facilitated communication has been linked to dozens of child sexual abuse allegations against the parents of children with autism. This has exposed these families to a great deal of needless emotional pain and suffering because studies show that the communications in facilitated communication do not come from the children themselves. Rather, they are unknowingly generated by the facilitators themselves as they guide the child’s hands over the keyboard.

All practicing clinicians and therapists owe it to their clients (and to the families of their clients) to educate themselves about research on potentially harmful treatments. They should also monitor their own behavior and adhere to high ethical standards of practice. In this way they can minimize the likelihood that they will cause damage to the people who come to them seeking help.

they will be able to be warned when their clients are not progressing in an expected manner. A major hurdle, however, is implementation. We would not be surprised to learn that the worst therapists are the ones most reluctant to use such patient-monitoring methods.

A special case of therapeutic harm concerns what are called *boundary violations*. This is when the therapist behaves in ways that exploit the trust of the patient or engages in behavior that is highly inappropriate (e.g., taking the patient to dinner, giving the patient gifts). One case involved a patient who had been treated by a psychiatrist for 10 years. During this time the patient gave the therapist gifts of a refrigerator and a dining table and six chairs. She also sold him her Waterford crystal, her china, and a silver service. The silver had an appraised value of \$1,600. However, it was purchased by the psychiatrist for only \$200. The psychiatrist also sold the patient two of his boats, without her even having seen them (Norris et al., 2003).

A sexual relationship between the patient and the therapist represents perhaps the most obvious and extreme example of a serious boundary violation. This is highly unethical conduct. Given the frequently intense and intimate quality of therapeutic relationships, it is not surprising that sexual attraction arises. However, it is the therapist’s professional responsibility to maintain the appropriate boundaries at all times. When exploitative and unprofessional behavior on the part of therapists does occur, it results in great harm to patients (Norris et al., 2003). Anyone seeking therapy needs to be sufficiently aware enough to determine that the therapist she or he has chosen is committed to high ethical and professional standards. For the vast majority of therapists, this is indeed the case.

## What Therapeutic Approaches Should Be Used?

Before optimal treatment can be provided, a number of important decisions must be made. In the sections below we consider some of the factors that are important.

### Evidence-Based Treatment

When a pharmaceutical company develops a new drug, it must obtain approval of the drug from the federal Food and Drug Administration (FDA) before that drug can be marketed. This involves, among other things, demonstrating through research on human subjects that the drug has **efficacy**—that is, the drug does what it is supposed to do in curing or relieving some target condition. These tests, using voluntary and informed patients as subjects, are called **randomized clinical trials (RCTs)** or, more simply, *efficacy trials*. Although these trials may become quite elaborate, the basic design is one of randomly assigning (e.g., by the flip of a coin) half the patients to the supposedly “active” drug and the other half to a visually identical but physiologically inactive placebo. Usually, neither the patient nor the prescriber is informed which is to be administered; that information is

recorded in code by a third party. This *double-blind procedure* (see Chapter 1) is an effort to ensure that expectations on the part of the patient and prescriber play no role in the study. After a predetermined treatment interval, the code is broken and the active-drug or placebo status of all subjects is revealed. If subjects on the active drug have improved in health significantly more than subjects on the placebo, the investigator has evidence of the drug's efficacy. Obviously, the same design could be modified to compare the efficacy of two or more active drugs, with the option of adding a placebo condition. Thousands of such studies are in progress daily across the country. They usually take place in academic medical settings, and many are financially supported by the pharmaceutical industry.

Investigators of psychotherapy outcomes have attempted to apply this research design to their own field of inquiry, with necessary modifications (see Chambless & Ollendick, 2001). A source of persistent frustration has been the difficulty of creating a placebo condition that will appear credible to patients. Most such research has thus adopted the strategy of either comparing two or more purportedly "active" therapies or using a no-treatment ("wait list") control of the same duration as the active-drug treatment. However, withholding treatment from patients in need (even temporarily) by placing them on a wait list sometimes raises ethical concerns. Another problem is that therapists, even those with the same theoretical orientations, often differ markedly in the manner in which they deliver therapy. (In contrast, pills of the same chemical compound and dosage do not vary.) To test a given therapy, it therefore becomes necessary to develop a treatment manual to specify just how the therapy under examination will be delivered. Therapists in the research trial are then trained (and monitored) to make sure that their therapy sessions do not deviate significantly from the procedures outlined in the manual (e.g., see Blum et al., 2008).

Efforts to "manualize" therapy represent one way that researchers have tried to minimize the variability in patients' clinical outcomes that might result from characteristics of the therapist themselves (such as personal charisma). Although **manualized therapies** originated principally to standardize psychosocial treatments to fit the RCT paradigm, some therapists recommend extending their use to routine clinical practice after efficacy for particular disorders has been established (e.g., see Wilson, 1998). Practicing clinicians, however, vary in their attitudes toward treatment manuals (Addis & Krasnow, 2000).

Efficacy, or RCT, studies of psychosocial treatments are increasingly common. These time-limited studies typically focus on patients who have a single *DSM* diagnosis (patients with comorbid diagnoses are sometimes excluded) and involve two or more treatment or control (e.g., wait list) conditions, where at least one of the treatment conditions is psychosocial (another could be some biological therapy, such as a particular drug). Client-participants are randomly assigned to these conditions,

whose effects, if any, are evaluated systematically with a common battery of assessment instruments, usually administered both before and after treatment.

Efficacy studies of the outcomes of specific psychosocial treatment procedures are considered the most rigorous type of evaluation researchers have for establishing that a given therapy "works" for clients with a given diagnosis. Treatments that meet this standard are often described as *evidence based* or *empirically supported*.

## Medication or Psychotherapy?

Advances in **psychopharmacology** have allowed many people who would otherwise need hospitalization to remain with their families and function in the community. These advances have also reduced the time patients need to spend in the hospital and have made restraints and locked wards largely relics of the past. In short, medication has led to a much more favorable hospital climate for patients and staff alike.

Nevertheless, certain issues arise in the use of psychotropic drugs. Aside from possible unwanted side effects, there is the complexity of matching drug and drug dosage to the needs of the specific patient. It is also sometimes necessary for patients to change medication in the course of treatment. In addition, the use of medications in isolation from other treatment methods may not be ideal for some disorders because drugs themselves generally do not cure disorders. Nonetheless, there is now a national trend toward greater use of psychiatric medications at the expense of psychotherapy. This may be problematic because, as many investigators have pointed out, drugs tend to alleviate symptoms by inducing biochemical changes, not by helping the individual understand and change the personal or situational factors that may be creating or reinforcing maladaptive behaviors. Moreover, when drugs are discontinued, patients may be at risk of relapsing (Dobson et al., 2008). For many disorders, a variety of evidence-based forms of psychotherapy may produce more long-lasting benefits than medications alone unless the medications are continued indefinitely.

## Combined Treatments

The integration of medication and psychotherapy remains common in clinical practice, particularly for disorders such as schizophrenia and bipolar disorder (Olson & Marcus, 2010). Such integrated approaches are also appreciated and regarded as essential by the patients themselves. The integrative approach is a good example of the biopsychosocial perspective that best describes current thinking about mental disorders and that is reflected throughout this book.

Medications can be combined with a broad range of psychological approaches. In some cases, they can help patients benefit more fully from psychotherapy. For example, patients with social anxiety disorder who receive exposure therapy do much better if they are given an oral dose of D-cycloserine before each session.

D-cycloserine is an antibiotic used in the treatment of tuberculosis. When taken alone, it has no effect on anxiety. However, D-cycloserine activates a receptor that is critical in facilitating extinction of anxiety. By making the receptor work better, the therapeutic benefits of exposure training are enhanced in people taking D-cycloserine versus placebo (Guastella et al., 2008; Hofman et al., 2006).

Typically, psychosocial interventions are combined with psychiatric medications. This may be especially beneficial for patients with severe disorders (see Gabbard & Kay, 2001). Keller and colleagues (2000) compared the outcomes of 519 depressed patients who were treated with an antidepressant (nefazodone), with psychotherapy (cognitive-behavioral), or with a combination of both of these treatments. In the medication-alone condition, 55 percent of patients did well. In the psychotherapy-alone condition, 52 percent of patients responded to treatment. However, patients for whom the two treatments were combined did even better, with an overall positive response rate of 85 percent. Quite possibly, combined treatment is effective because medications and psychotherapy may target different symptoms and work at different rates. As Hollon and Fawcett (1995) have noted, “Pharmacotherapy appears to provide rapid, reliable relief from acute distress, and psychotherapy appears to provide broad and enduring change, with combined treatment retaining the specific benefits of each” (p. 1232).

It is important to note that combined treatments are not always superior to single treatments. Adding psychiatric medications does not generally improve the clinical efficacy of psychosocial treatments for anxiety disorders, for example. However, for people suffering from chronic or recurrent depression, combined treatments often result in better clinical outcomes (Aaronson et al., 2007).

## Psychosocial Approaches to Treatment

People are fascinated by psychotherapy. As practicing therapists, we are often asked about the work that we do and the kinds of patients we see. In this section, we try to give you a sense of the different clinical approaches that therapists sometimes use. Although we have discussed treatment in the earlier chapters in the context of specific disorders, our goal here is to provide you with a better sense of the different therapeutic approaches, illustrating them with case studies whenever possible.

### Behavior Therapy

**Behavior therapy** is a direct and active treatment that recognizes the importance of behavior, acknowledges the role of learning, and

includes thorough assessment and evaluation. Instead of exploring past traumatic events or inner conflicts, behavior therapists focus on the presenting problem—the problem or symptom that is causing the patient great distress. A major assumption of behavior therapy is that abnormal behavior is acquired in the same way as normal behavior—that is, by learning. A variety of behavioral techniques have therefore been developed to help patients “unlearn” maladaptive behaviors by one means or another.

**EXPOSURE THERAPY** As you know, a behavior therapy technique that is widely used in the treatment of anxiety disorders is exposure (see Chapter 6). If anxiety is learned, then, from the behavior therapy perspective, it can be unlearned. This is accomplished through guided exposure to anxiety-provoking stimuli. During exposure therapy, the patient or client is confronted with the fear-producing stimulus in a therapeutic manner. This can be accomplished in a very controlled, slow, and gradual way, as in **systematic desensitization**, or in a more extreme manner, as in **flooding**, in which the patient directly confronts the feared stimulus at full strength. (An example is a housebound patient with agoraphobia being accompanied outdoors by the therapist.) Moreover, the form of the exposure can be real (also known as **in vivo exposure**) or imaginary (**imaginal exposure**).

The rationale behind systematic desensitization is quite simple: Find a behavior that is incompatible with being anxious (such as being relaxed or experiencing something pleasant) and repeatedly pair this with the stimulus that provokes anxiety in the patient. Because it is difficult if not impossible to feel both pleasant and anxious at the same time, systematic desensitization is aimed at teaching a person, while in the presence (real or imagined) of the anxiety-producing stimulus, to relax or behave in some other way that is inconsistent with anxiety. It may therefore be considered a type of counterconditioning procedure. The term systematic refers to the carefully graduated manner in which the person is exposed to the feared stimulus.

The prototype of systematic desensitization is the classic experiment of Mary Cover Jones (1924), in which she successfully eliminated a small boy’s fears of a white rabbit and other furry animals. She began by bringing the rabbit just inside the door at the far end of the room while the boy, Peter, was eating. On successive days, the rabbit was gradually brought closer until Peter could pat it with one hand while eating with the other.

Joseph Wolpe (1958; Rachman & Hodgson, 1980) elaborated on the procedure developed by Jones and coined the phrase **systematic desensitization** to refer to it. On the assumption that most anxiety-based patterns are, fundamentally, conditioned responses, Wolpe worked out a way to train a client to remain calm and relaxed in situations that formerly produced anxiety. Wolpe’s approach is elegant in its simplicity, and his method is equally straightforward.

Exposure therapy involves confronting anxiety-provoking situations. It can be done *in vivo* (in real life) or in thoughts or imagination. *In vivo* is preferable whenever practically possible.

A client is first taught to enter a state of relaxation, typically by progressive concentration on relaxing various muscle groups. Meanwhile, patient and therapist collaborate in constructing an anxiety hierarchy that consists of imagined scenes graded as to their capacity to elicit anxiety. For example, for a dog-phobic patient, a low-anxiety step might be imagining a small dog in the distance being walked on a leash by its owner. In contrast, a high-anxiety step might be imagining a large and exuberant dog running toward the patient. Therapy sessions consist of the patient's repeatedly imagining, under conditions of deep relaxation, the scenes in the hierarchy, beginning with low-anxiety images and gradually working toward those in the more extreme ranges. Treatment continues until all items in the hierarchy can be imagined without notable discomfort, at which point the client's real-life difficulties typically have shown substantial improvement.

Imaginal procedures have some limitations, an obvious one being that not everybody is capable of vividly imagining the required scenes. In an influential early study of clients with agoraphobia, Emmelkamp and Wessels (1975) conclude that prolonged exposure *in vivo* is superior to imaginal exposure. Since then, therapists have sought to use *in vivo* exposure whenever practical, encouraging clients to confront anxiety-provoking situations directly. As practicing clinicians, we sometimes receive requests from behavior therapists using electronic mailing lists for instructions on making concoctions that look like vomit. In these cases the therapist is treating someone who has a vomiting phobia and has a need for something that looks realistic for an *in vivo* exposure.

Of course, *in vivo* exposure is not possible for all stimuli. In addition, occasionally a client is so fearful that he or she cannot be induced to confront the anxiety-arousing situation directly. Imaginal

procedures are therefore a vital part of the therapeutic exposure repertoire. An important development in behavior therapy is the use of virtual reality to help patients overcome their fears and phobias (Rothbaum, Hodges, et al., 2000). Such approaches are obviously needed when the source of the patient's anxiety is something that is not easily reproduced in real life, such as flying. Overall, the outcome record for exposure treatments is impressive (Barlow et al., 2007; Emmelkamp, 2004). It is also encouraging that the results from virtual reality exposure are comparable to the results obtained from *in vivo* exposure (Powers & Emmelkamp, 2008).

**AVERSION THERAPY** Aversion therapy involves modifying undesirable behavior by the old-fashioned method of punishment. Probably the most commonly used aversive stimuli today are drugs that have noxious effects, such as Antabuse, which induces nausea and vomiting when a person who has taken it ingests alcohol. In another variant, the client is instructed to wear a substantial elastic band on the wrist and to "snap" it when temptation arises, thus administering self-punishment.

In the past, painful electric shock was commonly employed in programs that paired it with the occurrence of the undesirable behavior, a practice that certainly contributed to aversion therapy's negative image among some segments of the public. Although aversive conditioning has been used to treat a wide range of maladaptive behaviors including smoking, drinking, overeating, drug dependence, gambling, sexual deviance, and bizarre psychotic behavior, interest in this approach has declined as other treatment options have become available (see Emmelkamp, 2004).

**MODELING** As the name implies, in **modeling** the client learns new skills by imitating another person, such as a parent or therapist,

who performs the behavior to be acquired. A younger client may be exposed to behaviors or roles in peers who act as assistants to the therapist and then be encouraged to imitate and practice the desired new responses. For example, modeling may be used to promote the learning of simple skills such as self-feeding for a child with profound mental retardation or more complex skills such as being more effective in social situations for a shy, withdrawn adolescent. In work with children especially, effective decision making and problem solving may be modeled when the therapist “thinks out loud” about everyday choices that present themselves in the course of therapy (Kendall, 1990; Kendall & Braswell, 1985).

Modeling and imitation are adjunctive aspects of various forms of behavior therapy as well as other types of therapy. For example, in an early classic work, Bandura (1964) found that live modeling of fearlessness, combined with instruction and guided exposure, was the most effective treatment for snake phobia, resulting in the elimination of phobic reactions in over 90 percent of the cases treated. The photographs taken during the treatment of spider phobia (see Chapter 6) provide a graphic example of a similar approach.

**SYSTEMATIC USE OF REINFORCEMENT** Systematic programs that use reinforcement to suppress (extinguish) unwanted behavior or to elicit and maintain desired behavior have achieved notable success. Often called contingency management programs, these approaches are often used in institutional settings, although this is not always the case.

Suppressing problematic behavior may be as simple as removing the reinforcements that support it, provided, of course, that they can be identified. Sometimes identification is relatively easy, as in the following case. In other instances, it may require extremely careful and detailed observation and analysis for the therapist to learn what is maintaining the maladaptive behavior.

→ **Showing Off in Class** Billy, a 6-year-old first grader, was brought to a psychological clinic by his parents because he hated school and because his teacher had told them that his showing off was disrupting the class and making him unpopular. It became apparent in observing Billy and his parents during the initial interview that both his mother and his father were noncritical and approving of everything Billy did. After further assessment, a three-phase program of therapy was undertaken: (1) Billy's parents were helped to discriminate between showing-off behavior and appropriate behavior on Billy's part. (2) They were instructed to ignore Billy when he engaged in showing-off behavior while continuing to show their approval of appropriate behavior. (3) Billy's teacher was also instructed to ignore Billy, insofar as it was feasible, when he engaged in showing-off behavior and to devote her attention at those times to children who were behaving more appropriately.

Although Billy's showing off in class increased during the first few days of this behavior therapy program, it diminished markedly after his parents and teacher no longer reinforced it. As his

maladaptive behavior diminished, he was better accepted by his classmates. This helped reinforce more appropriate behavior patterns and changed Billy's negative attitude toward school.

Billy's was a case in which unwanted behavior was eliminated by eliminating its reinforcers. On other occasions, therapy is administered to establish desired behaviors that are missing. Examples of such approaches are *response shaping* and use of *token economies*. In **response shaping**, positive reinforcement is used to establish, by gradual approximation, a response that is actively resisted or is not initially in an individual's behavioral repertoire. This technique has been used extensively in working with children's behavior problems (Kazdin, 2007). For example, a child who refuses to speak in front of others (selective mutism) may be first rewarded (with praise or a more tangible treat) for making any sound. Later, only complete words, and later again only strings of words, would be rewarded.

**TOKEN ECONOMIES** Years ago, when behavior therapy was in its infancy, token economies based on the principles of operant conditioning were developed for use with chronic psychiatric inpatients. When they behaved appropriately on the hospital ward, patients earned tokens that they could later use to receive rewards or privileges (Paul, 1982; Paul & Lentz, 1977).

Token economies have been used to establish adaptive behaviors ranging from elementary responses such as eating and making one's bed to the daily performance of responsible hospital jobs. In the latter instance, the **token economy** resembles the outside world, where an individual is paid for his or her work in tokens (money) that can later be exchanged for desired objects and activities. Although sometimes the subject of criticism and controversy, token economies remain a relevant treatment approach for the seriously mentally ill and those with developmental disabilities (see Higgins et al., 2001; Le Blanc et al., 2000).

Similar reinforcement-based methods are now being used to treat substance abuse. In one study, people being treated for cocaine dependence were rewarded with vouchers worth 25 cents if their urine tests came back negative (see Higgins, Wong, et al., 2000). Patients could then ask a staff member to purchase for them items from the community with the vouchers they had accumulated. Patients who received the incentive vouchers based on their abstinence from cocaine had better clinical outcomes than a comparison group of patients who also received vouchers but whose vouchers were not contingent on their abstinent behavior.

**EVALUATING BEHAVIOR THERAPY** Compared with some other forms of therapy, behavior therapy has some distinct advantages. Behavior therapy usually achieves results in a short period of time because it is generally directed to specific symptoms, leading to faster relief of a client's distress and to lower costs. The methods to be used are also clearly delineated, and the results can be readily evaluated. Overall, the outcomes achieved with behavior therapy compare very favorably with those of other approaches (Emmelkamp, 2004; Nathan & Gorman, 2007).

As with other approaches, behavior therapy works better with certain kinds of problems than with others. Generally, the more pervasive and vaguely defined the client's problem, the less likely behavior therapy is to be useful. For example, it appears to be only rarely employed to treat complex personality disorders, although *dialectical behavior therapy* (see Chapter 10) for patients with borderline personality disorder is an exception (Crits-Christoph & Barber, 2007). On the other hand, behavioral techniques remain central to the treatment of anxiety disorders (Barlow et al., 2007; Franklin & Foa, 2007). Because behavioral treatments are often quite straightforward, behavior therapy can be used with psychotic patients (Kopelowicz et al., 2007). Recent research also shows that behavior therapy is an effective treatment for the vocal and motor tics that are found in people with Tourette's syndrome (Wilhelm et al., 2012). This is welcome news because the alternative treatment approach involves the use of antipsychotic medications.

A recent development in the treatment of depression is a brief and structured form of therapy called *behavioral activation* (see Chapter 7). In this treatment the patient and the therapist work together to help the patient find ways to become more active and engaged with life. The patient is encouraged to engage in activities that will help improve mood and lead to better ways of coping with specific life problems. Although this sounds quite simple, it is not always that easy to accomplish. However, evidence to date suggests that this form of therapy is very beneficial for patients and can lead to enduring change (Dimidjian et al., 2011; Dobson et al., 2008).

### Cognitive and Cognitive-Behavioral Therapy

The early behavior therapists focused on observable behavior and regarded the inner thoughts of their clients as unimportant. However, starting in the 1970s, a number of behavior therapists began to reappraise the importance of "private events"—thoughts, perceptions, evaluations, and self-statements—and started to see them as processes that mediated the effects of objective stimulus conditions to determine behavior and emotions (Borkovec, 1985; Mahoney & Arnkoff, 1978).

*Cognitive* and *cognitive-behavioral therapy* (terms for the most part used interchangeably) stem from both cognitive psychology (with its emphasis on the effects of thoughts on behavior) and behaviorism (with its rigorous methodology and performance-oriented focus). No single set of techniques defines cognitively oriented treatment approaches. However, two main themes are important: (1) the conviction that cognitive processes influence emotion, motivation, and behavior; and (2) the use of cognitive and behavior-change techniques in a pragmatic (hypothesis-testing) manner. In the following discussion, we briefly describe the rational emotive behavior therapy of Albert Ellis and then focus in more detail on the cognitive therapy approach of Aaron Beck.

**RATIONAL EMOTIVE BEHAVIOR THERAPY** The first form of behaviorally oriented cognitive therapy was developed by Albert Ellis and called **rational emotive behavior therapy (REBT)**

(see Ellis & Dryden, 1997). REBT attempts to change a client's maladaptive thought processes, on which maladaptive emotional responses, and thus behavior, are presumed to depend.

Ellis posited that a well-functioning individual behaves rationally and in tune with empirical reality. Unfortunately, however, many of us have learned unrealistic beliefs and perfectionistic values that cause us to expect too much of ourselves, leading us to behave irrationally and then to feel that we are worthless failures. For example, a person may continually think, "I should be able to win everyone's love and approval" or "I should be thoroughly adequate and competent in everything I do." Such unrealistic assumptions and self-demands inevitably spell problems.

The task of REBT is to restructure an individual's belief system and self-evaluation, especially with respect to the irrational "shoulds," "oughts," and "musts" that are preventing the individual from having a more positive sense of self-worth and an emotionally satisfying, fulfilling life. Several methods are used. One method is to dispute a person's false beliefs through rational confrontation ("Why should your failure to get the promotion you wanted mean that you are worthless?").

REBT therapists also use behaviorally oriented techniques. For example, homework assignments might be given to encourage clients to have new experiences and to break negative chains of behavior. Although the techniques differ dramatically, the philosophy underlying REBT has something in common with that underlying humanistic therapy (discussed later) because both take a clear stand on personal worth and human values. Rational emotive behavior therapy aims to increase an individual's feelings of self-worth and clear the way for self-actualization by removing the false beliefs that have been stumbling blocks to personal growth.

**BECK'S COGNITIVE THERAPY** Beck's cognitive therapy approach was originally developed for the treatment of depression and later for anxiety disorders. Now, however, this form of

According to the cognitive model, how we think about situations is closely linked to our emotional responses to them. If this young man is having automatic thoughts such as, "I'll never get to play. I'm such a loser," he is likely to be more emotionally distressed about waiting on the sideline than if he has a thought such as, "There's a lot I can learn from watching how this game is going."

treatment is used for a broad range of conditions, including eating disorders and obesity, personality disorders, substance abuse, and even schizophrenia (Beck, 2005; Beck & Rector, 2005; Hollon & Beck, 2004). The cognitive model is basically an information-processing model of psychopathology. A fundamental assumption of the cognitive model is that problems result from biased processing of external events or internal stimuli. These biases distort the way that a person makes sense of the experiences that she or he has in the world, leading to cognitive errors.

But why do people make cognitive errors at all? According to Beck (2005), underlying these biases is a relatively stable set of cognitive structures or schemas that contain dysfunctional beliefs. When these schemas become activated (by external or internal triggers), they bias how people process information. In the case of depression, people become inclined to make negatively biased interpretations of themselves, their world, and their future.

In the initial phase of cognitive therapy, clients are made aware of the connection between their patterns of thinking and their emotional responses. They are first taught simply to identify their own automatic thoughts (such as, "This event is a total disaster") and to keep records of their thought content and their emotional reactions (see Wright et al., 2006). With the therapist's help, they then identify the logical errors in their thinking and learn to challenge the validity of these automatic thoughts. The errors in the logic behind their thinking lead them (1) to perceive the world selectively as harmful while ignoring evidence to the contrary; (2) to overgeneralize on the basis of limited examples—for example, seeing themselves as totally worthless because they were laid off from work; (3) to magnify the significance of undesirable events—for example, seeing the job loss as the end of the world for them; and (4) to engage in absolutistic thinking—for example, exaggerating the importance of someone's mildly critical comment and perceiving it as proof of their instant descent from goodness to worthlessness. In the case study below, the therapist describes some of these errors in thinking to a depressed patient.

## → Cognitive Therapy

THERAPIST: You have described many instances today where your interpretations led to particular feelings. You remember when you were crying a little while ago and I asked you what was going through your mind? You told me that you thought that I considered you pathetic and that I wouldn't want to see you for therapy. I said you were reading my mind and putting negative thoughts in my mind that were not, in fact, correct. You were making an arbitrary inference, or jumping to conclusions without evidence. This is what often happens when one is depressed. One tends to put the most negative interpretations on things, even sometimes when the evidence is contrary, and this makes one even more depressed.

Do you recognize what I mean?

PATIENT: You mean even my thoughts are wrong?

THERAPIST: No, not your thoughts in general, and I am not talking about right and wrong. As I was explaining before,

interpretations are not facts. They can be more or less accurate, but they cannot be right or wrong. What I mean is that some of your interpretations, in particular those relating to yourself, are biased negatively. The thoughts you attributed to me could have been accurate. But there were also many other conclusions you could have reached that might have been less depressing for you, in that they would reflect less badly on you. For example, you could have thought that since I was spending time with you, that meant I was interested and that I wanted to try and help. If this had been your conclusion, how do you think that you would have felt? Do you think that you would have felt like crying?

PATIENT: Well, I guess I might have felt less depressed, more hopeful.

THERAPIST: Good. That's the point I was trying to make. We feel what we think. Unfortunately, these biased interpretations tend to occur automatically. They just pop into one's head and one believes them. What you and I will do in therapy is to try and catch these thoughts and examine them. Together we will look at the evidence and correct the biases to make the thoughts more realistic. Does this sound all right with you?

PATIENT: Yes.

Much of the content of the therapy sessions and homework assignments is analogous to experiments in which a therapist and a client apply learning principles to alter the client's biased and dysfunctional cognitions and continuously evaluate the effects that these changes have on subsequent thoughts, feelings, and overt behavior. It is important to note, however, that in Beck's cognitive therapy, clients do not change their beliefs by debate and confrontation as is common in REBT. Rather, they are encouraged to gather information about themselves. For example, a young man who believes that he will be rejected by any attractive woman he approaches would be led to a searching analysis of the reasons why he holds this belief. The client might then be assigned the task of "testing" this dysfunctional "hypothesis" by actually approaching seemingly appropriate women whom he admires. The results of the "test" would then be discussed with the cognitive therapist, and any cognitive "errors" that may have interfered with a skillful performance would be identified and corrected.

In addition, the client is encouraged to discover the faulty assumptions or dysfunctional schemas that may be leading to problem behaviors and self-defeating tendencies (Young et al., 2008). These generally become evident over the course of therapy as the client and the therapist examine the themes of the client's automatic thoughts. Because these dysfunctional schemas are seen as making the person vulnerable (e.g., to depression), this phase of treatment is considered essential in ensuring

resistance to relapse when the client faces stressful life events in the future. That is, if the underlying cognitive vulnerability factors are not changed, the client may show only short-term improvement and will still be subject to recurrent depression.

For disorders other than depression, the general approach is quite similar. However, the nature of the patient's automatic thoughts and underlying beliefs is obviously quite different across disorders. In panic disorder, for example, the focus is on identifying the automatic thoughts about feared bodily sensations and on teaching the client to "decatastrophize" the experience of panic (Craske & Barlow, 2008). In bulimia nervosa, the cognitive approach centers on the person's overvalued ideas about body weight and shape, which are often fueled by low self-esteem and fears of being unattractive. In addition, faulty cognitions about which foods are "safe" and which are "dangerous" are explored (Fairburn et al., 2008; Wilson, 2005).

**EVALUATING COGNITIVE-BEHAVIORAL THERAPIES** In spite of the widespread attention that Ellis's REBT has enjoyed, it has been less well assimilated into the mainstream than Beck's cognitive therapy (David et al., 2005). Nonetheless, REBT is still very much alive and well. In general, this approach may be most useful in helping basically healthy people to cope better with everyday stress and perhaps in preventing them from developing full-blown anxiety or depressive disorders (Haaga & Davison, 1989, 1992). With respect to controlled research studies with carefully diagnosed clinical populations, REBT appears to be inferior to exposure-based therapies in the treatment of anxiety disorders such as agoraphobia, social phobia (Haaga & Davison, 1989, 1992), and probably obsessive-compulsive disorder (Franklin & Foa, 1998).

In contrast, the efficacy of Beck's cognitive treatment methods has been well documented. Research suggests that these approaches are extremely beneficial in alleviating many different types of disorders (see Hollon & Beck, 2004). For all but the most severe cases of depression (e.g., psychotic depression), cognitive-behavioral therapy is at least comparable to drug treatment. It also offers long-term advantages, especially with regard to the prevention of relapse (Craighead et al., 2007). Cognitive therapy also produces dramatic results in the treatment of panic disorder and generalized anxiety disorder (Hollon & Beck, 2004), and cognitive-behavioral therapy is now the treatment of choice for bulimia (Wilson, 2010; Wilson & Fairburn, 2007). Finally, cognitive approaches have promise in the treatment of conduct disorder in children (Kazdin, 2007), substance abuse (Beck et al., 1993), and certain personality disorders (Beck et al., 1990; Linehan, 1993).

The combined use of cognitive and behavior therapy approaches is now quite routine. Some disagreement remains about whether the effects of cognitive treatments are actually the result of cognitive changes as the cognitive theorists propose (Hollon & Beck, 2004; Jacobson et al., 1996). At least for depression and panic disorder, it does appear that cognitive

change is the best predictor of long-term outcome, just as cognitive theory maintains (Hollon et al., 1990). Exactly what the "active ingredients" of cognitive treatments really are, however, remains a source of debate and research (e.g., Garratt et al., 2007; Teasdale et al., 2001).

## Humanistic-Experiential Therapies

The humanistic-experiential therapies emerged as significant treatment approaches after World War II. In a society dominated by self-interest, mechanization, computerization, mass deception, and mindless bureaucracy, proponents of the humanistic-experiential therapies see psychopathology as stemming in many cases from problems of alienation, depersonalization, loneliness, and a failure to find meaning and genuine fulfillment. Problems of this sort, it is held, are not likely to be solved either by delving into forgotten memories or by correcting specific maladaptive behaviors.

The humanistic-experiential therapies are based on the assumption that people have both the freedom and the responsibility to control their own behavior—that they can reflect on their problems, make choices, and take positive action. Humanistic-experiential therapists feel that a client must take most of the responsibility for the direction and success of therapy, with the therapist serving merely as counselor, guide, and facilitator. Although humanistic-experiential therapies differ in their details, their central focus is always expanding a client's "awareness."

**CLIENT-CENTERED THERAPY** The **client-centered** (person-centered) **therapy** of Carl Rogers (1902–1987) focuses on the natural power of the organism to heal itself (Rogers, 1951, 1961). Rogers saw therapy as a process of removing the constraints and restrictions that grow out of unrealistic demands that people tend to place on themselves when they believe, as a condition of self-worth, that they should not have certain kinds of feelings such as hostility. By denying that they do in fact have such feelings, they become unaware of their actual "gut" reactions. As they lose touch with their own genuine experience, the result is lowered integration, impaired personal relationships, and various forms of maladjustment.

The primary objective of Rogerian therapy is to resolve this incongruence—to help clients become able to accept and be themselves. To this end, client-centered therapists establish a psychological climate in which clients can feel unconditionally accepted, understood, and valued as people. Within this context, the therapist employs nondirective techniques such as empathic reflecting, or restatement of the client's descriptions of life difficulties. If all goes well, clients begin to feel free, for perhaps the first time, to explore their real feelings and thoughts and to accept hates and angers and ugly feelings as parts of themselves. As their self-concept becomes more congruent with their actual experience, they become more self-accepting and more open to new experiences and new perspectives; in short, they become better-integrated people.

In contrast to most other forms of therapy, the client-centered therapist does not give answers, interpret what a client says, probe for unconscious conflicts, or even steer the client toward certain topics. Rather, he or she simply listens attentively and acceptingly to what the client wants to talk about, interrupting only to restate in different words what the client is saying. Such restatements, devoid of any judgment or interpretation by the therapist, help the client to clarify further the feelings and ideas that he or she is exploring—really to look at them and acknowledge them. The following excerpt from a therapist's second interview with a young woman will serve to illustrate these techniques of reflection and clarification.

### → Client-Centered Therapy

JENNY: I was thinking about how I always try to make people around me feel at ease. It's so important for me to make things go along smoothly.

THERAPIST: In other words, you are always trying to make other people feel better and to do all you can to keep things on an even keel and going well.

JENNY: Yes. That's right. I mean, it's not because I am such a kind person and all I want to see is other people being happy. I think the reason I do it is probably because that has always been the role that has felt the easiest for me to play. It's the role I played at home. I didn't stand up for my own convictions. And now I'm at the point where I don't really know whether I have any convictions to stand up for.

THERAPIST: So you feel this is a role you have been playing for a long time, smoothing out frictions and avoiding saying anything that might be challenging in any way.

JENNY: I think that's right.

THERAPIST: And so now you aren't sure if you even have any genuine opinions or reactions of your own. Is that right?

JENNY: That's it. Or maybe I haven't really been honest with myself and let myself even consider what I really think about things. I've just been playing a sort of a false role—being a people-pleaser. Whatever I felt other people needed me to be, that's who I was. And in the process I just got lost.

Pure client-centered psychotherapy, as originally practiced, is rarely used today in North America, although it is still relatively popular in Europe. Motivational interviewing is a new form of therapy that is based on this empathic style.

**MOTIVATIONAL INTERVIEWING** People tend to be ambivalent about making changes in their lives. They want to change, but they also don't want to change. **Motivational interviewing (MI;** see Hettema, Steele, & Miller, 2005) is a brief form of therapy that can be delivered in one or two sessions. It was developed as a way to help people resolve their ambivalence about change and make a commitment to treatment (Miller, 1983). At its center is a supportive and empathic style of relating to

the client that has its origins in the work of Carl Rogers. However, MI differs from client-centered counseling because it also employs a more direct approach that explores the client's own reasons for wanting to change. The therapist encourages this "change talk" by asking the client to discuss his or her desire, ability, reasons, and need for change. These are reflected back by the therapist, thus exposing the client to periodic summaries of his or her own motivational statements and thoughts about change. The result is that clients can develop and strengthen their commitment to change in an active, accepting, and supportive atmosphere.

Motivational interviewing is most often used in the areas of substance abuse and addiction. When added to the beginning of a treatment program, it appears to benefit patients, perhaps because it facilitates patients' staying in treatment and following the treatment plan. Hettema and colleagues' (2005) meta-analysis of the MI literature has also shown that MI has a large effect when it is used with ethnic minorities. In one alcoholism-treatment trial, Native American participants did better if they received four sessions of MI than if they received 12 sessions of cognitive-behavior therapy or else participated in a 12-step program (Villanueva et al., 2003). Quite possibly, the supportive and nonconfrontational style of MI may be more congruent with the typical and culturally sanctioned communication style of Native Americans and thus represent a culturally appropriate intervention. The collaborative and nonconfrontational style of MI may also make it acceptable to adolescents. Even a very small number of sessions of MI can promote behavior change in adolescents who use drugs and alcohol (Jensen et al., 2011).

**GESTALT THERAPY** In German, the term *gestalt* means "whole," and gestalt therapy emphasizes the unity of mind and body—placing strong emphasis on the need to integrate

Motivational interviewing is a brief intervention that helps people resolve their ambivalence about making change. It is often used in the treatment of substance abuse and addiction.

thought, feeling, and action. **Gestalt therapy** was developed by Frederick (Fritz) Perls (1969) as a means of teaching clients to recognize the bodily processes and emotions they had been blocking off from awareness. As with the client-centered and humanistic approaches, the main goal of gestalt therapy is to increase the individual's self-awareness and self-acceptance.

Although gestalt therapy is commonly used in a group setting, the emphasis is on one person at a time, with whom a therapist works intensively, trying to help identify aspects of the individual's self or world that are not being acknowledged in awareness. The individual may be asked to act out fantasies concerning feelings and conflicts or to represent one side of a conflict while sitting in one chair and then switch chairs to take the part of the adversary. Often the therapist or other group members will ask such questions as, "What are you aware of in your body now?" and "What does it feel like in your gut when you think of that?"

In Perls's approach to therapy, a good deal of attention is also paid to dreams, but with an emphasis very different from that of classical psychoanalysis. In gestalt theory, all elements of a dream, including seemingly inconsequential, impersonal objects, are considered to be representations of unacknowledged aspects of the dreamer's self. The therapist urges the client to suspend normal critical judgment, to "be" the object in the dream, and then to report on the experience. This is illustrated in the following case study.

→ **Gestalt Therapy** A college professor was preoccupied with his academic promotion and tenure and found himself unable to experience any joy. He sought the assistance of a friend who was a gestalt therapist. She asked him to conjure up a daydream rather than a dream. The daydream that emerged spontaneously was one of skiing. The therapist asked him to be the mountain, and he began to experience how warm he was when he was at his base. As he got closer to the top, what looked so beautiful was also very cold and frozen. The therapist asked the professor to be the snow, and he experienced how hard and icy he could be near the top. But near the bottom, people ran over him easily and wore him out. When the session was finished, the professor did not feel like crying or shouting; he felt like skiing. So he went, leaving articles and books behind. In the sparkle of the snow and sun, he realized that joy in living emerges through deeds and not through words. In his rush to succeed, he had committed one of the cardinal sins against himself—the sin of not being active.

#### EVALUATING HUMANISTIC-EXPERIENTIAL THERAPIES

Many of the humanistic-experiential concepts—the uniqueness of each individual, the importance of therapist genuineness, the satisfaction that comes from realizing one's potential, the importance of the search for meaning and fulfillment, and the human

capacity for choice and self-direction—have had a major impact on our contemporary views of both human nature and the nature of good psychotherapy.

However, humanistic-experiential therapies have been criticized for their lack of agreed-upon therapeutic procedures and their vagueness about what is supposed to happen between client and therapist. In response, proponents of such approaches argue against reducing people to abstractions, which can diminish their perceived worth and deny their uniqueness. Because people are so different, they argue, we should expect different techniques to be appropriate for different cases.

Controlled research on the outcomes achieved by many forms of humanistic-existential therapy was lacking in the past. However, research in this area is now on the increase. There is evidence to suggest that these treatment approaches are helpful for patients with a variety of problems including depression, anxiety, trauma, and marital difficulties (Elliot et al., 2004). And, as we have already noted, motivational interviewing is now established as an effective method for promoting behavior change in people with substance abuse problems (Ball et al., 2007; Jensen et al., 2011).

#### Psychodynamic Therapies

**Psychodynamic therapy** is a broad treatment approach that focuses on individual personality dynamics, usually from a psychoanalytic or some psychoanalytically derived perspective. Psychoanalytic therapy is the oldest form of psychological therapy and began with Sigmund Freud. The therapy is mainly practiced in two basic forms: classical psychoanalysis and psychoanalytically oriented psychotherapy. As developed by Freud and his immediate followers, classical psychoanalysis is an intensive (at least three sessions per week), long-term procedure for uncovering repressed memories, thoughts, fears, and conflicts presumably stemming from problems in early psychosexual development—and helping individuals come to terms with them in light of the realities of adult life. For example, excessive orderliness and a grim and humorless focus on rigorous self-control would probably be viewed as deriving from difficulties in early toilet training.

In psychoanalytically oriented psychotherapy, the treatment and the ideas guiding it may depart substantially from the principles and procedures laid out by orthodox Freudian theory, yet the therapy is still loosely based on psychoanalytic concepts. For example, many psychoanalytically oriented therapists schedule less frequent sessions (e.g., once per week) and sit face-to-face with the client instead of having the latter recline on a couch with the analyst out of sight behind him or her. Likewise, the relatively passive stance of the analyst (primarily listening to the client's "free associations" and rarely offering "interpretations") is replaced with an active conversational style in which the therapist attempts to clarify distortions and gaps in the client's construction of the origins and consequences of his or her problems, thus challenging client "defenses" as they present themselves.

It is widely believed that this more direct approach significantly shortens total treatment time. We will first examine Freud's original treatment methods, in part because of their historical significance and enormous influence; we will then look briefly at some of the contemporary modifications of psychodynamic therapy, which for the most part focus on interpersonal processes. Before we do so, however, let's consider the case of Karen.

→ **Psychodynamic Therapy** Karen was about to be terminated from her nursing program if her problems were not resolved. She had always been a competent student who seemed to get along well with peers and patients. Now, since the beginning of her rotation on 3 South, a surgical ward, she was plagued by headaches and dizzy spells. Of more serious consequence were the two medical errors she had made when dispensing medications to patients. She realized that these errors could have proved fatal, and she was as concerned as her nursing faculty about why such problems had begun in this final year of her education. Karen knew she had many negative feelings toward the head nurse on 3 South, but she did not believe these feelings could account for her current dilemma. She entered psychotherapy.

After a few weeks of psychotherapy, the therapist realized that one of Karen's important conflicts revolved around the death of her father when she was 12 years old. Karen had just gone to live with her father after being with her mother for 7 years. She remembered how upset she was when her father had a heart attack and had to be rushed to the hospital. For a while it looked as though her father was going to pull through, and Karen began enjoying her daily visits to see him. During one of these visits, her father clutched his chest in obvious pain and told Karen to get a nurse. She remembered how helpless she felt when she could not find a nurse, although she did not recall why this was so difficult. Her search seemed endless, and by the time she finally found a nurse, her father was dead.

The therapist asked Karen the name of the ward on which her father had died. She paused and thought, and then she blurted out, "3 South." She cried at length as she told how confused she was and how angry she felt toward the nurses on the ward for not being more readily available, although she thought they might have been involved with another emergency. After weeping and shaking and expressing her resentment, Karen felt calm and relaxed for the first time in months. Her symptoms disappeared, and her problems in the nursing program were relieved.

Source: Adapted from Prochaska & Norcross, 2003, p. 28.

In classical (Freudian) psychoanalysis the technique of free association may be used to explore the contents of the preconscious.

techniques of this form of therapy: (1) free association, (2) analysis of dreams, (3) analysis of resistance, and (4) analysis of transference. Then we will note some of the most important changes that have taken place in psychodynamic therapy since Freud's time.

**Free Association** The basic rule of *free association* (see Chapter 2) is that an individual must say whatever comes into her or his mind regardless of how personal, painful, or seemingly irrelevant it may be. Usually a client lies in a relaxed position on a couch and gives a running account of all the thoughts, feelings, and desires that come to mind as one idea leads to another. The therapist normally takes a position behind the client so as not to disrupt the free flow of associations in any way.

Although such a running account of whatever comes into one's mind may seem random, Freud did not view it as such; rather, he believed that associations are determined just like other events. The purpose of free association is to explore thoroughly the contents of the preconscious—that part of the mind considered subject to conscious attention but largely ignored. Analytic interpretation involves a therapist's tying together a client's often disconnected ideas, beliefs, and actions into a meaningful explanation to help the client gain insight into the relationship between his or her maladaptive behavior and the repressed (unconscious) events and fantasies that drive it.

**Analysis of Dreams** Another important, related procedure for uncovering unconscious material is the analysis of dreams. When a person is asleep, repressive defenses are said to be

**FREUDIAN PSYCHOANALYSIS** Psychoanalysis is a system of therapy that evolved over a period of years during Freud's long career. Psychoanalysis is not easy to describe, and the problem is complicated by the fact that many people have inaccurate conceptions of it based on cartoons and other forms of caricature. The best way to begin our discussion is to describe the four basic

lowered, and forbidden desires and feelings may find an outlet in dreams. For this reason, dreams have been referred to as the “royal road to the unconscious.” Some motives, however, are so unacceptable to an individual that even in dreams they are not revealed openly but are expressed in disguised or symbolic form. Thus a dream has two kinds of content: (1) **manifest content**, which is the dream as it appears to the dreamer, and (2) **latent content**, which consists of the actual motives that are seeking expression but are so painful or unacceptable that they are disguised.

It is a therapist’s task, in conjunction with the associations of the patient, to uncover these disguised meanings by studying the images that appear in the manifest content of a client’s dream and in the client’s associations to them. For example, a client’s dream of being engulfed in a tidal wave may be interpreted by a therapist as indicating that the client feels in danger of being overwhelmed by inadequately repressed fears or hostilities.

**Analysis of Resistance** During the process of free association or of associating to dreams, an individual may evidence **resistance**—an unwillingness or inability to talk about certain thoughts, motives, or experiences. For example, a client may be talking about an important childhood experience and then suddenly switch topics, perhaps stating, “It really isn’t that important” or “It is too absurd to discuss.” Resistance may also be evidenced by the client’s giving a too-glib interpretation of some association, or coming late to an appointment, or even “forgetting” an appointment altogether. Because resistance prevents painful and threatening material from entering awareness, its sources must be sought if an individual is to face the problem and learn to deal with it in a realistic manner (Horner, 2005).

**Analysis of Transference** As client and therapist interact, the relationship between them may become complex and emotionally involved. Often people carry over, and unconsciously apply to their therapist, attitudes and feelings that they had in their relations with a parent or other person close to them in the past, a process known as **transference**. Thus clients may react to their analyst as they did to that earlier person and feel the same love, hostility, or rejection that they felt long ago. If the analyst is operating according to the prescribed role of maintaining an impersonal stance of detached attention, the often affect-laden reactions of the client can be interpreted, it is held, as a type of projection—inappropriate to the present situation yet highly revealing of central issues in the client’s life. For example, should the client vehemently (but inaccurately) condemn the therapist for a lack of caring and attention to the client’s needs, this would be seen as a “transference” to the therapist of attitudes acquired (possibly on valid grounds) in childhood interactions with parents or other key individuals.

In helping the client to understand and acknowledge the transference relationship, a therapist may provide the client with insight into the meaning of his or her reactions to others. In

doing so, the therapist may also introduce a corrective emotional experience by refusing to engage the person on the basis of his or her unwarranted assumptions about the nature of the therapeutic relationship. If the client expects rejection and criticism, for example, the therapist is careful to maintain a neutral manner. Or contrarily, the therapist may express positive emotions at a point where the client feels particularly vulnerable, thereby encouraging the client to reframe and rethink her or his view of the situation. In this way it may be possible for the client to recognize these assumptions and to “work through” the conflict in feelings about the real parent or perhaps to overcome feelings of hostility and self-devaluation that stem from the earlier parental rejection. In essence, the negative effects of an undesirable early relationship are counteracted by working through a similar emotional conflict with the therapist in a therapeutic setting. A person’s reliving of a pathogenic past relationship in a sense recreates the neurosis in real life, and therefore this experience is often referred to as a *transference neurosis*.

It is not possible here to consider at length the complexities of transference relationships, but a client’s attitudes toward his or her therapist usually do not follow such simple patterns as our examples suggest. Often the client is ambivalent—distrusting the therapist and feeling hostile toward him or her as a symbol of authority, but at the same time seeking acceptance and love. In addition, the problems of transference are not confined to the client, for the therapist may also have a mixture of feelings toward the client. This **countertransference**, wherein the therapist reacts in accord with the client’s transferred attributions rather than objectively, must be recognized and handled properly by the therapist. For this reason, it is considered important that therapists have a thorough understanding of their own motives, conflicts, and “weak spots”; in fact, all psychoanalysts undergo psychoanalysis themselves before they begin independent practice.

The resolution of the transference neurosis is said to be the key element in effecting a psychoanalytic “cure.” Such resolution can occur only if an analyst successfully avoids the pitfalls of countertransference. That is, the analyst needs to keep track of his or her own transference or reaction to a client’s behavior. Failure to do so risks merely repeating, in the therapy relationship, the typical relationship difficulties characterizing the client’s adult life. Analysis of transference and the phenomenon of countertransference are also part of most psychodynamic derivatives of classical psychoanalysis, to which we now turn.

**Psychodynamic Therapy Since Freud** The original version of psychoanalysis is practiced only rarely today. Arduous and costly in time, money, and emotional commitment, it may take several years before all major issues in the client’s life have been satisfactorily resolved. In light of these heavy demands, psychoanalytic or psychodynamic therapists have worked out modifications in procedure designed to shorten the time and expense required. A good review of some of these approaches can be found in Prochaska and Norcross (2003).

**Object Relations, Attachment-Based Approaches, and Self-Psychology** The most extensive revisions of classical psychoanalytic theory undertaken within recent decades have been related to the object-relations perspective (in psychoanalytic jargon, “objects” are other people) and, to a lesser extent, the attachment and self-psychology perspectives (see Prochaska & Norcross, 2003). Whether or not psychotherapy investigators and clinicians use the term *object relations* (or *attachment* or *self-psychology*) to denote their approach, increasing numbers of them describe procedures that focus on interpersonal relationship issues, particularly as they play themselves out in the client-therapist relationship.

Interpersonally oriented psychodynamic therapists vary considerably in their time focus: whether they concentrate on remote events of the past, on current interpersonal situations and impasses (including those of the therapy itself), or on some balance of the two. Most seek to expose, bring to awareness, and modify the effects of the remote developmental sources of the difficulties the client is currently experiencing. These therapies generally retain, then, the classical psychoanalytic goal of understanding the present in terms of the past. What they ignore are the psychoanalytic notions of staged libidinal energy transformations and of entirely internal (and impersonal) drives that are channeled into psychopathological symptom formation.

**EVALUATING PSYCHODYNAMIC THERAPIES** The practice of classical psychoanalysis is routinely criticized by outsiders for being relatively time consuming and expensive; for being based on a questionable, stultified, and sometimes cult-like approach to human nature; for neglecting a client’s immediate problems in the search for unconscious conflicts in the remote past; and for there being no adequate proof of its general effectiveness. Concerning this, we note that there have been no rigorous, controlled outcome studies of classical psychoanalysis. This is understandable, given the intensive and long-term nature of the treatment and the methodological difficulties inherent in testing such an approach. Nonetheless, there are some hints that this treatment approach has some value (Gabbard et al., 2002). Psychoanalysts also argue that manualized treatments unduly limit treatment for a disorder. They note that simply because a treatment cannot be standardized does not mean that it is invalid or unhelpful. Whether the clinical benefits justify the time and expense of psychoanalysis, however, remains uncertain.

In contrast, there is much more research on some of the newer psychodynamically oriented approaches. There are signs that psychodynamic approaches may be helpful in the treatment of depression, panic disorder, PTSD, and substance abuse disorders (Gibbons et al., 2008). Recent research also supports the idea that increases in insight (“insight” is a key construct in psychodynamic theory and involves cognitive and emotional understanding of inner conflicts) must occur before there is long-term clinical change (Johansson et al., 2010).

Psychoanalytically oriented treatments are also showing promise in the treatment of borderline personality disorder. One example is *transference-focused psychotherapy*, or TFP. Developed by Kernberg and colleagues, this treatment approach uses such techniques as clarification, confrontation, and interpretation to help the patient understand and correct the distortions that occur in his or her perception of other people, including the therapist. In a clinical trial, patients with borderline personality disorder who received TFP did as well as those who were assigned to receive dialectical behavior therapy (Clarkin et al., 2007). A recent meta-analysis provides further support for the idea that long-term psychodynamic psychotherapy (50 sessions or more) may be more beneficial than less intensive forms of treatment for patients with complex mental disorders (Leichsenring & Rabung, 2011). Findings such as these are creating renewed interest in psychodynamic forms of psychotherapy and energizing the field of treatment research.

## Couple and Family Therapy

Many problems that therapists deal with concern distressed relationships. A common example is couple or marital distress. Here, the maladaptive behavior exists between the partners in the relationship. Extending the focus even further, a family systems approach reflects the assumption that the within-family behavior of any particular family member is subject to the influence of the behaviors and communication patterns of other family members. It is, in other words, the product of a “system” that may be amenable to both understanding and change. Addressing problems deriving from the in-place system thus requires therapeutic techniques that focus on relationships as much as, or more than, on individuals.

**COUPLE THERAPY** Relationship problems are a major cause of emotional distress. The large numbers of couples seeking help with troubled relationships have made couple counseling a growing field of therapy. Typically the couple is seen together. Improving communication skills and developing more adaptive problem-solving styles are both major foci of clinical attention. Although it is quite routine at the start of therapy for each partner secretly to harbor the idea that only the other will have to do the changing, it is nearly always necessary for both partners to alter their reactions to the other.

For many years the gold standard of **couple therapy** has been **traditional behavioral couple therapy (TBCT)**; see Christensen et al., 2007). TBCT is based on a social-learning model and views marital satisfaction and marital distress in terms of reinforcement. The treatment is usually short term (10 to 26 sessions) and is guided by a manual. The goal of TBCT is to increase caring behaviors in the relationship and to teach partners to resolve their conflicts in a more constructive way through training in communication skills and adaptive problem solving.

Traditional behavioral couple therapy is an empirically supported treatment for couple distress (Snyder et al., 2006).

Couple therapists try to help couples improve their communication skills and develop more adaptive ways of solving their problems.

Early research established that two-thirds of couples tend to do well and to show improvement in relationship satisfaction (Jacobson et al., 1987). However, it rapidly became apparent that this form of treatment does not work for all couples (Jacobson & Addis, 1993). Moreover, even among couples who do show an improvement in relationship satisfaction, the improvement is not always maintained over time (Jacobson et al., 1987).

These limitations of TBCT led researchers to conclude that a change-focused treatment approach was not appropriate for all couples. This created the impetus for the development of **integrative behavioral couple therapy (IBCT)**; see Jacobson et al., 2000; Wheeler et al., 2001). Instead of emphasizing change (which sometimes has the paradoxical effect of making people not want to change), IBCT focuses on acceptance and includes strategies that help each member of the couple come to terms with and accept some of the limitations of his or her partner. Of course, change is not forbidden. Rather, within IBCT, acceptance strategies are integrated with change strategies to provide a form of therapy that is more tailored to individual characteristics, relationship “themes” (long-standing patterns of conflicts), and the needs of the couple.

Although IBCT is a relative newcomer in the couple therapy field, the preliminary findings are quite promising. In one study, improvement rates were 80 percent in the couples treated with IBCT versus 64 percent in couples receiving TBCT (Jacobson et al., 2000). In another, larger study, 70 percent of couples who received IBCT showed clear improvement in their relationship compared with 61 percent of couples receiving TBCT (see Christensen et al., 2007). Although these differences are not statistically different from each other, other data show that couples who stay together after receiving IBCT are significantly happier than couples who stay together following treatment with TBCT (Atkins et al., 2005).

**FAMILY THERAPY** Therapy for a family obviously overlaps with couple and marital therapy but has somewhat different roots. Couple therapy developed in response to the large

number of clients who came seeking help for relationship problems. **Family therapy** began with the finding that many people who had shown marked clinical improvement after individual treatment—often in institutional settings—had a relapse when they returned home. As you have already learned, family-based treatment approaches designed to reduce high levels of criticism and family tension have been successful in reducing relapse rates in patients with schizophrenia and mood disorders (Miklowitz & Craighead, 2007; Pfammatter et al., 2006).

Another approach to resolving family disturbances is called **structural family therapy** (Minuchin, 1974). This approach, which is based on systems theory, holds that if the family context can be changed, then the individual members will have altered experiences in the family and will behave differently in accordance with the changed requirements of the new family context. Thus an important goal of structural family therapy is changing the organization of the family in such a way that the family members will behave more supportively and less pathogenically toward each other.

Structural family therapy is focused on present interactions and requires an active but not directive approach on the part of a therapist. Initially, the therapist gathers information about the family—a structural map of the typical family interaction patterns—by acting like one of the family members and participating in the family interactions as an insider. In this way, the therapist discovers whether the family system has rigid or flexible boundaries, who dominates the power structure, who gets blamed when things go wrong, and so on. Armed with this understanding, the therapist then operates as an agent for altering the interaction among the members, which often has transactional characteristics of enmeshment (overinvolvement), overprotectiveness, rigidity, and poor conflict resolution skills. The “identified client” is often found to play an important role in the family’s mode of conflict avoidance. As discussed in Chapter 9, structural family therapy has quite a good record of success in the treatment of anorexia nervosa.

## Eclecticism and Integration

The various “schools” of psychotherapy that we have just described once stood more in opposition to one another than they do now. Today, clinical practice is characterized by a relaxation of boundaries and a willingness on the part of therapists to explore differing ways of approaching clinical problems (see Castonguay et al., 2003, for a discussion), a process sometimes called *multimodal therapy* (Lazarus, 1997). When asked what their orientation is, most psychotherapists today reply “eclectic,” which usually means that they try to borrow and combine concepts and techniques from various schools, depending on what seems best for the individual case. This inclusiveness extends to efforts to combine biological and psychosocial approaches as well as individual and family therapies.

One example of an eclectic form of therapy is *interpersonal psychotherapy* (see also Chapter 7). Developed by Klerman and colleagues (1984) as a treatment for depression, IPT focuses on current relationships in the patient's life and has the goals of reducing symptoms and improving functioning. Interpersonal therapy was based on the interpersonal theory of Harry Stack Sullivan as well as on Bowlby's attachment theory. Its central idea is that all of us, at all times, involuntarily invoke schemas acquired from our earliest interactions with others, such as our parents, in interpreting what is going on in our current relationships. Although it is sometimes considered to be a form of psychodynamic psychotherapy, IPT uses techniques from several other treatment approaches. It is also focused and time limited. In addition, the emphasis in treatment is on the present, not the past (see Bleiberg & Markowitz, 2008).

IPT has demonstrable value in the treatment of depression (de Mello et al., 2005). It has also been adapted for other disorders including bulimia nervosa (Fairburn, Jones, et al., 1993), anxiety disorders (Stangier et al., 2011), and borderline personality disorder (Markowitz et al., 2006).

### in review

- Describe the different techniques that can be used to provide anxious patients with exposure to the stimuli they fear.
- In what ways are REBT and cognitive therapy similar? In what ways are they different?
- Explain the concepts of transference and countertransference.
- What special difficulties do clinicians face when they work with couples? How have techniques of marital therapy evolved over recent years?

## Sociocultural Perspectives

The criticism has been raised—from both inside and outside the mental health professions—that psychotherapy can be viewed as an attempt to get people adjusted to a “sick” society rather than to encourage them to work toward its improvement. As a consequence, psychotherapy has often been considered the guardian of the status quo. This issue is perhaps easier for us to place in perspective by looking at other cultures. For example, there had been frequent allegations that psychiatry was used as a means of political control in the former Soviet Union, an abuse that was eventually officially acknowledged (see *Schizophrenia Bulletin*, 1990, vol. 16, no. 4). Although few would claim that psychiatry in most industrialized societies is used to gain control over social critics, there is nevertheless the possibility that therapists in some ways play the role of “gatekeepers” of social values. Such charges, of course, bring us back to the question we raised in Chapter 1: What do we mean by “abnormal”? That question can be answered only in the light of our values.

## Social Values and Psychotherapy

In a broader perspective, there is the complex and controversial issue of the role of values in science. Psychotherapy is not, or at least should not be, a system of ethics; it is a set of tools to be used at the discretion of a therapist in pursuit of a client's welfare. Thus mental health professionals are confronted with the same kinds of questions that confront scientists in general: Should a physical scientist who helps develop weapons of mass destruction be morally concerned about how they are used? Similarly, should a psychologist or behavioral scientist who develops powerful techniques to influence or control how people behave be concerned about how those techniques are used?

Many psychologists and other scientists try to sidestep this issue by insisting that science is value free—that it is concerned only with gathering facts, not with how the facts are applied. Each time therapists decide that one behavior should be eliminated or substituted for another, however, they are making a value judgment. For example, is a therapist to assume that the depression of a young mother who is abused by an alcoholic husband is an internally based disorder requiring “treatment,” as once would have been the routine interpretation? Or does the therapist have a larger responsibility to look beyond individual pathology and confront the abnormality of the marital relationship? Therapy takes place in a context that involves the values of the therapist, the client, and the society in which they live. There are strong pressures on a therapist—from parents, schools, courts, and other social institutions—to help people adjust to the world as it is. At the same time, there are many counterpres- sures, particularly from young people who are seeking support in their (sometimes overdone) attempts to become authentic people rather than blind conformists.

The dilemma in which contemporary therapists may find themselves is illustrated by the following case study.

→ **Who Needs Therapy?** A 15-year-old high school sophomore is sent to a therapist because her parents have discovered that she has been having sex with her boyfriend. The girl tells the therapist that she feels no guilt or remorse over her behavior even though her parents strongly disapprove. In addition, she reports that she is quite aware of the danger of becoming pregnant and is careful to take contraceptive measures.

What is the role of the therapist here? And what is the goal of treatment? Should the girl be encouraged to conform to her parents' expectations and postpone sexual activity until she is older and more mature? Or should the parents be helped to adjust to the pattern of sexual behavior their daughter has chosen? As we noted earlier, it is not unusual for an individual to be referred for psychological treatment because her or his behavior, though not particularly destructive or disturbing, has caused concern among family members, who want the therapist to “fix” her or him.

## Psychotherapy and Cultural Diversity

As we have seen, the establishment and maintenance of an effective psychotherapeutic “working alliance” between client and therapist is generally regarded as a crucial and indispensable element in determining the success of the outcome. What does this mean for a client whose background is considerably different from that of the therapist?

As yet, there is little or no solid evidence that psychotherapeutic outcomes are diminished when client and therapist differ in race or ethnicity (Beutler et al., 2004; Sue et al., 1994). However, members of minority groups are seriously underrepresented in treatment research studies, and this makes it difficult to fully assess their needs and outcomes (Miranda et al., 2005; Nagayama Hall, 2001). Moreover, racial and ethnic minorities are clearly underserved by the mental health system (Snowden & Yamada, 2005; U.S. Department of Health and Human Services, 2001). However, the factors that are behind these disparities are complex and not well understood.

Many minorities are economically disadvantaged and simply do not have the health insurance they need to seek treatment. It is also difficult for patients to find the kind of therapists they want. In general, minority patients tend to prefer ethnically similar therapists over European American therapists. Mexican Americans state a strong preference for therapists who share their ethnic background and express the view that such therapists are more “credible” than Anglo therapists would be (Lopez et al., 1991; Ponce & Atkinson, 1989). However, finding an ethnically matched therapist may present difficulties. In one survey, for example, only 2 percent of psychiatrists, 2 percent of psychologists, and 4 percent of social workers said they were African Americans (Holzer et al., 1998). The number of mental health professionals who are representative of other minority groups is no better (U.S. Department of Health and Human Services, 2001). The lack of trained therapists familiar with the issues important to different ethnic groups is a serious drawback, given the unique problems often associated with certain groups. This is illustrated in the following case, which concerns a Southeast Asian refugee woman in her mid-40s who was relocated to the United States.

**→ A Khmer Woman** “I lost my husband, I lost my country, I lost every property/fortune we owned. And coming over here, I can’t learn to speak English and the way of life here is different; my mother and oldest son are very sick: I feel crippled, I can do nothing. I can’t control what’s going on. I don’t know what I’m going to do once my public assistance expires. I may feel safe in a way—there is no war here, no Communist to kill or torture you—but deep down inside me, I still don’t feel safe or secure. I get scared. I get scared so easily.” (From Rumbaut, 1985, p. 475.)

When specialized, culturally adapted interventions are made available in community settings, minority clients are less likely to drop out of treatment and often do well (Gonzales-Castro et al.,

2010; Snowden & Yamada, 2005). However, such programs are still lacking in many communities. Also lacking are research investigations designed to understand how culture and ethnicity affect a person’s ability to access and receive psychiatric and psychological treatments. Nonetheless, there are encouraging developments. For example, Weisman and colleagues are developing culturally informed treatments for the families of patients with schizophrenia (Weisman et al., 2006). This approach considers the role of family cohesiveness as well as spirituality and religion in the therapy process. Researchers are also developing culturally informed psychotherapy for Hispanic patients with major depression (Markowitz et al., 2009), as well as for African American women who are suicidal and in abusive relationships (Kaslow et al., 2010).

- Can psychotherapy ever be value free? Why or why not?
- What special issues do racial and ethnic minorities face when they seek therapy?

## Biological Approaches to Treatment

The field of psychopharmacology is characterized by rapid and exciting progress. Clinical breakthroughs are occurring on a regular basis, and there is now real hope for patients previously considered to be beyond help. In the following sections we discuss some of the major classes of medications that are now routinely used to help patients with a variety of mental disorders, as well as some additional treatment approaches (such as electroconvulsive therapy) that are less widely used but highly effective, especially for patients who fail to show a good clinical response to other treatments.

These drugs are sometimes referred to as psychoactive (literally, “mind-altering”) medications, indicating that their major effects are on the brain. As we examine these medications, it is important to remember that people differ in how rapidly they metabolize drugs—that is, in how quickly their bodies break down the drugs once ingested. For example, many African Americans metabolize antidepressant and antipsychotic medications more slowly than whites do. What this means is that African Americans sometimes show a more rapid and greater response to these medications but also experience more side effects (see U.S. Department of Health and Human Services, 2001, p. 67). Determining the correct dosage is critical because too little of a drug can be ineffective; on the other hand, too much medication can cause toxicity that may be life-threatening, depending on the individual and the medication concerned.

### Antipsychotic Drugs

As their name suggests, *antipsychotic drugs* (also called neuroleptics) are used to treat psychotic disorders such as schizophrenia and psychotic mood disorders. You have already read about

**TABLE 16.1**  
**Commonly Prescribed Antipsychotic Medications**

Drug Class	Generic Name	Trade Name	Dose Range (mg)
Second-Generation (Atypical)	clozapine	Clozaril	300–900
	risperidone	Risperdal	1–8
	olanzapine	Zyprexa	5–20
	quetiapine	Seroquel	100–750
	ziprasidone	Geodon	80–160
	aripiprazole	Abilify	15–30
	lurasidone	Latuda	40–120
First-Generation (Conventional)	chlorpromazine	Thorazine	75–900
	perphenazine	Trilafon	12–64
	molindone	Moban	50–200
	thiothixene	Navane	15–60
	trifluoperazine	Stelazine	6–40
	haloperidol	Haldol	2–100
	fluphenazine	Prolixin	2–20

Sources: Bechlibnyk-Butler & Jeffries (2003); Buckley & Waddington (2001); and Sadock et al. (2009).

these medications in Chapter 13. The key therapeutic benefit of antipsychotics derives from their ability to alleviate or reduce the intensity of delusions and hallucinations. They do this by blocking dopamine receptors. Table 16.1 lists some of the more commonly used neuroleptic drugs as well as information about typical dose ranges.

Studies have found that approximately 60 percent of patients with schizophrenia who are treated with traditional antipsychotic medications have a resolution of their positive symptoms within 6 weeks, compared to only about 20 percent of those treated with placebo (see Sharif et al., 2007). These drugs are also useful in treating other disorders with psychotic symptoms such as mania, psychotic depression, and schizoaffective disorder, and they are occasionally used to treat transient psychotic symptoms when these occur in people with borderline personality disorder and schizotypal personality disorder (Koenigsberg et al., 2007). Finally, antipsychotic medications are sometimes used to treat the delusions, hallucinations, paranoia, and agitation that can occur with Alzheimer's disease. However, antipsychotic medications pose great risks to patients with dementia because they are associated with increased rates of death (Sultzer et al., 2008). Because of this, there is now a "black box warning" about using these medications with dementia patients.

Antipsychotic medications are usually administered daily by mouth. However, some patients are not able to remember to take their medications each day. In such cases, depot neuroleptics can be very helpful. These are neuroleptics that can be administered in a long-acting, injectable form. The clinical benefits of one injection can last for up to 4 weeks, which makes depot neuroleptics very valuable for patients who need medication but are unwilling or unable to take drugs every day. Research suggests that patients with schizophrenia who take

depot medications do better than those who use oral compounds (Tiihonen et al., 2011).

One very problematic side effect that can result from treatment with conventional antipsychotic medications such as chlorpromazine is **tardive dyskinesia** (see Chapter 13). Tardive (from *tardy*) dyskinesia is a movement abnormality that is a delayed result of taking antipsychotic medications. Because movement-related side effects are a little less common with atypical antipsychotic medications such as clozapine (Clozaril) and olanzapine (Zyprexa), these medications are often preferred in the clinical management of schizophrenia. Clozapine also seems to be especially beneficial for psychotic patients at high risk of suicide (Meltzer et al., 2003).

Even the atypical neuroleptics have side effects, however. Weight gain and diabetes are a major source of clinical concern (Sernyak et al., 2002). You may recall that an even more serious side effect of clozapine is a potentially life-threatening drop in white blood cell count called agranulocytosis, which occurs in 1 percent of patients (Sharif et al., 2007). Accordingly, patients must have their blood tested every week for the first 6 months of treatment and then every 2 weeks thereafter for as long as they are on the medication. Because of this, clozapine is best regarded as a medication to consider after other medications (e.g., some of the other atypical antipsychotic medications) have proved ineffective. Current thinking is that the atypical antipsychotics described above (with the exception of clozapine) are the first-choice treatments for psychosis and that clozapine and conventional antipsychotics (e.g., Haldol) are best considered as second-line therapies.

## Antidepressant Drugs

Antidepressants are the most commonly prescribed psychiatric medications. More than 90 percent of patients being treated for depressive disorders will be given these medications (Olfson & Marcus, 2010).

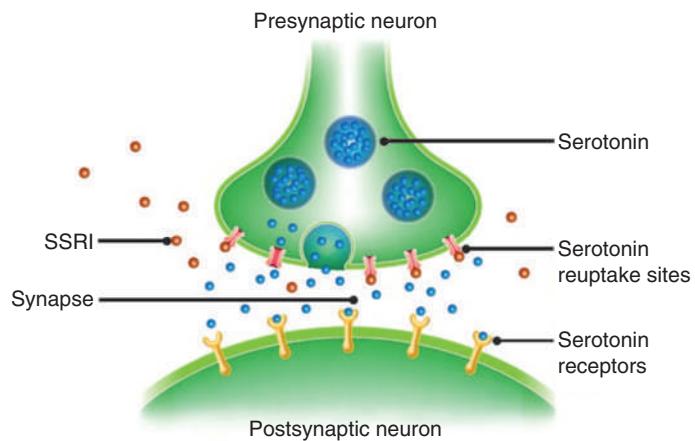

**SELECTIVE SEROTONIN REUPTAKE INHIBITORS** As is the case for antipsychotic medications, the drugs that were discovered first (so-called classical antidepressants such as monoamine oxidase [MAO] inhibitors and tricyclic antidepressants [TCAs]) have now been replaced in routine clinical practice by "second-generation" treatments such as the SSRIs. In 1988 fluoxetine (Prozac) became the first SSRI to be released in the United States. Its pharmacological cousins include sertraline (Zoloft) and paroxetine (Paxil). More recent additions to the SSRI family are fluvoxamine (Luvox), which is used in the treatment of OCD; citalopram (Celexa); and escitalopram (Lexapro). All are equally effective. Table 16.2 lists some of the most widely used antidepressant medications.

SSRIs are chemically unrelated to the older, TCAs and to the MAO inhibitors. However, most antidepressants work by increasing the availability of serotonin, norepinephrine, or both. As their name implies, the SSRIs serve to inhibit the reuptake

Actress Brooke Shields is one of many public figures who have been open with the public about their experiences with depression.

of the neurotransmitter serotonin following its release into the synapse. Unlike the tricyclics (which inhibit the reuptake of both serotonin and norepinephrine), SSRIs selectively inhibit the

**FIGURE 16.1**

**SSRIs.** Serotonin is synthesized from the amino acid tryptophan. After being released into the synaptic cleft, it binds to receptors on the postsynaptic neuron. A serotonin reuptake transporter then returns it back to the presynaptic neuron. SSRI medications block this reuptake process, leaving more serotonin available in the synapse.

reuptake of serotonin (see Figure 16.1). They have become the preferred **antidepressant drugs**, in large part due to very aggressive advertising by the pharmaceutical companies. SSRIs are also easier to use, have fewer side effects, and are generally not found to be fatal in overdose, as the tricyclics can be. However, there is no compelling evidence that they are more effective than other types of antidepressants (Sussman, 2009b).

More recently, another class of medications has been introduced. These are called serotonin and norepinephrine reuptake inhibitors (SNRIs; see Thase, 2009). Examples of antidepressants in this drug family are venlafaxine (Effexor) and duloxetine (Cymbalta). SNRIs block reuptake of both norepinephrine and serotonin. They have similar side effects to the SSRIs, and they are relatively safe in overdose. SNRIs seem to help a significant number of patients who have not responded well to other antidepressants, and they are slightly more effective than SSRIs in the treatment of major depression (Papakostas et al., 2007).

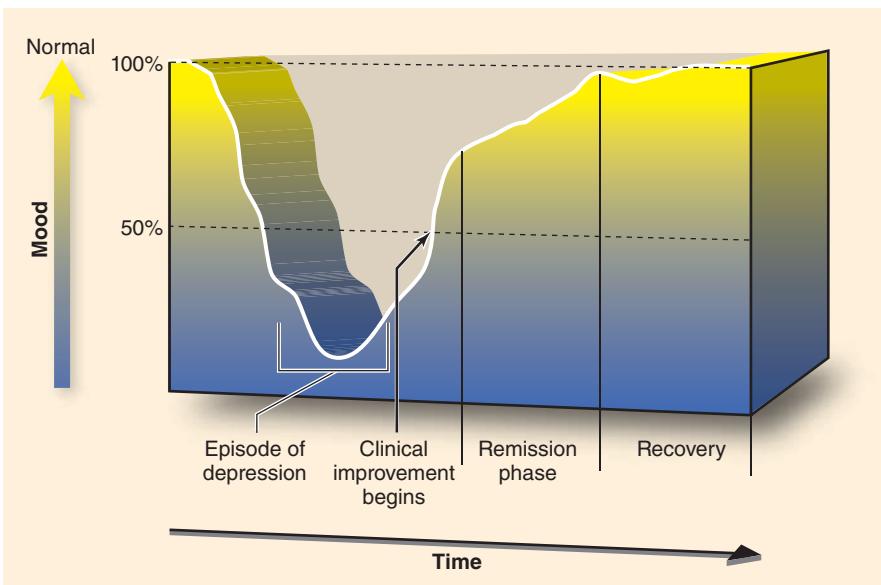

The newest antidepressant, which received FDA approval in 2011, is called Viibryd (vilazodone). It is a novel combination of an SSRI and a serotonin receptor agonist. Early reports suggest that vilazodone is safe and well tolerated by patients (Robinson et al., 2011) and that it works better than placebo for patients who are depressed (Khan et al., 2011). However, it remains to be learned how efficacious this medication is compared to other antidepressants in widespread use.

Clinical trials with the SSRIs indicate that patients tend to improve after about 3 to 5 weeks of treatment. Patients who show at least a 50 percent improvement in their symptoms are considered to have had a positive response to treatment (see Figure 16.2). However, although considerably better, such patients are not fully well. When treatment removes all of a patient's symptoms, patients are considered to be in a period

**FIGURE 16.2**

**Defining a Positive Response.** When treatment of depression results in at least 50 percent improvement in symptoms, it is called a response. Such patients are better, but not well.

**FIGURE 16.3**

**Defining Recovery.** When treatment of depression results in removal of essentially all symptoms, it is called remission for the first several months, and then recovery if it is sustained for longer than 6 to 12 months. Such patients are not just better—they are well.

of remission (see Figure 16.3). If this remission is sustained for 6 to 12 months or more, the patient is considered to have recovered. In other words, he or she is fully well again.

Side effects of the SSRIs include nausea, diarrhea, nervousness, insomnia, and sexual problems such as diminished sexual interest and difficulty with orgasm (Nemeroff & Schatzberg, 2007). After early reports linking Prozac with increased risk of suicide (e.g., Cole & Bodkin, 1990; Papp & Gorman, 1990) there was a decline in its use. However, Prozac is no more associated with suicide than other antidepressants are (Jick et al., 2004). Recently there has also been concern that, when used during pregnancy, fluoxetine (Prozac) and paroxetine (Paxil) may increase the risk of heart abnormalities in the baby (Diav-Citrin et al., 2008; Malm et al., 2011). For this reason these medications are not recommended as a first option for women planning to become pregnant. It is important to keep in mind, however, that all the risks we have just described are small when weighed against the risks associated with leaving depressed people without adequate treatment.

Although SSRIs help many people, some people have side effects that are so extreme that they are unable to continue to take their medication as prescribed. Researchers are now exploring the role that genes play in making some people especially susceptible to the adverse effects of specific medications (Hu et al., 2007).

**MONOAMINE OXIDASE INHIBITORS** Although they are used infrequently now, these were the first antidepressant medications to be developed, in the 1950s. These drugs were being studied for the treatment of tuberculosis when they were found to elevate the mood of patients (Stahl, 2000). They were later shown to be effective in treating depression. Monoamine oxidase inhibitors include isocarboxazid (Marplan), phenelzine (Nardil), tranylcypromine (Parnate), and selegiline (Eldepryl). They inhibit the activity of monoamine oxidase, an enzyme present in the synaptic cleft that helps break down the monoamine neurotransmitters (such as serotonin and norepinephrine) that have been released into the cleft. Patients taking MAO inhibitors must

avoid foods rich in the amino acid tyramine (such as salami and Stilton cheese). This limits the drugs' clinical usefulness. Nevertheless, they are used in certain cases of atypical depression that are characterized by hypersomnia and overeating and do not respond well to other classes of antidepressant medication (Nemeroff & Schatzberg, 2007).

**TRICYCLIC ANTIDEPRESSANTS** The TCAs operate to inhibit the reuptake of norepinephrine and (to a lesser extent) serotonin once these have been released into the synapse. Their discovery was also serendipitous in that the first TCA—imipramine—was being studied as a possible treatment for schizophrenia when it was found to elevate mood. The theory that these drugs work by increasing norepinephrine activity is now known to be oversimplified. It is also known that when the tricyclics are taken for several weeks, they alter a number of other aspects of cellular functioning including how receptors function and how cells respond to the activation of receptors and the synthesis of neurotransmitters. Because these alterations in cellular functioning parallel the time course for these drugs to exert their antidepressant effects, one or more of these changes are likely to be involved in mediating their antidepressant effects (refer back to Figure 16.3).

**OTHER ANTIDEPRESSANTS** Trazodone (Desyrel) was the first antidepressant to be introduced in the United States that was not lethal when taken in overdose. It specifically inhibits the reuptake of serotonin. Trazodone has heavy sedating properties that limit its usefulness. It is sometimes used in combination with SSRIs and taken at night to help counter the adverse effects the SSRIs often have on sleep. In rare cases, it can produce a condition in men called priapism (Nemeroff & Schatzberg, 2007). Priapism is prolonged erection in the absence of any sexual stimulation.

Bupropion (Wellbutrin) is an antidepressant that is not structurally related to other antidepressants. It inhibits the reuptake of both norepinephrine and dopamine. In addition to being an antidepressant medication, bupropion also reduces nicotine cravings and symptoms of withdrawal in people who want to stop smoking. One clinical advantage of bupropion is that, unlike some of the SSRIs, it does not inhibit sexual functioning (Nemeroff & Schatzberg, 2007).

**USING ANTIDEPRESSANTS TO TREAT ANXIETY DISORDERS, BULIMIA NERVOSA, AND PERSONALITY DISORDERS** In addition to their usefulness in treating depression, the antidepressant drugs are also widely used in the treatment of various other disorders. For example, SSRIs are often used in the treatment of panic disorder, social phobia, and generalized anxiety disorder, as well as obsessive-compulsive disorder (Dougherty et al., 2007; Roy-Byrne & Cowley, 2007). However, some people with panic disorder are greatly bothered by the side effects of these drugs (which create some of the symptoms to which panic patients are hypersensitive), so they quickly discontinue

the medication. SSRIs and tricyclic antidepressants are also used in the treatment of bulimia nervosa. Many studies have shown that these antidepressants are useful in reducing binge eating and purging (Wilson & Fairburn, 2007). Patients with Cluster B personality disorders such as borderline personality disorder may show a decrease in certain symptoms, most notably mood lability, if they take SSRIs (Rinne et al., 2002).

## Antianxiety Drugs

**Antianxiety drugs** are used for conditions in which tension and anxiety are significant components. They do not provide a cure. However, these medications can keep symptoms under control until patients are able to receive other forms of effective psychological treatments. The fact that they are so widely prescribed has caused concern among some leaders in the medical and psychiatric fields because of these drugs' addictive potential and sedating effects. Antianxiety medications have little place in the treatment of psychosis. However, they are often used as supplementary treatments in certain neurological disorders to control such symptoms as convulsive seizures.

**BENZODIAZEPINES** The most important and widely used class of antianxiety (or anxiolytic) drugs are the benzodiazepines. Another class of drugs, the barbiturates (e.g., phenobarbital), is seldom used today except to control seizures or as anesthetics during electroconvulsive therapy.) The first benzodiazepines were released in the early 1960s. They are now the drugs of choice for the treatment of acute anxiety and agitation. They are rapidly absorbed from the digestive tract and start to work very quickly. At low doses they help quell anxiety; at higher doses they act as sleep-inducing agents and can be used to treat insomnia. For this reason, people taking these medications are cautioned about driving or operating machinery.

Antianxiety medications are widely prescribed. Why has this caused concern among some leaders in the medical and psychiatric fields?

One problem with benzodiazepines is that patients can become psychologically and physiologically dependent on them (Roy-Byrne & Cowley, 2007). Patients taking these medications must be “weaned” from them gradually because of the risk of withdrawal symptoms, which include seizures in some cases. Moreover, relapse rates following discontinuation of these drugs are extremely high (Roy-Byrne & Cowley, 2007). For example, as many as 60 to 80 percent of panic patients relapse following discontinuation of Xanax. Table 16.3 lists some commonly prescribed antianxiety medications.

Benzodiazepines and related anxiolytic medications are believed to work by enhancing the activity of GABA receptors (Stahl, 2000). GABA (gamma aminobutyric acid) is an inhibitory neurotransmitter that plays an important role in the way our brain inhibits anxiety in stressful situations. The benzodiazepines appear to enhance GABA activity in certain parts of the brain known to be implicated in anxiety such as the limbic system.

**OTHER ANTIANXIETY MEDICATIONS** The only new class of antianxiety medication that has been released since the early

**TABLE 16.3**

1960s is buspirone (Buspar), which is completely unrelated to the benzodiazepines and is thought to act in complex ways on serotonergic functioning rather than on GABA. It has been shown to be as effective as the benzodiazepines in treating generalized

## THINKING CRITICALLY about DSM-5

### What Are Some of the Clinical Implications of the Recent Changes?

**DSM5**

The recent publication of *DSM-5* has created a number of new diagnoses. It has also changed the diagnostic criteria for others. Of course, as a diagnostic manual, the *DSM* does not provide any information about treatment or make recommendations on that topic. However, changes in the *DSM* always have implications for treatment because a *DSM* diagnosis is necessary for clinical services to be covered by insurance. Here, we highlight some changes that are likely to have an impact on prevalence rates and medication usage in the years to come.

1. New to *DSM-5* is the diagnosis of Disruptive Mood Regulation Disorder. This disorder is characterized by temper tantrums in a child older than 6 years of age. In order for the diagnosis to be made the angry outbursts must occur at least three times a week and be inconsistent with the child's developmental level. On the plus side, this diagnosis may allow children with very irritable temperaments to receive specialized help at an early age. However, there is also a risk that many children whose parents might benefit from parental skills training will instead receive powerful tranquilizing medications while their young brains are still maturing and developing.
2. To be diagnosed with Attention Deficit Hyperactivity Disorder (ADHD) in *DSM-IV* symptoms had to develop before the child reached the age of 7. In *DSM-5* this age of onset has been raised to age 12. Many children who would not have been eligible to be diagnosed with ADHD (because their symptoms developed when they were 8, 9, or 10) will

now receive the diagnosis. This simple change in the diagnostic criteria will dramatically increase the prevalence of ADHD. And, although it will allow many more children to receive treatment, it will undoubtedly result in many more children being medicated.

3. Another major change that was proposed for *DSM-5*, but not accepted, was to lower the threshold for the diagnosis of Generalized Anxiety Disorder (GAD). In addition to excessive anxiety and worry, *DSM-IV* required the presence of three additional symptoms. In *DSM-5* it was proposed that only one symptom (either muscle tension or a feeling of being on edge) should be required. This change would undoubtedly have led to a substantial increase in the number of people diagnosed with GAD. Had the change been approved, some people might have been relieved to learn that their worrying reflected a psychiatric disorder. However, had it been accepted, this change would likely have further increased the numbers of people who come to rely on antianxiety medications to get through the day.

What do you think about the changes that were made (or not made)? Are you in favor of relaxing diagnostic criteria and making more and more people eligible to receive clinical treatment? Or are you concerned that we are in danger of pathologizing normal life and increasing the inappropriate use of psychiatric medications?

Source: Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, (Copyright 2013). American Psychiatric Association.

anxiety disorder (Roy-Byrne & Cowley, 2007), although patients who have previously taken benzodiazepines tend not to respond as well as patients who have never taken them. Buspar has a low potential for abuse, probably because it has no sedative or muscle-relaxing properties and so is less pleasurable for patients. It also does not cause any withdrawal effects. The primary drawback to the use of buspirone is that it takes 2 to 4 weeks to exert any anxiolytic effects. It is therefore not useful in acute situations. Because it is nonsedating, it cannot be used to treat insomnia.

## Lithium and Other Mood-Stabilizing Drugs

In the late 1940s John Cade in Australia discovered that lithium salts such as lithium carbonate were effective in treating manic disorders. One of Cade's (1949) own cases serves well as an illustration of the effects of lithium treatment.

**→ Lithium Helps a Difficult Patient** Mr. W. B. was a 51-year-old man who had been in a state of chronic manic excitement for 5 years. So obnoxious and destructive was his behavior that he had long been regarded as the most difficult patient on his ward in the hospital.

He was started on treatment with a lithium compound, and within 3 weeks his behavior had improved so much that transfer to the convalescent ward was deemed appropriate. He remained in the hospital for another 2 months, during which time his behavior continued to be essentially normal. Prior to discharge, he was switched to another form of lithium salts because the one he had been taking had caused stomach upset.

He was soon back at his job and living a happy and productive life. In fact, he felt so good that, contrary to instructions, he stopped taking his lithium. Thereafter he steadily became more irritable and erratic; some 6 months following his discharge, he had to cease work. In another 5 weeks he was back at the hospital in an acute manic state.

Lithium therapy was immediately reestablished, with prompt positive results. In another month Mr. W. B. was pronounced ready to return to home and work, provided that he not fail to continue taking a prescribed dosage of lithium.

It was about 20 years until lithium treatment was introduced, around 1970, in the United States. There were at least two reasons for this delay. First, lithium had been used in the 1940s and 1950s as a salt substitute for patients with hypertension before its toxic side effects were known. Some tragic deaths resulted, making the medical community very wary of using it for any reason. Second, because it is a naturally occurring compound, it is unpatentable. This meant that drug companies did not find it profitable to investigate its effects. Nevertheless, lithium is still widely used for the treatment of bipolar disorder and is marketed as Eskalith and Lithobid. Although lithium has been

used for many years, exactly how it brings about its therapeutic effect is still not certain (Stahl, 2000).

Even though we still do not know exactly how it works, there is no doubt about the effectiveness of lithium. As many as 70 to 80 percent of patients in a clear manic state show marked improvement after 2 to 3 weeks of taking lithium (Keck & McElroy, 2002). In addition, lithium sometimes relieves depression, although probably mainly in patients with bipolar depression (Stahl, 2000). There is increasing evidence that lithium maintenance treatment may be less reliable at preventing future episodes of mania than was once thought. For example, several studies of bipolar patients maintained on lithium for 5 years or more found that only just over one-third remained in remission. Nevertheless, discontinuation of lithium is also very risky. The probability of relapse is estimated to be 28 times higher after withdrawal than when the patient is on lithium, with about 50 percent relapsing within 6 months (Keck & McElroy, 2007).

Side effects of lithium include increased thirst, gastrointestinal difficulties, weight gain, tremor, and fatigue. In addition, lithium can be toxic if the recommended dose is exceeded or if the kidneys fail to excrete it from the body at a normal rate. Lithium toxicity is a serious medical condition. If not treated swiftly and appropriately, it can cause neuronal damage or even death.

Despite the clinical benefits of lithium, not all patients with bipolar disorder take it exactly as prescribed. Many seem to miss the "highs" and the abundance of energy associated with their hypomanic episodes, so when faced with unpleasant side effects and the loss of these highs they may stop taking the drug.

Although lithium is still widely used, other drugs are also considered first-line treatments for bipolar disorder (see Table 16.4). These include divalproic acid (Depakote) and carbamazepine (Tegretol). Other drugs that are currently being researched and used clinically as treatments for rapid cycling bipolar disorders are gabapentin (Neurontin), lamotrigine (Lamictal), and topiramate (Topamax). Many of these drugs are also used in the treatment of epilepsy and are anticonvulsant agents (Keck & McElroy, 2007). Carbamazepine has been associated with significant side effects including blood problems, hepatitis, and serious skin conditions

**TABLE 16.4**  
**Commonly Prescribed Mood-Stabilizing Medications**

Drug Class	Generic Name	Trade Name	Dose Range (mg)
Lithium	lithium	Eskalith	400–1200
Anticonvulsants	carbamazepine	Tegretol	300–1600
	divalproex	Depakote	750–3000
	lamotrigine	Lamictal	100–500
	gabapentin	Neurontin	900–3600
	topiramate	Topamax	50–1300

(Post & Frye, 2009). As with lithium, careful blood monitoring of patients is required. Valproate probably has the fewest and mildest side effects, which can include nausea, diarrhea, sedation, tremor, and weight gain. Abilify, an antipsychotic medication, is also now being marketed as a treatment for bipolar disorder.

## Electroconvulsive Therapy

Using convulsions to treat mental disorders dates back to the Swiss physician and alchemist Paracelsus (1493–1541), who induced a patient with “lunacy” to drink camphor until he experienced convulsions (Abrams, 2002; Mowbray, 1959). However, Ladislas von Meduna, a Hungarian physician, is generally regarded as the modern originator of this treatment approach. Von Meduna noted—erroneously, as it turned out—that schizophrenia rarely occurred in people with epilepsy. This observation caused him to infer that schizophrenia and epilepsy were somehow incompatible and to speculate that one might be able to cure schizophrenia by inducing convulsions. In an early treatment effort, von Meduna used camphor to induce convulsions in a patient with schizophrenia, who relatively quickly regained lucidity after the convulsive therapy. Later, von Meduna began to use a drug called Metrazol to induce convulsions because it operated more rapidly.

Another early approach, adopted by Sakel in the 1930s, was to cause convulsions by injecting patients with insulin (see Fink, 2003). However, these chemical methods gave physicians no control over the induction and timing of the seizures. Then, in 1938, Italian physicians Ugo Cerletti and Lucio Bini tried the simplest method of all—passing an electric current through a patient’s head. This method, which became known as **electroconvulsive therapy (ECT)**, is still used today (see Chapter 7). In the United States, about 100,000 patients are treated with ECT each year (Prudic, 2009).

The general public often views ECT as a horrific and primitive form of treatment, influenced no doubt by its depiction in movies such as *One Flew Over the Cuckoo’s Nest*. Indeed,

a number of malpractice lawsuits have been brought against psychiatrists who use ECT, primarily over the failure to obtain appropriate patient consent, which can be very difficult when patients may not be legally competent to give such consent due to their illness (Abrams, 2002; Leong & Eth, 1991). However, despite the distaste with which some people regard ECT, it is a safe, effective, and important form of treatment. In fact, it is the only way of dealing with some severely depressed and suicidal patients—patients who may have failed to respond to other forms of treatment. In addition, it is often the treatment of choice for severely depressed women who are pregnant, for whom taking antidepressants may be problematic, as well as for the elderly, who may have medical conditions that make taking antidepressant drugs dangerous (Pandya et al., 2007).

Reviews evaluating research on ECT have concluded that it is an effective treatment for patients with severe or psychotic-level depression, as well as for some patients with mania (Prudic, 2009). Properly administered, ECT is not thought to cause structural damage to the brain (Devanand et al., 1994), although this issue remains controversial (Reisner, 2003). Every neurotransmitter system is affected by ECT, and ECT is known to downregulate the receptors for norepinephrine, increasing the functional availability of this neurotransmitter. However, exactly how ECT works is still not fully clear (Abrams, 2002).

ECT can be administered in one of two ways. In bilateral ECT, electrodes are placed on either side of the patient’s head (see Figure 16.4 on p. 577), and brief constant-current electrical pulses of either high or low intensity are passed from one side of the head to the other for up to about 1.5 seconds. In contrast, unilateral ECT (see Figure 16.4 on p. 577) involves limiting current flow to one side of the brain, typically the nondominant side (right side, for most people). A general anesthetic allows the patient to sleep through the procedure, and muscle relaxants are used to prevent the violent contractions that, in the early days of ECT, could be so severe as to cause the patient to fracture bones.

Carrie Fisher, who played Princess Leia in the Star Wars films, has been helped by ECT.

A patient who receives electroconvulsive therapy (ECT) today is given sedative and muscle-relaxant medications prior to the procedure to prevent violent contractions. In the days before such medication was available, the initial seizure was sometimes so violent as to fracture vertebrae.

**FIGURE 16.4**

**Electrode Placement for ECT.** In unilateral ECT, current is limited to one side of the brain. In bilateral ECT, electrodes are placed on each side of the head. Bilateral ECT is more effective but is also associated with more cognitive side effects and memory problems. Based on Sadock & Sadock (2003, p. 1142).

A bite block is also used to avoid injury to the teeth. Today, if you were to observe someone receiving ECT, all you might see would be a small twitch of the hand, perhaps, as the convulsions occurred.

After the ECT is over, the patient has amnesia for the period immediately preceding the therapy and is usually somewhat confused for the next hour or so. Normally, a treatment series consists of fewer than a dozen sessions, although occasionally more are needed. Treatments are usually administered two or three times per week (Pandya et al., 2007).

Empirical evidence suggests that bilateral ECT is more effective than unilateral ECT. Unfortunately, bilateral ECT is also associated with more severe cognitive side effects and memory problems (Reisner, 2003). For instance, patients often have difficulty forming new memories (anterograde amnesia) for about 3 months after ECT ends. Physicians must therefore weigh the greater clinical benefits of bilateral ECT against its tendency to cause greater cognitive side effects. Some clinicians recommend starting with unilateral ECT and switching to bilateral after five or six treatments if no improvement is seen (Abrams, 2002).

A dramatic early example of successful ECT treatments is provided in the autobiographical account of Lenore McCall (1947/1961), who suffered a severe depressive disorder in her middle years.

### → Using ECT to Treat Severe Depression

Ms. McCall, a well-educated woman of affluent circumstances and the mother of three children, noticed a feeling of persistent fatigue as the first sign of her impending descent into depression. Too fearful to seek help, she at first attempted to fight off her increasingly profound apathy by engaging in excessive activity, a defensive strategy that accomplished little but the depletion of her remaining strength and emotional reserves.

In due course, she noticed that her mental processes seemed to be deteriorating—her memory appeared impaired and she could concentrate only with great difficulty. Emotionally, she felt an enormous loneliness, bleakness of experience, and increasingly intense fear about what was happening to her mind. She came to view her past small errors of commission and omission as the most heinous of crimes and increasingly withdrew from contact with her husband and children. Eventually, at her husband's and her physician's insistence, she was hospitalized despite her own vigorous resistance. She felt betrayed and shortly thereafter attempted suicide by shattering a drinking glass and ingesting its fragments. To her great disappointment, she survived.

Ms. McCall then spent nearly 4 years continuously in two separate mental hospitals, during which time she deteriorated further. She was silent and withdrawn, behaved in a mechanical fashion, lost an alarming amount of weight, and underwent a seemingly premature aging process. She felt that she emitted an offensive odor. At this time, ECT was introduced into the therapeutic procedures in use at her hospital.

A series of ECT treatments was given to Ms. McCall over about a 3-month period. Then one day, she woke up in the morning with a totally changed outlook: "I sat up suddenly, my heart pounding. I looked around the room and a sweep of wonder surged over me. God in heaven, I'm well. I'm myself. . ." After a brief period of convalescence, she went home to her husband and children.

### Neurosurgery

Although **neurosurgery** was used occasionally in the nineteenth century to treat mental disorders by relieving pressure in the brain (Berrios, 1990), it was not considered a treatment for psychological problems until the twentieth century. In 1935 in Portugal, Antonio Moniz introduced a neurosurgical procedure in which the frontal lobes of the brain were severed from the deeper centers underlying them. This technique eventually evolved into an operation known as prefrontal lobotomy, which stands as a dubious tribute to the extremes to which professionals have sometimes been driven in their search for effective treatments for the psychoses. In retrospect, it is ironic that this procedure—which results in permanent structural changes in the brain of the patient and has been highly criticized by many within the profession—won Moniz the 1949 Nobel Prize in medicine (although he was later shot by a former patient who was, presumably, less than grateful).

From 1935 to 1955 (when antipsychotic drugs became available), tens of thousands of mental patients in the United States and abroad were subjected to prefrontal lobotomies and related neurosurgical procedures. In some settings, as many as 50 patients were treated in a single day (Freeman, 1959). Initial reports of results tended to be enthusiastic, downplaying complications (which included a 1 to 4 percent death rate) and

undesirable side effects. It was eventually recognized, however, that the side effects of psychosurgery could be very undesirable indeed. In some instances they included a permanent inability to inhibit impulses, in others an unnatural "tranquility" with undesirable shallowness or absence of feeling.

The introduction of the major antipsychotic drugs caused an immediate decrease in the widespread use of psychosurgery, especially prefrontal lobotomy. Such operations are rare today and are used only as a last resort for patients who have not responded to any other form of treatment for a period of 5 years and who are experiencing extreme and disabling symptoms.

Modern surgical techniques involve the selective destruction of minute areas of the brain. Psychosurgery is sometimes used for patients with debilitating obsessive-compulsive disorder (Dougherty et al., 2007), treatment-resistant severe self-mutilation (Price et al., 2001), or even intractable anorexia nervosa (Morgan &

Rosemary Kennedy, sister of former president John F. Kennedy, had developmental delays and behavioral problems. When she was 21, medical professionals recommended a prefrontal lobotomy. The surgery was a tragic failure, wiping out all her accomplishments and leaving little of her former personality. Rosemary is shown here on the right with her sister Kathleen (left) and mother Rose (center) before the surgery.

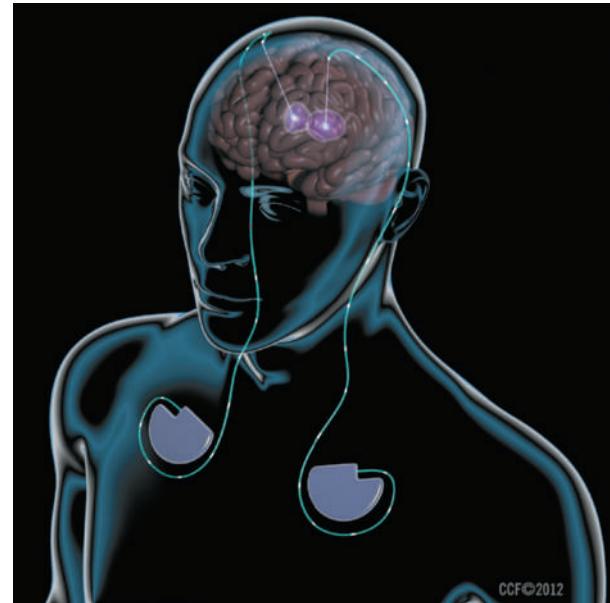

## the WORLD around us

### Deep Brain Stimulation for Treatment-Resistant Depression

An important development in the treatment of patients with severe and chronic mental health problems is deep brain stimulation. This involves stimulating patients' brains electrically over a period of several months. First, surgeons drill holes into the brain and implant small electrodes. Because this procedure is done under local anesthetic, patients can talk to the doctors about what is happening to them and tell the doctors about the changes they experience. In an early study involving six patients, all reported a response to the electrical stimulation even though they had no cues to tell them when current was being passed through the electrodes or when the current was off (Mayberg et al., 2005). When current was flowing into an area of the brain that is thought to be metabolically overactive in depression (the cingulate region), patients reported that they felt better and had experiences of "sudden calmness or lightness," "connectedness," or "disappearance of the void" (p. 652).

After the electrodes have been implanted, patients receive short sessions of deep brain stimulation in which current is passed through the implanted electrodes. Using the reports of the patients as a guide, the researchers can select the settings that will be used to provide stimulation through an implanted pulse device after the patients leave the hospital.

How effective is deep brain stimulation as a treatment for unrelenting depression? A total of 20 people who have received this treatment have now been followed up for an average of 3.5 years (Kennedy et al., 2011). The results suggest that this treatment is beneficial for approximately half of the patients. Many of those who responded also returned to work or began to volunteer in their communities. Although a 50 percent

**FIGURE 16.5**

**Deep Brain Stimulation.** In deep brain stimulation, electrodes are implanted into the brain. These are stimulated by pulse generators implanted into the chest region.

response rate may not strike you as very high, keep in mind that only the most chronically ill people are eligible to receive this treatment. Although it is invasive, deep brain stimulation may be able to help a small majority of patients who have failed to show improvement with any other methods.

Crisp, 2000). However, such approaches carry serious risks. In one study, 25 patients who had received brain lesions to treat severe OCD were followed up an average of 11 years later. Twelve of the 25 patients experienced significant relief from their OCD symptoms after the surgery. They also showed reductions in depression. However, 10 of the patients who showed clinical improvement also showed evidence of frontal lobe dysfunction at follow-up, including impaired executive functioning on cognitive tests, problems with apathy, and disinhibited behavior (Rück et al., 2008). These results highlight the risks of brain surgery even when it is effective in treating the symptoms of OCD.

Deep brain stimulation is a treatment approach that involves surgery but does not result in a permanent lesion being made in

the brain. As The World Around Us box describes, this innovative form of therapy is now being used to help patients get some relief from their unrelenting symptoms of depression.

### Do Psychiatric Medications Help or Harm?

**D**espite the benefits provided by evidence-based psychotherapies, an increasing number of mental health outpatients are now being treated solely with medications. Recent findings from a national survey show that, over the 10-year period from 1998 to 2007, the percentage of people being treated with medications and psychotherapy declined from 40 percent to 32 percent. In contrast, the number of people being treated with medications alone rose from 41 percent to 51 percent (Olfson & Marcus, 2010). This is a surprising trend because the number of people who receive therapy in a given year has remained stable at around 3 percent.

The trend may be related to the billions of dollars spent by the pharmaceutical industry to promote its products both to physicians and the general public alike. How many times have you seen a TV ad telling you to ask your doctor whether a certain medication is right for you? Because of this, many people are now receiving their psychiatric medications from their primary care physician and are never referred for (or do not seek) psychotherapy from a mental health specialist. Managed care organizations have also had financial incentives to get patients to

substitute medications for psychotherapy because, in the short term, medications are cheaper (Druss, 2010).

But are we paying the price in a different currency? All of these changes are occurring at a time when serious concerns are being raised about psychiatric drugs and the harm that they may be causing in our society (Whitaker, 2010). Some observers believe that the pharmaceutical industry has made questionable claims about the biological causes of mental disorders in order to maximize profits (Wyatt & Midkiff, 2006). Although no one would argue that they do not provide benefits for patients, psychiatric medications are often less helpful than people think. There is also evidence that some of the drugs used in the treatment of mental disorders may actually make things worse for patients in the long run, creating chemical imbalances and chronic illnesses rather than curing them (Whitaker, 2010). In light of these concerns it is important for all of us to be as informed as possible about the medications we take. This is especially so when children are involved. It also remains essential to preserve treatment options for patients and to improve access to evidence-based psychotherapies for all who need them.

## summary

### 16.1 Who seeks therapy and what are the goals of therapy?

- People seek therapy for many reasons. These include stressful current circumstances, long-standing problems or chronic unhappiness, as well as a search for personal growth and insight into their own lives. In other cases, people are referred by their physician or required to seek treatment by a court.
- Psychological treatment is aimed at reducing abnormal behavior through psychological means. The goals of psychotherapy include changing maladaptive behavior, minimizing or eliminating stressful environmental conditions, reducing negative affect, improving interpersonal competencies, resolving personal conflicts, modifying people's inaccurate assumptions about themselves, and fostering a more positive self-image.

### 16.2 How is the success of psychotherapy measured?

- Evaluation of the success of treatment can be based on the therapist's impression of change, the report of the client, reports of the client's family or friends, measures of change in specific target behaviors, or changes in scores from pre- to post-treatment on relevant measures or scales.
- Treatments that have been demonstrated to result in therapeutic change in controlled trials are referred to as evidence-based treatments.

### 16.3 What are some of the factors that must be considered to provide optimal treatment?

- One must consider whether the treatment is evidence-based or empirically supported by efficacy studies, whether the use of medication is appropriate, and whether a combination of treatments is the best option.
- A key element in all therapies is the development of an effective "working alliance." A principal social issue in psychotherapy is ensuring the development of a good therapeutic working alliance between client and therapist, even when they differ widely in cultural, ethnic, and/or socioeconomic backgrounds.

### 16.4 What psychological approaches are used to treat abnormal behavior?

- Behavior therapy is extensively used to treat many clinical problems. Behavior therapy approaches include exposure, aversion therapy, modeling, and reinforcement approaches.
- Cognitive or cognitive-behavioral therapy attempts to modify a person's self-statements and construal of events in order to change his or her behavior. Cognitive-behavioral methods have been used for a wide variety of clinical problems—from depression to anger control—and with a range of clinical populations. Much research attests to the efficacy of these approaches.

- Other psychological treatment approaches include humanistic-experiential therapies and gestalt therapy.
- Classical psychoanalysis dates back to Sigmund Freud. It is rarely practiced today, and there is little empirical support for its efficacy.
- Several variants of therapy have developed out of the psychoanalytic tradition. These diverge from classical psychoanalysis on matters such as the duration of therapy and the role of primitive psychosexual drives in personality dynamics. Many of the newer psychodynamic forms of treatment emphasize the way interpersonal processes are affected by early interactions with parents and other family members.
- In addition to their use in treating individuals, some psychological treatment methods are applied to problematic relationships through couple or family therapy. These approaches typically assume that a person's problems lie partly in his or her interactions with others. Consequently, the focus of treatment is on changing the ways in which members of the social or family unit interact.

### 16.5 What roles do social values and culture play in psychotherapy?

- Although psychotherapy is a set of tools to be used in pursuit of a client's welfare, not an ethics system, therapists are often faced with moral dilemmas in the course of treatment.
- Racial and ethnic minorities are currently underserved by the mental health system.

### 16.6 What biological approaches to treating abnormal behavior are available?

- Medications are important in the treatment of many disorders. It is now common in clinical practice to combine medication and psychological treatments.
- The most commonly used antipsychotic medications are the atypical neuroleptics. These improve both positive and negative symptoms and have fewer extrapyramidal symptoms (unwanted side effects involving movement) than conventional (first-generation) antipsychotics.
- Some of the earlier antidepressant medications (e.g., tricyclics and MAO inhibitors) have now been replaced by SSRIs and SNRIs. Although more widely used, there is no compelling evidence that these newer medications are more effective than the older antidepressants. In general, antidepressants work through their influence on the serotonin and norepinephrine neurotransmitter systems.
- Anxiolytic (antianxiety) medications work via their effect on the GABA system. They are widely prescribed.
- Lithium is an important medication in the treatment of mania. However, some of the newer mood-stabilizing drugs (which are also used to treat epilepsy) are now more frequently prescribed.
- Although not frequently used, ECT is a safe and effective treatment for depression and other disorders. It causes some short-term cognitive side effects, especially when administered bilaterally.
- Neurosurgery is used as a treatment of last resort. Even when patients improve clinically, they may have permanent, adverse side effects.

### → A Tragic Case of Murder as an Outcome of Severe Mental Illness

On Mother's Day weekend in 2003, Deanna Laney, a very religious 39-year-old housewife and mother from Texas, began to see "signs from God" that she was supposed to do something drastic about her children. The first sign indicated to her that she was supposed to destroy her children when she saw her fourteen-month-old son, Aaron, playing with a spear. She hesitated because she was uncertain of exactly what the sign from God meant. Then she received another sign when Aaron handed her a rock that he was playing with. She then saw him squeezing a frog and began to conclude that she was supposed to kill her children, either by stoning them, strangling them, or stabbing them. She believed that God had given her three ways to kill them but concluded that killing them with rocks would be better than strangulation.

She killed two of her sons by beating them with a rock; her third son, Aaron, was severely injured but survived her attack. She called 911 and reported that she had killed her sons.

After she was arrested, she was very puzzled and behaved in an extreme manner, for example, lying in a fetal position and crying in the cell, walking around the cell singing gospel songs, and often praying and crying. The sheriff in the prison reported that "when she suddenly realizes what she's done she goes an extreme blank stare and withdrawal." She was placed on a suicide watch because of her intense and psychotic behavior.

Laney had a history of serious mental illness including a prior psychotic experience in which she was hospitalized. During this episode, she reported that she had smelled sulfur and concluded

that this was God's way of warning her that the devil was close. She was diagnosed with schizophrenia.

At her murder trial, Laney pleaded Not Guilty by Reason of Insanity (NGRI) (to be discussed later in the chapter). Her defense was based on her belief that God had told her the world was going to end and "she had to get her house in order," which included killing her children. The psychiatric evaluations of her mental health status prior to the trial reflected a strong consensus as to her condition. Psychiatrists who served as experts from both the defense and the prosecution in this case testified that Laney was psychotic at the time of the crime and met the criteria for NGRI. The evaluating psychiatrists concluded that Laney had crushed her sons' skulls with rocks because she was suffering from delusions and did not know right from wrong.

The jury acquitted her of all charges on grounds that she was insane at the time of the crime. Apparently, there was no pre-meditation, and Laney did not believe that she was doing wrong; thus she was found not guilty by reason of insanity (Associated Press, 2004; Ramsland, 2005).

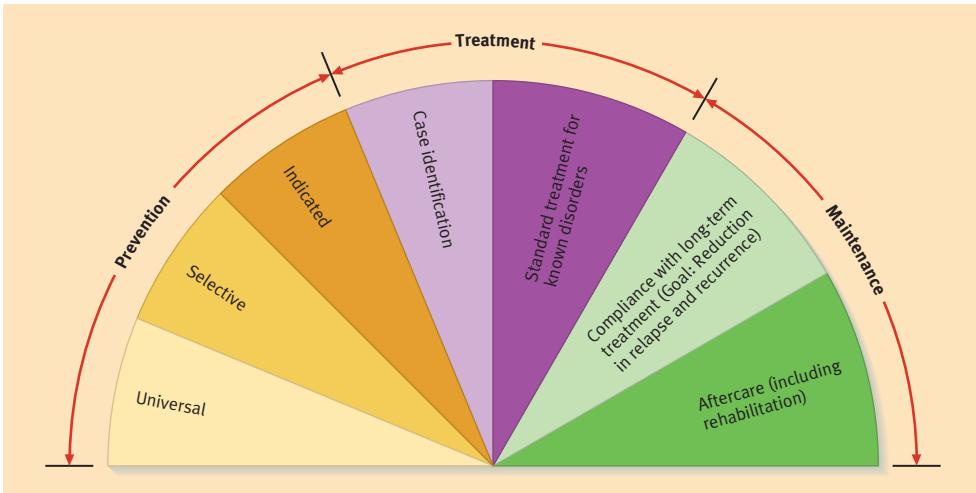

.....

The final chapter of this book has traditionally been somewhat of a highlight for several important topics in abnormal psychology that have been noted only briefly in earlier chapters. These issues are very important to understanding the field of abnormal psychology and will give the reader a broader perspective on ways our society deals with, or in some cases fails to deal with, abnormal behavior or its consequences. We begin with the topic of prevention of mental disorders. Over the years, most mental health efforts have been geared toward helping people after they have already developed serious problems. If the goal is to reduce or eliminate emotional problems in our country or the world, then a major alteration in thinking is required. We need to expand efforts at prevention through early intervention (Breitborde et al., 2010; Tortolero, 2010).

Next, we will describe inpatient mental health treatment and the state of mental hospitals in contemporary society, including a discussion of the prison system where many mental health patients end up. We will discuss changes that have taken place and some of the forces that have affected inpatient psychiatric care today. Following this, several legal issues pertinent to psychiatric care and the hospitalization of people with severe psychological problems will be addressed. We will then briefly survey the scope of organized efforts for mental health both in the United States and throughout the world. Finally, we will consider what each of us can do to foster mental health.

## Perspectives on Prevention

In the early 1990s, the U.S. Congress directed the National Institute of Mental Health (NIMH) to work with the Institute of Medicine (IOM) to develop a report detailing a long-term

**FIGURE 17.1**

**Classification of Prevention Strategies, Treatment, and Maintenance.** The traditional terminology for describing general strategies of disease prevention in the field of public health has been revised to provide a more useful perspective on prevention efforts. The new classification system for prevention (universal, selective, and indicated strategies) is shown in this context as distinct from treatment interventions and maintenance approaches to mental health problems.

Source: From P. J. Mrazek & R. J. Haggerty (Eds.). (1994). *Reducing risks for mental disorders: Frontiers for preventive intervention research*. Copyright © 1994 by the National Academy of Sciences. Courtesy of the National Academy Press, Washington, DC.

prevention research program. Among other things, the IOM report focused attention on the distinction between prevention and treatment efforts (Dozois & Dobson, 2004; Munoz, 2001; Munoz et al., 1996). Prevention efforts are classified into three subcategories:

1. **Universal interventions:** Efforts that are aimed at influencing the general population.
2. **Selective interventions:** Efforts that are aimed at a specific subgroup of the population considered at risk for developing mental health problems—for example, adolescents or ethnic minorities (Coie et al., 2000).
3. **Indicated interventions:** Efforts that are directed toward high-risk individuals who are identified as having minimal but detectable symptoms of mental disorder but who do not meet criteria for clinical diagnosis—for example, individuals forced from their homes by a flood or some other disaster (see Reyes & Jacobs, 2006).

As shown in Figure 17.1, preventive efforts are clearly differentiated from treatment and maintenance interventions.

## Universal Interventions

Universal interventions perform two key tasks: (1) altering conditions that can cause or contribute to mental disorders (risk factors) and (2) establishing conditions that foster positive mental health (protective factors). Epidemiological studies help investigators obtain information about the incidence and distribution of various maladaptive behaviors (Dozois & Dobson, 2004) such as those seen in anxiety-based disorders (Feldner et al., 2004). These findings can then be used to suggest what preventive efforts might be most appropriate. For example, various epidemiological studies and reviews have shown that certain groups are at high risk for mental disorders: recently divorced people (Bullock et al., 2009), the physically disabled (Goodheart & Rozensky, 2011), elderly people (Houtjes et al., 2010), the physically abused (Panuzio & DiLillo, 2010), people who have been uprooted from their homes (Caracci & Mezzich, 2001), and victims of severe trauma

(Jaranson et al., 2004). Although findings such as these may be the basis for immediate selective or indicated prevention, they may also aid in universal prevention by telling us what to look for and where to look—in essence, by focusing our efforts in the right direction. Universal prevention is very broad and includes biological, psychosocial, and sociocultural efforts. Virtually any effort that is aimed at improving the human condition would be considered a part of universal prevention of mental disorder.

**BIOLOGICAL STRATEGIES** Biologically based universal strategies for prevention begin with promoting adaptive lifestyles. Many of the goals of health psychology can be viewed as universal prevention strategies. Efforts geared toward improving diet, establishing a routine of physical exercise, and developing overall good health habits can do much to improve physical well-being (Martins et al., 2010). Physical illness always produces some sort of psychological stress that can result in such problems as depression, so with respect to good mental health, maintaining good physical health is prevention.

**PSYCHOSOCIAL STRATEGIES** In viewing normality as optimal development and viewing high functioning (rather than the mere absence of pathology) as the goal, we imply that people need opportunities to learn physical, intellectual, emotional, and social competencies.

1. The first requirement for psychosocial health is that a person develop the skills needed for effective problem solving, for expressing emotions constructively, and for engaging in satisfying relationships with others. Failure to develop these protective skills places the individual at a serious disadvantage in coping with stresses and the unavoidable risk factors for mental disorder.
2. The second requirement for psychosocial health is that a person acquire an accurate frame of reference on which to build his or her identity. We have seen repeatedly that when people's assumptions about themselves or their world are inaccurate, their behavior is likely to be maladaptive.

Preventing mental disorders and maintaining psychosocial health require that a person be prepared for the types of problems likely to be encountered during given life stages. For example, how might young people who want to marry and have children prepare themselves for the tasks of building a mutually satisfying relationship and helping children develop their abilities?

Consider, for example, the young woman who believes that being thin can bring happiness and so becomes anorexic.

3. The third requirement for psychosocial health is that a person be prepared for the types of problems likely to be encountered during given life stages. For example, young people who want to marry and have children must be prepared for the tasks of building a mutually satisfying relationship and helping children develop their abilities. Similarly, a middle-aged adult needs to be prepared for problems that are likely to arise during retirement and old age.

In recent years, psychosocial measures aimed at prevention have received a great deal of attention. The field of behavioral medicine has been influential (Hunter et al., 2009), with efforts being made to change the psychological factors underlying unhealthy habits such as smoking, excessive drinking, and poor eating habits.

**SOCIOCULTURAL STRATEGIES** As has been demonstrated many times throughout this book, without a supportive community, individual development is stifled. At the same time, without responsible, psychologically healthy individuals, the community will not thrive and, in turn, cannot be supportive. The psychosocially impaired victims of disorganized communities lack the wherewithal to create better communities to protect and sustain the psychological health of those who come after them, and a persistently unprotective environment results. Sociocultural efforts toward universal prevention are focused on making the community as safe and attractive as possible for the individuals within it.

With our growing recognition of the role that pathological social conditions play in producing maladaptive behavior (in socially impoverished communities), increased attention must be devoted to creating social conditions that will foster healthy development and functioning in individuals. Efforts to create these

conditions include a broad spectrum of measures—ranging from public education and Social Security to economic planning and social legislation directed at ensuring adequate health care for all.

## Selective Interventions

Preventing mental health problems through social change in the community is difficult. Although the whole psychological climate can ultimately be changed by a social movement such as the civil rights movement of the 1960s, the payoff of such efforts is generally far in the future and may be difficult or impossible to predict or measure. Attempts to effect psychologically desirable social change are also likely to involve ideological and political issues that may inspire powerful opposition, including opposition from government itself. Efforts to bring about change through targeting a smaller segment of the population can have more effective results. For example, a recent review of the research in reducing depression in children concludes that selective intervention programs are more effective than universal programs (Horowitz & Garber, 2006) in reducing the extent of depressive disorders.

### AN ILLUSTRATION OF SELECTIVE PREVENTION STRATEGIES

**STRATEGIES** Though difficult to formulate, mobilize, and carry out, selective intervention can bring about major improvements. In this section, we will look at the mobilization of prevention resources aimed at curtailing or reducing the problem of teenage alcohol and drug abuse. Prominent social forces such as advertising and marketing campaigns that are attractive to youth, the influence of peer groups, and the ready availability of alcohol, tobacco, and even many illicit drugs are instrumental in promoting the early use of alcohol in young people.

Although recent years have witnessed a decrease in the rate of adolescent substance use in the United States (Johnston et al., 2007), alcohol, tobacco, and other drug use by teenagers remains a persistent public health problem. Alcohol is the most commonly used drug among adolescents (Komro et al., 2008). Alcohol use among youth is related to many social, emotional, and behavioral problems (e.g., using illegal drugs, fighting, stealing, driving under the influence, having unplanned sex, and having school problems). In fact, early alcohol use is a strong predictor of lifetime alcohol abuse or dependence (Grant & Dawson, 1997).

Because the factors that entice adolescents to begin using alcohol and drugs are influenced by social factors, it is tempting to think that if these forces could be counterbalanced with equally powerful alternative influences, the rate of substance abuse might radically decline. But this is easier said than done. The U.S. government has approached the drug-abuse problem with three broad strategies for dealing with adolescent substance use, all of which have proved insufficient:

1. *Intercepting and/or Reducing the Supply of Drugs Available.* The reduction of supply by policing our borders has

Efforts to teach schoolchildren about the dangers of drugs before they reach the age of maximum risk are based on the premise that if children are made aware of the dangers of drugs and alcohol, they will choose not to use them. However, evaluative studies have cast doubt on the effectiveness of programs such as D.A.R.E. What do you think might account for D.A.R.E.'s lack of success?

had minimal impact on the availability of drugs. These programs do little to affect the supply of the two drugs most abused by adolescents—alcohol and tobacco—which are, of course, available in corner stores and even in the adolescent's home. Reducing the supply of these drugs to adolescents is especially challenging given mass-media messages and other societal signals that these legal products can bring about social acceptance, are essential for celebrations, and can mark a young person's passage into adulthood, with limited cautions about their potential to damage health.

2. *Providing Treatment Services for Those Who Develop Drug Problems.* Although much money is spent each year on treatment, treating substance abuse is perhaps the least effective way to reduce the problem. Addictive disorders are very difficult to overcome, and treatment failure or relapse are the rule rather than the exception. Therapeutic programs for those addicted to drugs or alcohol, though necessary, are not the answer to eliminating or even significantly reducing the problems in our society.
3. *Encouraging Prevention.* By far the most desirable—and potentially the most effective—means of reducing the drug problem in our country is through prevention methods aimed at alerting citizens to the problems that surround drugs and teaching young people ways to avoid using them (Bloom et al., 2009). Although past efforts have had some limited success in discouraging adolescent drug use, many initially promising prevention efforts have failed to bring about the desired reduction in substance use. There are a number of reasons for this: The intervention typically has not been conducted for a long enough period to show the desired effect; the intervention efforts have not been powerful enough to make a sufficient impact on the participants; or the strategy may not have been well implemented.

In recent years prevention specialists have taken a more proactive position and have attempted to establish programs that prevent the development of abuse disorders before young people become so involved with drugs or alcohol that future adjustment becomes difficult, if not impossible. These recent prevention strategies have taken some diverse and promising directions. We will examine several such efforts and then discuss the limitations of these prevention approaches.

**School-Based Interventions** The most promising alcohol- and drug-prevention curricula are based on behavioral theory; they target the risk (e.g., peer pressure, mass-media messages) and protective (e.g., alcohol-free activities, messages supporting "no use" norms) factors associated with adolescent use; include developmentally appropriate information about alcohol and other drugs; are skill-based and interactive; and emphasize normative education that increases the awareness that most students do not use alcohol, tobacco, or other drugs (Komro & Toomey, 2002). While several such programs exist, some have been evaluated more extensively than others; for example, the Drug Abuse Resistance Education Program, or D.A.R.E. (a program that uses local police officers who are invited by the local school districts to speak and work with students after undergoing special training), recently underwent an extensive number of evaluative studies that have generally concluded that the program has limited success at deterring substance use. In fact, a 10-year follow-up study reported no success of the D.A.R.E. program (Lynam et al., 2009).

**Intervention Programs for High-Risk Teens** Intervention programs identify high-risk teenagers and take special measures to circumvent their further use of alcohol or other potentially dangerous drugs (Hawkins et al., 2004). Programs such as these are often school-based efforts and are not strictly prevention programs because they intervene with young people who have already developed problems. Programs for early intervention can be effective in identifying adolescents before their alcohol or drug problems become entrenched (Foley & Hochman, 2006).

### research CLOSE-UP

#### Intervention Programs of High-Risk Populations

This research strategy involves identifying high-risk individuals and providing special approaches to circumvent their problems; for example, identifying adolescents at risk for abusing alcohol and implementing a program to prevent the problem behavior.

Why do you think peer programs, like those offered at the Boys and Girls Clubs, tend to be more successful than adult-driven programs in getting children and adolescents to avoid drug and alcohol abuse?

#### **Parent Education and Family-Based Intervention Programs**

Through their own drinking or positive verbalizations about alcohol, parents may encourage or sanction alcohol use among teens. Some research has shown that parental involvement and monitoring reduces substance use among adolescents (Ramirez et al., 2004). Thus, many prevention programs focus upon family interventions (Spoth et al., 2004) with good success.

#### **Extracurricular Strategies**

Various extracurricular activities and youth programs have the potential to reduce problem behaviors like alcohol and drug use, school dropouts, violence, and juvenile delinquency (Scales & Leffert, 1999). These programs may be especially beneficial for high-risk teens who are

Recognizing the huge market potential of teenagers, advertisers exploit the tremendous value that the appearance of sophistication has for this age group. Some efforts have been aimed at deglamorizing these messages by showing ads that graphically depict the negative aspects alcohol and drug use, like the antismoking ad on the right.

unsupervised outside of school or who, because of poverty, may not have access to opportunities like sports, music, or other programs available to middle-class youth.

#### **Internet-Based Intervention Programs**

One recent study (Schwinn et al., 2010) examined adolescent girls (seventh through ninth grade) who were given an online test battery and 12 sessions of gender-specific drug prevention strategies. At follow-up, girls receiving the Internet intervention program reported lower rates of use for alcohol and drugs compared with the control sample.

#### **Comprehensive Prevention Strategies**

A consensus seems to be developing in the field that the most effective way to prevent complex problems like adolescent alcohol and other drug use is through the use of multicomponent programs that combine aspects of the various strategies described previously (Stigler, Neusel, and Perry, 2011). Typically, classroom curricula are used as the core component to which other strategies (e.g., parent programs, mass media, extracurricular activities, and community strategies to reduce access to alcohol via enforcement of age of drinking laws) are added.

Partly because of this lack of positive results for alcohol use, a team of University of Minnesota researchers developed Project Northland—an exemplary research-based set of interventions that aims to delay the onset of drinking in young adolescents, reduce alcohol use among those already drinking, and limit the number of alcohol-related problems during adolescence. Project Northland included multiple years of behavioral curricula, parental involvement and education, peer leadership opportunities, community task forces, and community-wide media campaigns (e.g., Perry et al., 1996, 2002). Interventions started with students in the sixth grade and continued until high school graduation. The program included peer-led and activity-driven learning strategies that involved students, parents, teachers, and community members in support of "no use" messages, while at the same time promoting alcohol-free norms for youth, providing fun alternatives to alcohol use, and reducing youth access to alcohol. Innovative activities and games were used to ensure high participation rates in the program, and comprehensive teacher and peer-leader trainings were core features (go to <http://www.hazelden.org/web/go/projectnorthland> for descriptions of the program).

The success of prevention programs has come to the attention of educators, and a number of efforts are under way to "export" these laboratory programs for broader use in America's schools. Perhaps the most noteworthy is the National Registry of Effective Prevention Programs (NREPP), a program of the U.S. Department of Health and Human Services Substance Abuse and Mental Health Services Administration (<http://www.samhsa.gov>). However, the jury

is still out on the relative success of the various substance-abuse prevention programs at reducing alcohol and drug problems in adolescents. For example, an effort to implement the Northland project in a large Midwestern inner city where problems with gangs, violence, drug dealing, and housing were perceived as more pressing than underage drinking did not have the positive outcomes that were obtained in the more rural environment of northern Minnesota (Komro et al., 2008). It will take time and further research efforts to determine which of the strategies are superior to others in reducing alcohol and drug problems in adolescents, and in which settings.

### Indicated Interventions

Indicated intervention emphasizes the early detection and prompt treatment of maladaptive behavior in a person's family and community setting. In some cases—for example, in a crisis or after a disaster (Garakani et al., 2004; see the discussion on crisis intervention in Chapter 5)—indicated prevention involves immediate and relatively brief intervention to prevent any long-term behavioral consequences of the traumatic events (Raphael & Wooding, 2004).

## Inpatient Mental Health Treatment in Contemporary Society

Mental disorders are common in the United States. An estimated 26.2 percent of Americans ages 18 and older, or about one in four adults, suffer from a diagnosable mental disorder in a given year (Kessler, Chiu et al., 2005). Over 57.7 million people ages 18 and older suffer from one or more psychiatric disorders. Of these, approximately 2.4 million American adults, or about 1.1 percent of the population ages 18 and older in a given year, are diagnosed as having schizophrenia. While most people experiencing mental health problems seek or obtain help in an outpatient program, some individuals require admission to an inpatient treatment program because of perceived danger they experience in their daily lives. Inpatient admission to a psychiatric hospital can be a significant step that is taken as a means of protecting the individual or those close to her or him from harm by providing a secure environment to allow the patient to recover from her or his extreme symptoms.

### The Mental Hospital as a Therapeutic Community

In cases where individuals might be considered dangerous to themselves or others (Richards et al., 1997) or where their symptoms are so severe that they are unable to care

for themselves in the community, psychiatric hospitalization may be necessary in order to prevent the development of further problems and the individual's further psychological deterioration. Most of the traditional forms of therapy that we discussed in Chapter 16 may, of course, be used in a residential or inpatient hospital setting. In addition, in many mental hospitals, these techniques are supplemented by efforts to make the hospital environment itself a "therapeutic community" (Kennard, 2004). That is, the social environment is manipulated to provide the patient with the greatest benefit. All the ongoing activities of the hospital are brought into the total treatment program, and the environment, or milieu, is a crucial aspect of the therapy. This approach is thus often referred to as **milieu therapy** (Petti, 2010; Zimmerman, 2004). Three general therapeutic principles guide this approach to treatment:

1. Staff expectations are clearly communicated to patients. Both positive and negative feedback are used to encourage appropriate verbalizations and actions by patients.
2. Patients are encouraged to become involved in all decisions made, and in all actions taken, concerning them. A self-care, do-it-yourself attitude prevails.
3. All patients belong to social groups on the ward. The group cohesiveness that results gives the patients support and encouragement, and the related process of group pressure helps shape their behavior in positive ways.

In a therapeutic community, as few restraints as possible are placed on patients' freedom, and patients are encouraged to take responsibility for their behavior and participate actively in their treatment programs. Open wards permit patients to use the grounds and premises. Self-government programs give patients responsibility for managing their own affairs and those of the ward. All hospital personnel are expected to treat the patients as human beings who merit consideration and courtesy. The interaction among patients—whether in group therapy sessions, social events, or other activities—is planned in such a way as to be of therapeutic benefit. In fact, it is becoming apparent that often the most beneficial aspect of a therapeutic community is the interaction among the patients themselves. Differences in social roles and backgrounds may make empathy between staff and patients difficult, but fellow patients have been there—they have had similar problems and breakdowns and have experienced the anxiety and humiliation of being labeled "mentally ill" and being hospitalized. Constructive relationships frequently develop among patients in a supportive, encouraging milieu. However, although **residential treatment** has improved over time, such treatment for children and adolescents continues to face challenges.

Another successful method for helping patients take increased responsibility for their own behavior is the use of

**social-learning programs.** Such programs normally make use of learning principles and techniques such as token economies (see Chapter 16) to shape more socially acceptable behavior (Corrigan, 1995, 1997; Mariotto et al., 2002; Paul et al., 1997).

Although a strong case can be made for the use of psychiatric hospitalization in stabilizing adjustment of people living with psychiatric disorders (Glick & Tandon, 2009), a persistent concern about hospitalization is that the mental hospital may become a permanent refuge from the world. Over the past four decades, considerable effort has been devoted to reducing the population of inpatients by closing hospitals and treating patients who have mental disorders as outpatients. This effort, which is often referred to as **deinstitutionalization**, was initiated to prevent the negative effects, for many psychiatric patients, of being confined to a mental hospital for long periods of time as well as to lower health care costs. To keep the focus on returning patients to the community and on preventing their return to the institution, contemporary hospital staffs try to establish close ties with patients' families and communities and to provide them with positive expectations about the patients' recovery.

The rise of the biological therapies described in Chapter 16 has meant that between 70 and 90 percent of patients diagnosed with psychosis and admitted to mental hospitals can now be discharged within a few weeks, or at most a few months. Even where disorders have become chronic, effective treatment methods have been developed. In one of the most extensive and well-controlled studies of chronic hospitalized patients, Paul and Lentz (1977) compared the relative effectiveness of three treatment approaches:

1. Milieu therapy focuses on structuring a patient's environment to provide clear communication of expectations and to get the patient involved in the treatment. One major goal is to encourage the patient to participate in the therapeutic community through the group process.
2. A social-learning treatment program, organized around learning principles and using a rigorously programmed token economy system, with ward staff as reinforcing agents. Undesirable behavior was not reinforced, whereas the accumulation of many tokens through effective functioning made a patient eligible for attractive amenities not normally available in public mental hospitals.
3. Traditional mental hospital treatments including pharmacotherapy, occupational therapy, recreational therapy, activity therapy, and individual or group therapy. No systematic application of milieu therapy or the social-learning program was given to this group.

The treatment project covered a period of 6 years: an initial phase of staff training, patient assessment, and baseline recording; a treatment phase; an aftercare phase; and a long (year and a half) follow-up. The changes targeted included resocialization,

learning new roles, and reducing or eliminating bizarre behavior. There were 28 chronic schizophrenic patients in each treatment group matched for age, sex, socioeconomic level, symptoms, and duration of hospitalization. The results of the study were impressive. Both milieu therapy and the social-learning program produced significant improvement in overall functioning and resulted in more successful hospital releases than the traditional hospital care. The behaviorally based social-learning program, however, was clearly superior to the more diffuse program of milieu therapy, as evidenced by the fact that over 90 percent of the released patients from the social-learning program remained continuously in the community, compared with 70 percent of the released patients who had had milieu therapy. The figure for the traditional treatment program was less than 50 percent.

Despite the promise of the token economy approach, emulating as it does certain "real-world" principles of exchange that the patient will face outside the institution, it has not enjoyed wide public acceptance (Mariotto et al., 2002). Many feel that it is cruel and inhumane to expect mental health patients to govern their behavior in accordance with a prescribed schedule of reinforcements. One might ask, however, whether it is more humane to consign the patient to the status of a passive and helpless recipient of whatever the environment has to offer, which in many institutional settings is not very much. Is that truly the message we want to convey about the patient's relationship to his or her environment? Probably not, especially in light of the considerable evidence that most chronic mental health patients are surprisingly adept at making successful adaptations that are within their range of control.

## Aftercare Programs

Even where hospitalization has successfully modified maladaptive behavior and a patient has learned needed occupational and interpersonal skills, readjustment in the community following release may still be difficult (Seidman, 2003; Thornicroft & Tansella, 2000). Many studies have shown that in the past, up to 45 percent of individuals with schizophrenia have been readmitted within the first year after their discharge. Community-based treatment programs, now referred to as "aftercare programs," are live-in facilities that serve as a home base for former patients as they make the transition back to adequate functioning in the community. Typically, community-based facilities are run not by professional mental health personnel but by the residents themselves. Aftercare programs can help smooth the transition from institutional to community life and reduce the number of relapses. However, some individuals do not function well in aftercare programs. Owen and colleagues (1997) found that clients who were likely to hold unskilled employment, to have nonpsychotic symptoms, to have committed a crime, or to be more transient tended to be noncompliant in aftercare programs. The investigators conclude that many of the discharged patients did not "fit" the services typically offered to released psychiatric

inpatients. Those with less severe symptoms may fail because they appear to aftercare staff as not needing much help; most services are geared to those patients who exhibit more extreme symptoms.

Sometimes aftercare includes a “halfway” period in which a released patient makes a gradual return to the outside world in what were formerly termed “halfway houses.” Aftercare programs do not always live up to their name, however. Levy and Kershaw (2001) disclose a number of problems in which relevant treatment was not made available and staff did not provide a secure environment.

Although some patients continue to have mental health problems including suicide attempts (Fenton et al., 1997), and many have trouble gaining the acceptance and support of the community (Fairweather, 1994; Seidman, 2003), efforts to treat severely disturbed patients in the community are often very successful.

## Deinstitutionalization

The population of psychiatric patients in the United States has shrunk considerably over the past 40 years. Between 1967 and 2007, the number of people in state mental hospitals dropped 81 percent (Scott et al., 2008). The deinstitutionalization movement, which involves closing down mental hospitals and treating persons with severe mental disorders in community programs, has not been limited to the United States. On the contrary, there has been a worldwide trend to shift the care of mental patients from inpatient hospitals to community-based programs (Emerson, 2004; Honkonen et al., 2003).

Deinstitutionalization has been a source of considerable controversy. Some authorities consider the emptying of mental hospitals a positive expression of society’s desire to free previously confined persons, maintaining that deinstitutionalized patients show significant improvement compared with those who remain hospitalized (Newton et al., 2000; Reinhartz et al., 2000). Others, however, speak of the “abandonment” of chronic patients to a cruel and harsh existence (Grob, 2008), which for many includes homelessness, violent victimization (Walsh et al., 2003), or suicide (Goldney, 2003). Many citizens, too, complain of being harassed, intimidated, and frightened by obviously disturbed persons wandering the streets of their neighborhoods. In an effort to address concerns of patients, some professionals and community members alike have lobbied to call attention to mental health challenges brought about by deinstitutionalization (Rosenberg & Rosenberg, 2006).

Some of the reduction in mental health services in recent years has come about because of changes in the health care system. (See the Unresolved Issues section at the end of this chapter.) The planned community efforts to fill the gaps in service never really materialized at effective levels (Lamb, 1998).

A number of factors have interacted to alter the pattern of mental hospital admissions and discharges in recent years. Antipsychotic drugs have made it possible for many patients who would otherwise have required confinement to live in the community, but not all mental health problems can be managed with medication. In addition, changing treatment philosophy and the desire to eliminate mental institutions were bolstered by the assumption that society wanted and could afford to provide better community-based care for chronic patients outside of large mental hospitals.

In theory, closing the public mental hospitals seemed workable. The plan was to open many community-based mental health centers that would provide continuing care to the residents of hospitals after discharge. Residents would be given welfare funds (supposedly at less cost to the government than maintaining large mental hospitals) and would be administered medication to keep them stabilized until they could obtain continuing care. Many patients would be discharged to home and family; others would be placed in smaller, home-like board-and-care facilities or nursing homes.

Unforeseen problems arose, however, and in many cases, homeless shelters in metropolitan communities have become a “makeshift alternative” to inpatient mental health care (Haugland et al., 1997). Many residents of mental institutions have no families or homes to go to; board-and-care facilities are often substandard; and the community mental health centers have often been ill prepared and insufficiently funded to provide needed services for chronic patients, particularly as national funding priorities shifted during the 1980s (Humphreys & Rappaport, 1993). Many patients are not carefully selected for discharge and are not ready for community living, and many

Aftercare facilities do not always provide the safe refuge promised. Homeless people often live in large cities under austere conditions, as noted in this photograph, that resemble those seen in mental institutions several decades ago.

of those who are discharged are not followed up sufficiently or often enough to ensure their successful adaptation outside the hospital. In addition, some research has suggested that deinstitutionalization has increased the rates of suicide among people with mental illness (Yoon & Bruckner, 2009).

One important court case (*Albright v. Abington Memorial Hospital*, 1997) involved charges that the hospital failed to provide sufficient care for a seriously disturbed woman who later killed herself. Countless patients have been discharged to fates harsher than the conditions in any of the hospitals. The following case illustrates the situation.

→ **From Institution to Homelessness** Dave B., 49 years old, had been hospitalized for 25 years in a state mental hospital. When the hospital was scheduled for phaseout, many of the patients, particularly those who were regressed or aggressive, were transferred to another state hospital. Dave was a borderline intellectually disabled man who had periodic episodes of psychosis. At the time of the hospital closing, however, he was not hallucinating and was "reasonably intact." Dave was considered to be one of the "less disturbed" residents because his psychotic behavior was less pronounced and he presented no dangerous problems. He was discharged to a board-and-care facility (actually an old hotel where most of the residents were former inpatients). At first, Dave seemed to fit in well at the facility; mostly he sat in his room or in the outside hallway, and he caused no trouble for the caretakers. Two weeks after he had arrived, however, he wandered off the hotel grounds and was missing for several days. The police eventually found him living in the city dump. He had apparently stopped taking his medication, and when he was discovered he was regressed and catatonic. He was readmitted to a state hospital.

Research on the effects of deinstitutionalization has been mixed. Some reports have noted positive benefits of briefer hospitalization (Honkonen et al., 2003; Rauktis, 2001), and some data suggest that deinstitutionalization appears not to be associated with an increased risk of homicide by people who are mentally ill (Simpson et al., 2004). However, others have reported problems with discharged patients and point to failures in programs to deinstitutionalize mental patients (Chan et al., 2001; Leff, 2001).

There is some recent indication that inpatient psychiatric hospitalization may be increasing because of the failures to provide adequate mental health care for patients in need of mental health services in the community (Marcotty, 2004). A similar increase in the number of people being hospitalized has been reported in the United Kingdom (Priebe & Turner, 2003).

The full extent of problems created by deinstitutionalization is not precisely known, partly because there has been little rigorous follow-up on patients discharged from mental hospitals. Such research investigations are difficult to conduct because the

patients are transient and hard to track over time. Certainly, not all homeless people are former mental patients, but deinstitutionalization has contributed substantially to the number of homeless people (Whitaker, 2009) and to the number of mentally ill people in prison (Markowitz, 2006). On the positive side, a study by Nelson and colleagues (2007) concluded that there has been a significant reduction in homelessness and significant improvements in "well-being" outcomes resulting from recent programs that provide permanent housing and support for the homeless. For example, Padgett, and colleagues (2006) showed that assertive community treatment and programs to reduce harm can be successful in producing housing stability and reduction in the trauma of homelessness.

- Define the term selective intervention. What selective intervention programs have shown promise in helping prevent teenage alcohol and drug abuse?
- What is indicated intervention?
- What is milieu therapy?
- What problems have resulted from deinstitutionalization?

## Controversial Legal Issues and the Mentally Ill

A number of important issues are related to the legal status of mentally ill people—the subject matter of **forensic psychology** or **forensic psychiatry**—and they center on the rights of patients and the rights of members of society to be protected from disturbed individuals (see Drogin et al., 2011 for a comprehensive overview). For a survey of some of the legal rights that mentally ill people have gained over the years, see The World Around Us box on the following page.

### Civil Commitment

Persons with psychological problems or behaviors that are so extreme and severe as to pose a threat to themselves or others may require protective confinement. Those who commit crimes, whether or not they have a psychological disorder, are dealt with primarily through the judicial system—arrest, court trial, and, if convicted, possible confinement in a penal institution. People who are judged to be potentially dangerous because of their psychological state may, after **civil commitment** procedures, be confined in a mental institution. The steps in the commitment process vary slightly depending on state law, the locally available community mental health resources, and the nature of the problem. For example, commitment procedures for a person who is intellectually disabled are different from those for a person whose problem is alcohol abuse.

## Important Court Decisions for Patient Rights

Several important court decisions have helped establish certain basic rights for individuals suffering from mental disorders. But they have also curtailed these rights, amid continuing controversy.

- **Right to Treatment.** In 1972 a U.S. district court in Alabama rendered a landmark decision in the case of *Wyatt v. Stickney*. It ruled that a mentally ill person or a person with mental retardation had a right to receive treatment. Since that decision, the state of Alabama has increased its budget for the treatment of mental illness and mental retardation by 300 percent (see Winick, 1997).
- **Freedom from Custodial Confinement.** In 1975 the U.S. Supreme Court upheld the principle that patients have a right to freedom from custodial confinement if they are not dangerous to themselves or others and if they can safely survive outside of custody. In *Donaldson v. O'Connor*, the defendants were required to pay Donaldson \$10,000 for having kept him in custody without providing treatment.
- **Right to Compensation for Work.** In 1973 a U.S. district court ruled in the case of *Souder v. Brennan* (the secretary of labor) that a patient in a nonfederal mental institution who performed work must be paid according to the Fair Labor Standards Act. Although a 1978 Supreme Court ruling nullified the part of the lower court's decision dealing with state hospitals, the ruling still applies to mentally ill persons and patients with mental retardation in private facilities.
- **Right to Live in a Community.** In 1974 a U.S. district court decided, in the case of *Staff v. Miller*, that released state mental hospital patients have a right to live in "adult homes" in the community.

• **Right to Less Restrictive Treatment.** In 1975 a U.S. district court issued a landmark decision in the case of *Dixon v. Weinberger*. The ruling established the right of individuals to receive treatment in less restrictive facilities than mental institutions.

- **Right to Legal Counsel at Commitment Hearings.** The Wisconsin State Supreme Court decided in 1976, in the case of *Memmel v. Mundy*, that an individual has the right to legal counsel during the commitment process.
- **Right to Refuse Treatment.** Several court decisions have provided rulings, and some states have enacted legislation, permitting patients to refuse certain treatments such as electroconvulsive therapy and psychosurgery.
- **The Need for Confinement Must Be Shown by Clear, Convincing Evidence.** In 1979 the U.S. Supreme Court ruled, in the case of *Addington v. Texas*, that a person's need to be kept in an institution must be based on demonstrable evidence.
- **Limitation on Patients' Rights to Refuse Psychotropic Medication.** In 1990 the U.S. Supreme Court ruled, in *Washington v. Harper*, that a Washington State prison could override a disturbed prisoner's refusal of psychotropic medications. This decision was based on a finding that the prison's review process adequately protected the patient's rights. We see in this instance that changes in the national political climate can reverse prior trends that favored patients' rights.

Sources: Grounds (2000), Mental Health Law Project (1987), Mrad & Watson (2011), Saks (2004), and Swartz, Swanson, & Elbogen (2004).

There is a distinction between voluntary hospitalization and involuntary commitment. In most cases, people accept voluntary commitment or hospitalization. In these cases, they can, with sufficient notice, leave the hospital if they wish. But in cases where a person may be considered dangerous or is unable to provide for her or his own care, the need for involuntary commitment may arise (Zerman & Schwartz, 1998).

Being mentally ill is not sufficient grounds for placing a person in a mental institution against his or her will. Although procedures vary somewhat from state to state, several conditions beyond mental illness usually must be met before formal involuntary commitment can occur (Simon & Aaronson, 1988). In brief, such individuals must be judged to be

- Dangerous to themselves or to others and/or
- Incapable of providing for their basic physical needs and/or

- Unable to make responsible decisions about hospitalization and
- In need of treatment or care in a hospital

Typically, filing a petition for a commitment hearing is the first step in the process of committing a person involuntarily. This petition is usually filed by a concerned individual such as a relative, physician, or mental health professional. When such a petition is filed, a judge appoints two examiners to evaluate the proposed patient. In Minnesota, for example, one examiner must be a physician (not necessarily a psychiatrist); the other can be a psychiatrist or a psychologist. The patient is asked to appear voluntarily for psychiatric examination before the commitment hearing. The hearing must be held within 14 days, which can be extended to 30 more days if good cause for the extension can be shown.

The law requires that the court-appointed examiners interview the patient before the hearing.

When a person is committed to a mental hospital for treatment, the hospital must report to the court within 60 days on whether the person needs to be confined even longer. If the hospital gives no report, the patient must be released. If the hospital indicates that the person needs further treatment, then the commitment period becomes indeterminate, subject to periodic reevaluations.

Because the decision to commit a person is based on the conclusions of others about the person's capabilities and her or his potential for dangerous behavior, the civil commitment process leaves open the possibility of the unwarranted violation of a person's civil rights. As a consequence, most states have stringent safeguards to ensure that any person who is the subject of a petition for commitment is granted due process, including rights to formal hearings with representation by legal counsel. If there is no time to get a court order for commitment or if there is imminent danger, however, the law allows emergency hospitalization without a formal commitment hearing. In such cases, a physician must sign a statement saying that an imminent danger exists. The patient can then be picked up (usually by the police) and detained under a "hold order," usually not to exceed 72 hours, unless a petition for commitment is filed within that period.

Involuntary commitment in a psychiatric facility is largely contingent on a determination that a person is dangerous and requires confinement out of a need to protect himself or herself or society. Once committed, a patient may refuse treatment—a situation that mental health professionals working in psychiatric facilities often face. We will now turn to the important issue of evaluating patients in terms of potential dangerousness. (For a discussion of prisoners who are released from prison and then returned because of other offenses, see The World Around Us box on following page.)

### Assessment of "Dangerousness"

Although most psychiatric patients are not considered dangerous, some are violent and require close supervision—perhaps confinement until they are no longer dangerous. Rates of assaultiveness vary from setting to setting, but in all reported studies the overall number of assaultive patients is relatively low. An increasing number of clinical researchers in recent years have discovered that a history of violent behavior and some classes of mental disorder appear to be associated with violence (Pinard & Pagani, 2001). Although most disordered people reportedly show no tendency toward violence (Lamberg, 1998), an increased risk of violence appears more likely among some who are experiencing symptoms of psychosis (Hodgins & Lalonde, 1999). The disorders that have an increased risk for violent behavior include schizophrenia, mania, personality disorder, substance abuse, and the rarer conditions of organic brain injury and Huntington's disease. One study from Finland (Eronen et al., 1996) reported that homicidal behavior among

Prediction of aggressive behavior is an important but not necessarily an easy task to accomplish in our society.

former patients was considerably more frequent among patients with schizophrenia and even more common among patients with antisocial personality or alcoholism. In another study, psychiatric patients who abused alcohol (Steadman et al., 1998) were found to be notably violent.

Practitioners are often called upon to evaluate the possibility that a patient might be dangerous, and there is some evidence that mental health professionals can contribute to such an assessment (Cunningham & Sorensen, 2007; Quinsey et al., 2006), at least on a short-term basis (Binder, 1999). The determination that a patient is potentially dangerous can be difficult to make (Bauer et al., 2003), yet this is one of the most important responsibilities of professionals working in the fields of law and psychology (Burke, 2010). Scott and colleagues (2010) point out that the accuracy of a clinician's assessment of future violence is determined by many factors, such as the circumstances of the evaluation and the length of time over which violence is predicted. When asked to perform an evaluation of dangerousness in a client, a clinician has a clear responsibility to try to protect the public from potential violence or other uncontrolled behavior of dangerous patients.

**ATTEMPTS TO PREDICT DANGEROUSNESS** It is very difficult—for professionals and laypersons alike—to accurately appraise "dangerousness" in some individuals (Heilbrun, 2009). The complex problem of risk assessment or prediction of dangerousness can be likened to predicting the weather. "Ultimately, the goal of a warning system in mental health law is the same as the goal of a warning system in meteorology: to maximize the number of people who take appropriate and timely actions for the safety of life and property" (Monahan & Steadman, 1997, p. 937).

## Controversial Not Guilty Pleas: Can Altered Mind States or Personality Disorder Limit Responsibility for a Criminal Act?

If a person commits a capital offense when his or her consciousness (and reason) is impaired, as in an altered state, should he or she be held responsible for the crime? Can using psychotropic medicine such as Prozac or Zoloft "poison" a person's mind to such an extreme degree that she or he commits murder? If a murder is committed while someone is heavily "sedated"—for example, with Xanax or Halcion—should that person be released from criminal responsibility because he or she was involuntarily intoxicated with medications prescribed by a health professional? If a person experiences "multiple personalities" and a crime is committed by one personality, should all of the personalities suffer the consequences? These defense strategies are interesting and controversial challenges to today's legal system.

### ALTERED STATES OF CONSCIOUSNESS

In a civil trial, the jury failed to find the manufacturer of Prozac (Eli Lilly) liable in court action that resulted from a 1989 mass murder allegedly committed "under the influence" of Prozac. The murderer (Joseph Wesbecker), in a rage against his employer, killed 8 people and wounded 12 others before killing himself. Survivors and family members of several people who were killed in the incident filed a suit against Eli Lilly because the killer was taking the drug Prozac at the time of the murders and because the drug was alleged to be responsible for "intoxicating" the assassin and lowering his inhibitions. After a long trial, the jury found in favor of the manufacturer (*Fentress et al. v. Shea Communications et al.*, 1990).

Courts have generally not considered altered states of consciousness such as being intoxicated on drugs or alcohol sufficient grounds for an insanity defense because of the issue of volition—that is, that the perpetrator of the crime consciously chose to become intoxicated in the first place. However, the question of intoxication by drugs that were taken for the purpose of medication has added a new dimension to the defense. This issue has not been fully resolved in the court system.

### ALTERED PERSONALITY STATES

Possibly the most fascinating of controversial insanity pleas are those raised by the phenomenon of dissociative identity disorder (DID), formerly known as multiple personality disorder, which has become a more common diagnosis in recent years. Although some professionals dispute even the existence of such a condition, others find it a plausible argument for a plea of not guilty by reason of insanity (NGRI).

The general nature of the problem can be stated quite succinctly: Within a legal system strongly oriented to the precise

identification of individual responsibility for acts, what, if any, are the limits of the assignment of responsibility and sanctions for infractions of the law where the same physical space and body are occupied at different times by more than one distinct and legally recognizable person? Consider the following legal dilemmas:

- Who, among various copersonalities, is empowered to sign for withdrawals from a bank account?
- Are the provisions and obligations of a contract entered into by one constituent personality binding on all others regardless of their particular desires in the matter?
- Does the swearing of an oath, as in court, apply to the entire collection of personalities, or must each be sworn individually if she or he is to testify?
- In the case of a guilty verdict for the criminal act of a given personality, where other personalities did not acquiesce to the crime, how should punishment be fairly meted out?
- If no constituent personality meets a test of insanity, is it reasonable and lawful to declare DID itself an instance of insanity?
- Has rape occurred if the copersonalities of a 26-year-old woman who had acquiesced to intercourse included one or more personalities who had vehemently objected to it? (Such a case was prosecuted in Wisconsin in 1990.)
- And, of course, the most common real-life legal dilemma: Should an individual, as the primary personality, be held legally accountable for, say, a capital crime that evidence suggests may have actually been committed surreptitiously, so to speak, by an alter personality?

The scenario just mentioned has rather often been the contention underlying a plea of not guilty by reason of insanity. Usually, as in the case of the "Hillside Strangler," Kenneth Bianchi (convicted of 12 rapes and murders in California and Washington State), and in the case of a woman who kidnapped a newborn from a hospital and later claimed that an alter personality had actually committed the crime (Appelbaum & Greer, 1994), the plea has failed. On a very few occasions, however, the NGRI plea has worked, as in the well-publicized 1978 case of Ohio resident Billy Milligan, who claimed to be host to 10 personalities and was accused of raping four women (New York Times, 1994). The legal maneuvers inspired by the DID construct admittedly have a quality of whimsy about them. It is consequently difficult to convince most juries that the defendant was so taken over by an alter personality who perpetrated the crime that he or she should be absolved of guilt and responsibility.

Student Seung Hui-Cho, the mass murderer responsible for the Virginia Tech massacre in 2007, was known to have severe mental health problems and was considered to be potentially dangerous.

It is usually easy to determine, after the fact, that a person has demonstrated dangerous behavior, but how well do mental health professionals do in predicting the occurrence of dangerous acts? Not as well as we would like (Edens et al., 2005). Violent acts are particularly difficult to predict because they are apparently determined as much by situational circumstances (for example, whether a person is under the influence of alcohol) as by an individual's personality traits or violent predispositions. One obvious and significantly predictive risk factor is a past history of violence (Burke, 2010; Megargee, 2009), but clinicians are not always able to unearth this type of background information.

As already noted, some types of patients, particularly individuals with active schizophrenia and mania (Hodgins & Lalonde, 1999) and patients with well-entrenched delusions (de Pauw & Szulecka, 1988), are far more likely than others to commit violent acts. Martell and Dietz (1992) reported a study of persons convicted of pushing or attempting to push unsuspecting victims in front of New York City subway trains and found that most were both psychotic and homeless at the time of the act. Norko and Baranoski (2005) noted that although many studies point to a modest increased risk of violence associated with mental illness, particularly psychosis, other studies have not confirmed these findings.

Expert testimony to establish dangerousness or future violence in offenders has become an important part of the U.S. legal system. However, the prediction of dangerousness is often questionable (Krauss & Lieberman, 2007). Mental health professionals typically overpredict violence and consider felons to be more dangerous than they actually are, and usually predict a greater percentage of clients to be dangerous than actually become involved in violent acts (Megargee, 2009). Such a tendency is of course understandable from the perspective of the practitioner, considering the potentially serious consequences of releasing a violent individual. It is likely, however, that many innocent patients thereby experience a violation of their civil rights. Given a certain irreducible level of uncertainty in the prediction of violence, it is not obvious how this dilemma can be completely resolved.

## THE DUTY TO PROTECT: IMPLICATIONS OF THE TARASOFF DECISION

What should a therapist do upon learning that a patient is planning to harm another person? Can the therapist violate the legally sanctioned confidence of the therapy contract and take action to prevent the patient from committing the act? Today, in most states, the therapist not only can violate confidentiality with impunity but also may be required by law to take action to protect people from the threat of imminent violence against them. In its original form, this requirement was conceived as a duty to warn the prospective victim.

The duty-to-warn legal doctrine was given great impetus in a 1976 California court ruling in the case of *Tarasoff v. Regents of the University of California et al.* (Mills et al., 1987). In this case, Prosenjit Poddar was being seen in outpatient psychotherapy by a psychologist at the university mental health facility. During his treatment, Mr. Poddar indicated that he intended to kill his former girlfriend, Tatiana Tarasoff, when she returned from vacation. Concerned about the threat, the psychologist discussed the case with his supervisors, and they agreed that Poddar was dangerous and should be committed for further observation and treatment. They informed the campus police, who picked up Poddar for questioning, subsequently judged him to be rational, and released him after he promised to leave Ms. Tarasoff alone. Poddar then terminated treatment with the psychologist. About 2 months thereafter, he stabbed Ms. Tarasoff to death. Her parents later sued the University of California and staff members involved in the case for their failure to hospitalize Poddar and their failure to warn Tarasoff about the threat to her life. In due course, the California Supreme Court in 1974 ruled that the defendants were not liable for failing to hospitalize Poddar; it did, however, find them liable for failing to warn the victim. Ironically, Prosenjit Poddar, the criminal, was released on a trial technicality and returned home to India. In a later analysis of the case, Knapp (1980) says that the court ruled that difficulty in determining dangerousness does not exempt a psychotherapist from attempting to protect others when a determination of dangerousness exists. The court acknowledged that confidentiality was important to the psychotherapeutic relationship but stated that the protection privilege ends where public peril begins.

The duty-to-warn ruling—which has come to be known as the **Tarasoff decision**—spelled out a therapist's responsibility in situations where there has been an explicit threat on a specific person's life, but it left other areas of application unclear. For example, does this ruling apply in cases where a patient threatens to commit suicide, and how might the therapist's responsibility be met in such a case? What, if anything, should a therapist do when the target of violence is not clearly named—for example, when global threats are made? Would the duty-to-warn ruling hold up in other states? Or might deleterious effects on patient–therapist relationships outweigh any public benefit to be derived from the duty to warn? Responding to mounting pressures for

clarification, chiefly from professional mental health organizations, the California Supreme Court in 1976 issued a revised opinion called the “duty to warn doctrine.” In this decision the court ruled that the duty was to protect, rather than specifically to warn, the prospective victim, but it left vague the question of how this duty might be discharged—presumably in order to give practitioners latitude in dealing with danger to third parties. Meanwhile, however, numerous other lawsuits in other jurisdictions have been filed and adjudicated in inconsistent and confusing ways (Mills et al., 1987).

The many perplexing issues for practitioners left in the wake of Tarasoff were partly resolved, at least in California, by the legislature’s adoption in 1985 of a new state law essentially establishing that the duty to protect is discharged if the therapist makes “reasonable efforts” to inform potential victims and an appropriate law enforcement agency of the pending threat. The Tarasoff ruling was extended in 2004 (*Ewing v. Goldstein*, 2004) when the California Court of Appeals ruled that a communication from a patient’s family member constitutes a “patient communication” that can trigger the therapist’s duty to protect.

In other court jurisdictions, however, the inconsistent judicial fallout from Tarasoff has continued and has been a source of much anxiety and confusion among mental health professionals, many of whom continue to believe, on ethical and clinical grounds, that strict confidentiality is an absolute and inviolable trust. Some states—for example, Maryland, Texas, and Pennsylvania—have explicitly affirmed that position, abandoning Tarasoff altogether, while 23 states impose a duty to warn, although the criteria for this typically vary (Barbee et al., 2007). There has been considerable debate over the need and utility of the Tarasoff ruling, and some authorities have raised questions about its survivability as a law (Quattrocchi & Schopp, 2005).

Official professional ethics codes, such as that of the American Psychological Association (2002), normally compel compliance with relevant laws regardless of one’s personal predilections. Where the law is itself vague or equivocal, however, as it often is in this area, there is much room for individual interpretation (Kachigian & Felthous, 2004). Today there is considerable confusion among practitioners about their responsibility with regard to rules of their state with respect to Tarasoff ruling. A recent survey of clinicians found that 76 percent of clinicians failed to correctly identify their state’s duty-to-protect law from a multiple-choice list (Pabian et al., 2009). Therapists are at greater risk of a lawsuit for failing to deal with risk of danger posed by some clients (Caudill, 2009).

## The Insanity Defense

Some people who are being tried for murder use the **insanity defense**—also known as the **NGRI plea** (“not guilty by reason of insanity”)—in an attempt to escape the legally prescribed

consequences of their crimes (Chappell, 2010; Sadoff & Dattilo, 2011). These defendants claim that they were not legally responsible for their criminal acts. In technical legal terms, they invoke the ancient doctrine that their acts, while guilty ones (*actus rea*), lacked moral blameworthiness because they were not intentional since the defendants did not possess their full mental faculties at the time of the crime and did not “know what they were doing” (*mens rea*)—the underlying assumption being that “insanity” somehow precludes or absolves the harboring of a guilty intent. One of the most notorious uses of the not guilty by reason of insanity plea in American history was in the case of Jeffrey Dahmer, on trial for the murder, dismemberment, and cannibalization of 15 men in Milwaukee. In the Dahmer case, the planned insanity defense proved unsuccessful, which is the usual outcome (Steadman et al., 1993).

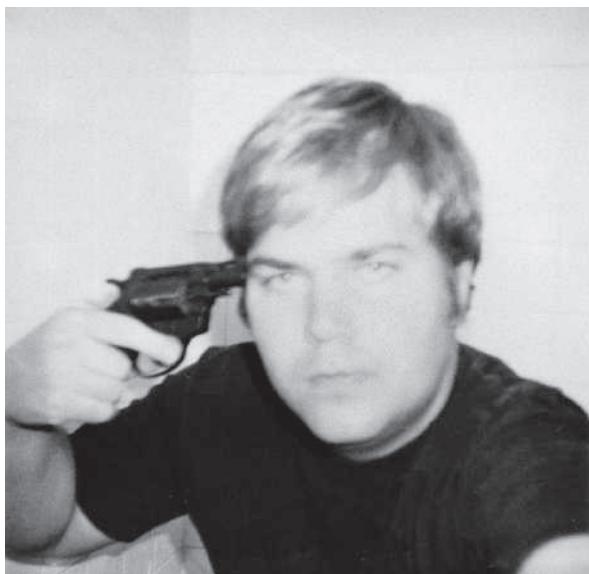

By contrast, attorneys for John Hinckley, who shot President Reagan and his press secretary, James Brady, in early 1981, successfully pleaded NGRI. (See the case study on p. 597.) The outcome of the Hinckley case was different in a number of important respects because the jury in this instance considered the defendant to be acting “outside of reason” and found him

Jeffrey Dahmer was torturing and drowning cats and dogs by age 7. He never heard voices or broke with reality. He tricked his victims into being handcuffed (they thought it was part of a sexual game) and then dripped acid into their flesh and skulls, rendering them zombies. Then he would engage them sexually and would occasionally cannibalize them. Dahmer was charged with and later convicted of murder after body parts of several young men were found in his apartment. While serving his time in prison, he was bludgeoned to death by a psychotic killer in 1994.

not guilty by reason of insanity. At trial in June 1982, Hinckley was acquitted on those grounds. This verdict immediately unleashed a storm of public protest and generated widespread, often hasty attempts to reform the law to make the NGRI defense a less attractive option to defendants and their attorneys. Hinckley himself was committed to the care of a federally operated, high-security mental hospital, to be involuntarily detained there until such time as his disorder remits sufficiently that his release would not constitute a danger to himself or others. He remains incarcerated; however, under a 1999 federal appeals court ruling, Hinckley has been able to take supervised day trips off hospital grounds, and most recently was allowed to spend several weeks at his mother's home. However, his "recovery" continues to be questioned. Psychiatric testimony (Associated Press, 2003) has indicated that Hinckley still suffers from the same narcissistic personality disorder that drove him to shoot Reagan and three others in 1981.

→ **Hinckley's Successful Insanity Plea** On March 30, 1981, in an apparent scheme to attract the attention of actress Jodie Foster, with whom he was obsessed, John Hinckley, Jr., shot six bullets at President Ronald Reagan in an assassination attempt. President Reagan was seriously injured, as was Press Secretary James Brady. At the end of his trial in 1982, Hinckley was found not guilty by reason of insanity. Since his trial, Hinckley has been confined to St. Elizabeth's Hospital in Washington, DC. After what seemed to be significant improvement in his mental health, Hinckley was allowed unsupervised visits in April 2000, but these visits were revoked when guards discovered a smuggled book on Jodie Foster in his room.

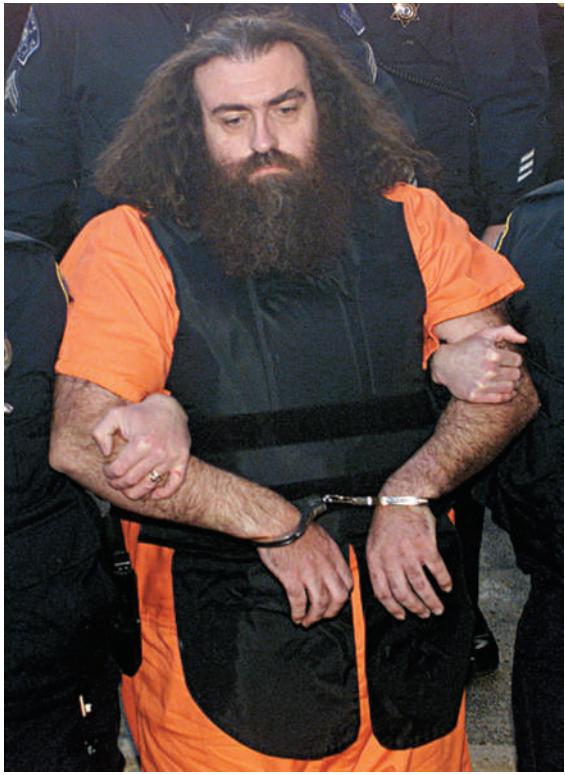

Releasing Hinckley from custody would almost certainly bring forth another public outcry demanding abolition or limitation of the insanity defense. This unfortunate public outrage at all insanity defense pleas results from a persistent failure of legal scholars to examine critically and rigorously the guilt-absolving insanity construct and the *mens rea* doctrine from which it derives.

In recent years the use of the NGRI defense in trials where the defendant's life is at stake has been surrounded by controversy, largely owing to the uproar created by the outcome of the Hinckley trial (Steadman et al., 1993). Some have contended that the objection to the insanity defense in capital crimes might reflect negative social attitudes toward the insane (Perlin, 1996). There has been some concern, especially in cases of high visibility, that guilty defendants may feign mental disorder and hence avoid criminal responsibility. Good defense attorneys are of course aware of this public cynicism, which is likely to be shared by juries. They attempt to counteract it in various ways, often by portraying their purportedly "insane at the time of the act" clients as having been themselves victims of heinous and traumatic acts at an earlier time in their lives. Some of them undoubtedly were victimized, but the strategy of creating sympathy while offering a plausible explanation for the "insane" act would have a compelling attraction in any case. On the other hand, the insanity defense is often not employed where it is appropriate, as it would have been, for example, in two high-visibility cases: those of John Salvi (the abortion clinic assassin) and Theodore Kaczynski (the Unabomber). Apparently neither defendant wanted his mental state to be a part of the proceedings. Severe delusional disorder is likely to have played a significant role in both of their crimes. (There have been notable efforts to fake the insanity defense to avoid punishment; see the following case study).

### → **Detected Faking of the Insanity Defense**

Michael McDermott testified that Michael the Archangel had sent him on a mission to prevent the Holocaust when he gunned down seven coworkers on December 26, 2000. McDermott also stated that he believed he was soulless and that by killing he would earn a soul. McDermott claimed to have been raped by a neighbor when he was a young boy and had a history of paranoia and suicide attempts. Despite this claim of insanity, a jury found McDermott guilty in the shooting deaths of his seven coworkers. The prosecution argued that McDermott was motivated to kill because his employer was about to deduct from his wages back taxes owed to the IRS. Evidence seized from his computer showed that McDermott had researched how to fake being mentally ill. McDermott is currently serving seven consecutive life sentences for his crimes.

In some cases in some states, individuals with psychosis who fail to meet the standards set for the NGRI plea and are convicted of murder can receive the death sentence even though they were actually psychologically disturbed at the time of the crime and remain so as the execution approaches. An appeals process can be effective at showing that there may be extenuating circumstances that warrant softening the sentence on grounds that the death penalty would be cruel and unusual punishment because of the person's severe mental health problems or mental retardation. Pirelli and colleagues (2011) conducted an analysis of the results of 68 studies that had been published between 1967 and 2008 that compared competent and incompetent defendants on a number of variables. The most robust findings were that defendants who were diagnosed with a psychotic disorder were about eight times more likely to be found incompetent than defendants without a psychotic disorder diagnosis. The likelihood of being found incompetent was approximately double for unemployed defendants as compared to employed defendants. Defendants who had a previous psychiatric hospitalization were about twice more likely to be found not guilty by reason of insanity than those without a hospitalization history.

There have been cases in which a failed use of the NGRI plea led to greater punishment. In one recent case (*United States v. Batista*, 2007) a defendant in a murder trial intentionally feigned mental illness in an effort to avoid prison. His charade was discovered and he actually received an enhanced

sentence after the trial because of his abuse of mental health protections in the legal system.

Despite some features that make it an appealing option to consider, especially when the undisputed facts are strongly aligned against the defendant, the NGRI defense has actually been employed quite rarely—in less than 2 percent of capital cases in the United States over time (Lymburner & Roesch, 1999; Steadman et al., 1993). Studies have confirmed, however, that in some jurisdictions, persons acquitted of crimes by reason of insanity spend less time, on the whole, in a psychiatric hospital than persons who are convicted of crimes spend in prison (Lymburner & Roesch, 1999) even though the determination that they are no longer dangerous might be difficult to ascertain. In addition, states differ widely in the amount of time that persons found not guilty by reason of insanity are actually confined. For example, one study by Callahan and Silver (1998) reported that in the states of Ohio and Maryland nearly all persons acquitted as NGRI have been released within 5 years, whereas in Connecticut and New York conditional release has been much more difficult to obtain. The rearrest rates for freed NGRI claimants vary, with some studies reporting rates as high as 50 percent (Callahan & Silver, 1998; Wiederanders et al., 1997). Monson and colleagues (2001) conducted a follow-up of 125 NGRI acquittees and found a similarly high rearrest rate. These investigators reported that persons discharged to live with their family of origin or to live alone or in semi-independent living were more likely to maintain their conditional release and not reoffend. These investigators also reported that such factors as minority status, comorbid substance abuse, and prior criminal history were associated with return to custody after release. One recent study in which an active community treatment program was implemented reported low rearrest rates (1.4 percent) and moderate rehospitalization rates (14 percent) (Parker, 2004).

Up to this point in the discussion, we have used the term *insanity defense* loosely. We must now become more attentive to the many precise legal nuances involved. Established precedents that define the insanity defense are as follows:

1. *The M'Naghten Rule (1843)*. Under this ruling, which is often referred to as the “knowing right from wrong” rule, people are assumed to be sane unless it can be proved that at the time of committing the act they were laboring under such a defect of reason (from a disease of the mind) that they did not know the nature and quality of the act they were doing—or, if they did know they were committing the act, they did not know that what they were doing was wrong.
2. *The Irresistible Impulse Rule (1887)*. A second precedent in the NGRI defense is the doctrine of the “irresistible impulse.” This view holds that accused persons might not be responsible for their acts—even when they knew that what they were doing was wrong (according to the M'Naghten rule)—if they had lost the power to choose between right

- and wrong. That is, they could not avoid doing the act in question because they were compelled beyond their will to commit the act.
3. *The Durham Rule*. In 1954, Judge David Bazelon, in a decision of the U.S. Court of Appeals, broadened the insanity defense further. Bazelon did not believe that the previous precedents allowed for a sufficient application of established scientific knowledge of mental illness and proposed a test that would be based on this knowledge. Under this rule, which is often referred to as the “product test,” the accused is not criminally responsible if her or his unlawful act was the product of mental disease or mental defect.
  4. *The American Law Institute (ALI) Standard (1962)*. Often referred to as the “substantial capacity test” for insanity, this test combines the cognitive aspect of M’Naghten with the volitional focus of irresistible impulse in holding that the perpetrator is not legally responsible if at the time of the act he or she, owing to mental disease or defect, lacked “substantial capacity” either to appreciate the act’s criminal character or to conform his or her behavior to the law’s requirements.
  5. *The Federal Insanity Defense Reform ACT (IDRA)*. Adopted by Congress in 1984 as the standard for the insanity defense to be applied in all federal jurisdictions, this act abolished the volitional element of the ALI standard and modified the cognitive standard to read “unable to appreciate,” thus bringing the definition quite close to M’Naghten. IDRA also specified that the mental disorder involved must be a severe one and shifted the burden of proof from the prosecution to the defense. That is, the defense must clearly and convincingly establish the defendant’s insanity, in contrast to the prior requirement that the prosecution clearly and convincingly demonstrate the defendant to have been sane when the prohibited act was committed.

This shifting of the burden of proof for the insanity defense, by the way, had been instituted by many states in the wake of the Hinckley acquittal. The intent of this reform was to discourage use of the insanity defense, and it proved quite effective in altering litigation practices in the intended direction (Steadman et al., 1993).

At the present time, most states and the District of Columbia subscribe to a version of either the ALI or the more restrictive M’Naghten standard. New York is a special case. It uses a version of M’Naghten to define insanity, with the burden of proof on the defense, but an elaborate procedural code has been enacted to promote fairness in outcomes while ensuring lengthy and restrictive hospital commitment for defendants judged to be dangerous; this approach appears to have worked well (Steadman et al., 1993). In some jurisdictions, when an insanity plea is filed, the case is submitted for pretrial screening, which includes a psychiatric evaluation, review of records, and appraisal of criminal responsibility. In one study of 190 defendants who entered a plea of not

criminally responsible, the following outcomes were obtained: 105 were judged to be criminally responsible, charges against 34 were dropped, and 8 defendants were agreed by both the prosecution and the defense to be insane and not responsible. A total of 134 withdrew their insanity pleas (Janofsky et al., 1996). The insanity defense was noted in this study to be somewhat of a “rich man’s defense” in that such cases involved private attorneys rather than public defenders.

Silver (1995) found that the successful use of the NGRI defense varied widely among states. In addition, Silver reports that the length of confinement was related more to the judged seriousness of the crime than to whether the person was employing the NGRI defense. One study (Cirinclone et al., 1995) found that an NGRI plea was most likely to be successful if one or more of the following factors were present:

- A diagnosed mental disorder, particularly a major mental disorder
- A female defendant
- The violent crime was other than murder
- There had been prior mental hospitalizations

Three states—Idaho, Montana, and Utah—have entirely abolished the attribution of insanity as an acceptable defense for wrongdoing—a somewhat more harsh or severe solution that compensates in clarity for what some feel it lacks in compassion. As expected, with the disappearance of the insanity acquittals in Montana, there was a corresponding rise in the use of the “incompetent to stand trial” plea (see the following section), in which the charges were actually dismissed, largely negating the desired result (more effective prosecution) of doing away with the insanity defense (Callahan et al., 1995).

How, then, is guilt or innocence determined? Many authorities believe that the insanity defense sets the courts an impossible task—determining guilt or innocence by reason of insanity on the basis of psychiatric testimony. In some cases, conflicting testimony has resulted because both the prosecution and the defense have their own panel of expert psychiatric witnesses, who are in complete disagreement (see discussion by Lareau, 2007).

Finally, states have adopted the optional plea and verdict of **guilty but mentally ill (GBMI)**. In these cases, a defendant may be sentenced but placed in a treatment facility rather than in a prison. This two-part judgment serves to prevent the type of situation in which a person commits a murder, is found not guilty by reason of insanity, is turned over to a mental health facility, is found to be rational and in no further need of treatment by the hospital staff, and is unconditionally released to the community after only a minimal period of confinement. Under the two-part decision, such a person would remain in the custody of the correctional department until the full sentence has been served. Marvit (1981) has suggested that this approach might “realistically balance the interest of the mentally ill offender’s rights and the community’s need to control criminal behavior” (p. 23).

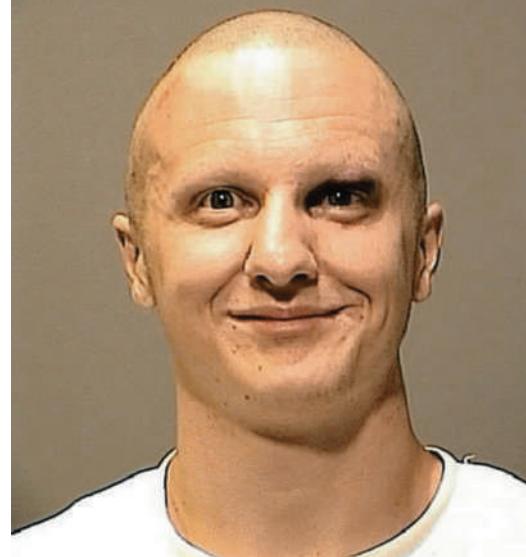

However, others have argued that the GBMI defense is confusing to jurors and should be eliminated (Melville & Naimark, 2002). Interestingly, in Georgia, one of the states adopting this option, GBMI defendants receive longer sentences and longer periods of confinement than those who plead NGRI and lose. Overall, outcomes from the use of the GBMI standard, which is often employed in a plea-bargaining strategy, have been disappointing (Steadman et al., 1993).

## Competence to Stand Trial

There is, in English common law, a principle that a person charged with a crime must be **competent to stand trial** (Stafford & Sadoff, 2011). If someone is charged with a crime and is considered to be unable to understand the trial proceedings as a result of intellectual deficit or mental health problems, they can be hospitalized until their mental state is judged to be improved sufficiently for them to be competent to stand trial. Several factors can influence a court decision that the defendant in the case is not competent to stand trial. Both cognitive abilities (such as capability in making decisions, having a working memory, being able to attend to proceedings, and being able to process events successfully) and psychiatric symptoms (psychoticism, withdrawal, depression, hostility) can be crucial factors in a person being able to stand trial.

In May 2011, a federal court judge ruled that Jared Loughner was not competent to stand trial for shooting Congresswoman Gabrielle Giffords and killing six others (Harris, 2011). This court decision was based upon the opinion of expert witness psychiatrists from both the defense and prosecution who examined Loughner. The defendant was held in a federal hospital for prisoners in Springfield, Illinois, until it was determined that he was able to stand trial. In August, 2012, after treatment for mental health problems, Loughner was judged to be mentally able to stand trial. He pleaded guilty to the criminal charges (Santos, 2012). In exchange for his guilty plea, the government agreed not to seek the death penalty.

Research has underscored the role of cognitive deficits or mental health problems in determining a defendant's competence to stand trial. Ryba and Zapf (2011) recently reported that cognitive abilities accounted for higher scores for all three competence-related abilities than did the psychiatric symptoms, although there was an additive effect when these groups of variables were considered collectively. In a recent evaluation of the published literature on competence to stand trial, Pirelli and colleagues (2011) concluded that defendants who had been diagnosed as having a psychotic disorder were approximately eight times more likely to be found incompetent than defendants without a psychotic disorder diagnosis. In addition, they found that defendants who had a previous psychiatric hospitalization, as compared with those never hospitalized, or had been unemployed, as compared to employed defendants, were more likely to be determined as incompetent to stand trial.

Jared Loughner, who killed six people and severely wounded congresswoman Gabrielle Giffords in May 2011, was determined to be not competent to stand trial as a result of his mental disorder. In August, 2012, after treatment for mental health problems, Loughner was judged to be mentally able to stand trial. He pleaded guilty to the criminal charges. In exchange for his guilty plea, the government agreed not to seek the death penalty.

## Does Having Mental Health Problems Result in Convicted Felons Being Returned to Prison After Being Released?

Given that many individuals with severe mental health problems are sentenced to prison terms and receive no mental health treatment while in prison, are they able to adjust to society once they are released? Are psychologically disturbed people who receive prison terms more vulnerable to maladjustment when they are freed from prison? Questions have been raised about the impact of mental health problems on the ability of convicted prisoners to successfully return to society if they are paroled, serve out their terms, or are released because they are believed to no longer be a threat to themselves or others in the case of a successful NGRI decision. Cloyes and colleagues (2010) evaluated parole violation rates among inmates who had significant mental health problems versus those who did not and found that there was a significant difference in return rates and community tenure for offenders with significant mental illness compared to inmates without mental health problems. They found that 23 percent of their sample of inmates with significant mental health problems returned to prison sooner than those without mental health problems.

Persons who have been charged with a crime but found not guilty by reason of insanity can be released from confinement if or when they are no longer judged to be of a danger to themselves or others. Although return to the community is not guaranteed for persons who are incarcerated after an NGRI plea, they can be released, and the state can determine explicit conditions for release, for example, follow-up mental health treatment, substance abuse treatment, frequent monitoring, and so forth. Some research has suggested that with conditional treatment and careful

monitoring many people are able to return to society. However, the efficacy of treatment or careful monitoring has shown mixed results with many people being returned to confinement. Vitacco and colleagues (2008) found that 33.8 percent of inmates were returned to prison, with the majority of these being returned for failure to comply with treatment. When the amount of monitoring was taken into consideration they found that those who were placed on higher restrictions and received closer monitoring had lower rates of return to confinement. Hiday and Burns (2010), in their evaluation of the role of mental illness in the criminal justice system, concluded although the arrest rates and incarceration rates were higher for mentally ill persons than the general population, most people with mental illness are not violent and only a small percentage of the population become violent.

### in review

- What conditions must be met before an individual can be involuntarily committed to a mental institution? Describe the legal process that follows.
- What are the implications of the Tarasoff decision for practicing clinicians?
- What is the insanity (NGRI) defense in criminal cases?
- What is the Federal Insanity Defense Reform Act? How does it differ from the M'Naghten rule?

## Organized Efforts for Mental Health

Public awareness of the magnitude of contemporary mental health problems and the interest of government, professional, and lay organizations have stimulated the development of programs directed at better understanding, more effective treatment, and long-range prevention. Efforts to improve mental health are apparent not only in our society but also in many other countries, and they involve international as well as national and local organizations and approaches.

### U.S. Efforts for Mental Health

In the United States in the eighteenth and nineteenth centuries, dealing with mental disorders was primarily the responsibility of state and local agencies. During World War II, however, the extent of mental disorders in the United States was brought to public attention when a large number of young men—two out of every seven recruits—were rejected for military service for psychiatric reasons. This discovery led to a variety of organized measures for taking care of people with mental illness.

**THE FEDERAL GOVERNMENT AND MENTAL HEALTH** In 1946, aware of the need for more research, training, and services in the field of mental health, Congress passed its first comprehensive mental health bill, the National Mental Health Act. In that same year, the NIMH was formed in Washington, DC. The agency was to serve as a central research and training center and as headquarters for the administration of a grant-in-aid program

designed to foster research and training elsewhere in the nation and to help state and local communities expand and improve their own mental health services. Congress authorized the Institute to provide mental health project grants for experimental studies, pilot projects, surveys, and general research. Today the NIMH is a separate institute under the National Institutes of Health within the Department of Health and Human Services (NIMH, 2001).

The NIMH (1) conducts and supports research on the biological, psychosocial, and sociocultural aspects of mental disorders; (2) supports the training of professional and paraprofessional personnel in the mental health field; (3) helps communities plan, establish, and maintain more effective mental health programs; and (4) provides information on mental health to the public and the scientific community. Two companion institutes—the National Institute on Alcohol Abuse and Alcoholism (NIAAA) and the National Institute on Drug Abuse (NIDA)—perform comparable functions in these more specialized fields.

Although the federal government provides leadership and financial aid, the states and local organizations actually plan and run most NIMH programs. Most state and local governments, however, have not been able to fund programs and facilities because of cuts in federal support. As a result, many programs devoted to mental health training, research, and services have been greatly reduced or abandoned even as the need for them has increased. There is considerable uncertainty about the extent to which mental health problems will be included in forthcoming revisions of national health care policy and about the forms any such inclusion might take.

### PROFESSIONAL ORGANIZATIONS AND MENTAL

**HEALTH** A number of national professional organizations exist in the mental health field. These include the American Psychological Association (APA), the American Psychological Society (APS), the American Psychiatric Association (APA), the American Medical Association (AMA), the Association for the Advancement of Behavior Therapy (AABT), the American Association for Correctional and Forensic Psychology (AACFP), and the National Association for Social Work (NASW).

A key function of professional organizations is the application of insights and methods to contemporary social problems—for example, in lobbying national and local government agencies to provide more services for underserved populations. Professional mental health organizations are in a unique position to serve as consultants on mental health problems and programs.

Another important function of these organizations is to set and maintain high professional and ethical standards within their specific areas. This function may include (1) establishing and reviewing training qualifications for professional and paraprofessional personnel; (2) setting standards and procedures for the accreditation of undergraduate and graduate training programs;

(3) setting standards for the accreditation of clinics, hospitals, or other service operations and carrying out inspections to see that the standards are followed; and (4) investigating reported cases of unethical or unprofessional conduct and taking disciplinary action when necessary.

**THE ROLE OF VOLUNTEER ORGANIZATIONS AND AGENCIES** Although professional mental health personnel and organizations can give expert technical advice with regard to mental health needs and programs, informed citizens are essential in planning and implementing these programs. In fact, it is primarily concerned nonprofessionals who have blazed the trails in the mental health field.

Prominent among the many volunteer mental health agencies is the National Mental Health Association (NMHA). This organization was founded in 1909 by Clifford Beers as the National Association for Mental Health and has subsequently expanded through various mergers. The NMHA works for the improvement of services in community clinics and mental hospitals; it helps recruit, train, and place volunteers for service in treatment and aftercare programs; and it works for enlightened mental health legislation and for the provision of needed facilities and personnel. It also offers special educational programs aimed at fostering positive mental health and helping people understand mental disorders. In addition, the National Mental Health Association has been actively involved in many court decisions affecting patient rights (1997). In several cases, the organization has sponsored litigation or served as *amicus curiae* (friend of the court) in efforts to establish the rights of mental patients to treatment, to freedom from custodial confinement, to freedom to live in the community, and to protection of their confidentiality.

The ARC, the largest national community-based organization advocating for people with intellectual and developmental disabilities, works to reduce the incidence of mental retardation, to seek community and residential treatment centers and services for people with mental retardation, and to carry on a program of education aimed at better public understanding of mental retardation and greater support for legislation. The ARC also fosters scientific research into mental retardation, recruitment and training of volunteer workers, and programs of community action.

These and other volunteer health organizations such as Alcoholics Anonymous and the National Alliance for the Mentally Ill (NAMI) need the backing of a wide constituency of knowledgeable and involved citizens in order to succeed.

#### MENTAL HEALTH RESOURCES IN PRIVATE INDUSTRY

Personal problems—such as marital distress or other family problems, alcohol or drug abuse, financial difficulties, and job-related stress—can adversely affect employee morale and performance. Sheid (2010) pointed out that employees' disagreement with organizational priorities can also lead to employee burnout,

emotional exhaustion, and depersonalization, which can contribute to adjustment problems that require mental health services. Moreover, violence in the workplace has grown to be a common occurrence in our society (Kelloway et al., 2006) and often requires that employers take special steps to limit mental-health-related aggression.

Psychological difficulties among employees may result in numerous problems such as absenteeism, accident proneness, poor productivity, and high job turnover. The National Institute for Occupational Safety and Health (NIOSH) recognizes psychological disorders as one of the 10 leading work-related health problems, and work-related mental health risk factors may be increasing with changes in the economy, in technology, and in demographic factors in the workforce (Sauter et al., 1990). Research has shown, however, that persons with severe mental health problems can be integrated into the workplace if a supportive employment model is used to assist their involvement (Bond et al., 2007). Since the passage of the Americans with Disabilities Act, people with psychiatric problems cannot be discriminated against in the workplace. Employers are encouraged to alter the workplace as needed to accommodate the needs of persons with mental illness. Although employers often object that it is too costly to hire psychiatrically impaired persons, great benefits for society can result from integrating into productive jobs people who have disabilities but who also have appropriate skills (Kramer, 1998).

A great deal more research is needed to identify specific mental health risk factors in work situations. We already know (e.g., Rosenstock et al., 2005) that serious, unrecognized problems may exist in the many areas of job design and conditions of work:

- **Workload and Pace.** The critical factor here appears to be the degree of control the worker has over the pace of work rather than output demand. Machine-paced assembly work may be particularly hazardous to mental health.
- **Work Schedule.** Rotating shifts and night work have been associated with elevated risk for psychological difficulties.
- **Role Stressors.** Role ambiguity (such as uncertainty about who has responsibility for what), said to be common in many work situations, has a negative impact on mental and physical health, as does role conflict (incompatible role demands).
- **Career Security Factors.** Feelings of insecurity related to issues such as job future or obsolescence, career development, and encouragement of early retirement adversely affect mental and physical health.
- **Interpersonal Relations.** Poor or unsupportive relationships among work colleagues significantly increase the risk of untoward psychological reactions.
- **Job Content.** Poor mental health has been associated with work assignments involving fragmented, narrow, unvarying

tasks that allow for little creativity and give the worker little sense of having contributed to the ultimate product.

Many corporations have long recognized the importance of worker mental health and of enhancing mental health-promoting factors in the workplace, yet only recently have many of them acted on this knowledge. Today many companies have expanded their “obligations” to employees to include numerous psychological services. Employee assistance programs (EAPs) are means through which larger corporations can actively provide mental health services to employees and their family members (Finkel & Ryan, 2007; Harlow, 2007).

## International Efforts for Mental Health

Mental health is a major issue not only in the United States but also in the rest of the world. Indeed, many of the problems in this country with regard to the treatment of mental disorders are greatly magnified in poorer countries and countries with repressive governments. The severity of the world mental health problem is reflected in the World Health Organization’s estimate that mental disorders affect more than 200 million people worldwide, partly because of the significant world refugee crisis (de Jong, 2002; Watters & Ingleby, 2004). Recognition of this great problem served to bring about the formation of several international organizations at the end of World War II. Here we will briefly discuss the World Health Organization (WHO) (2010) and the World Federation for Mental Health (WFMH).

**THE WORLD HEALTH ORGANIZATION** The World Health Organization (2001) has always been keenly aware of the close interrelationships among biological, psychosocial, and sociocultural factors. Examples include the influence of rapid change and social disruption on both physical and mental health; the impossibility of major progress toward mental health in societies where a large proportion of the population suffers from malnutrition, parasites, and disease; and the frequent psychological and cultural barriers to successful programs in family planning and public health (Rutz, 2001).

Formed after World War II as part of the United Nations system, WHO’s earliest focus was on physical diseases; it has helped make dramatic progress toward the conquest of such ancient scourges as smallpox and malaria. Over the years, mental health, too, has become an increasing concern among the member countries. WHO’s goals are to integrate mental health resources to deal with the broad problems of overall health and socioeconomic development that many member countries face (World Health Organization, 2010).

Another important contribution of WHO has been its International Classification of Diseases (ICD), which enables clinicians and researchers in different countries to use a uniform set of diagnostic categories. As discussed in Chapter 4, the American Psychiatric Association’s diagnostic classification system has been coordinated with the

WHO’s ICD-10 classification (Sartorius et al., 1993). Currently ICD-10 is undergoing revision and is slated for publication in 2015.

**THE WORLD FEDERATION FOR MENTAL HEALTH** The World Federation for Mental Health was established in 1948 as an international congress of nongovernmental organizations and individuals concerned with mental health. Its purpose is to promote international cooperation among governmental and nongovernmental mental health agencies, and its membership now extends to more than 50 countries (Brody, 2004). The federation has been granted consultative status by WHO, and it assists the UN agencies by collecting information on mental health conditions all over the world (World Health Organization, 2007).

The last century witnessed an amazing openness and a lowering of previously impassable barriers between nations. Along with this increased interchange of ideas and cooperation, we expect to see a broader mental health collaboration. It is vital that greater international cooperation in the sciences and in health planning continue, along with more sharing of information and views on mental health.

- What is the NMHA, and how does it contribute to improvement in mental health services?
- What have been the major contributions of WHO in improving services in mental health?

## Challenges for the Future

Even though international cooperation in efforts to understand and enhance mental health is encouraging, the media confront us daily with the stark truth that we have a long way to go before our dreams of a better world are realized. Many people question whether the United States or any other technologically advanced nation can achieve improvements in mental health for the majority of its citizens in our time. Racism, poverty, youth violence, terrorism, the uprooting of developing world populations, and other social problems that contribute to mental disorder sometimes seem insurmountable.

Other events in the rest of the world affect us also, both directly and indirectly. Worldwide economic instability and shortages and the possibility of the destruction of our planet’s life ecology breed widespread anxiety about the future. The vast resources we have spent on military programs over the past half century to protect against perceived threats have absorbed funds and energy that otherwise might have been devoted to meeting human and social needs here and elsewhere in the world. The limited resources we are now willing to allocate to mental

health problems prevent our solving major problems resulting from drug and alcohol abuse, homelessness, broken families, and squalid living conditions.

## The Need for Planning

The Institute of Medicine (2006) recently reported that sweeping quality improvements are needed in the U.S. mental health care system. The report noted that only 20 percent of people with substance abuse or dependency and only 40 percent of people with serious mental illness actually receive treatment for their problems. If mental health problems are going to be reduced or eliminated, it is imperative that more effective planning be done at community, national, and international levels. Many challenges must be met if we are to create a better world for ourselves and future generations. Without slackening our efforts to meet needs at home, we will probably find it essential to participate more broadly in international measures aimed at reducing group tensions and promoting mental health and a better world for people everywhere. At the same time, we can expect that the measures we undertake to reduce international conflict and improve the general condition of humankind will make a significant contribution to our own nation's social progress and mental health. Both kinds of measures will require understanding and moral commitment from concerned citizens.

Within our own country and the rest of the industrialized world, progress in prolonging life has brought with it burgeoning problems in the prevalence of disorders associated with advanced age, particularly in the area of conditions such as Alzheimer's disease. Judging by the numbers of people already affected, it is not certain at this time that we will find the means of eradicating or arresting this threat before it has overwhelmed us. Planning and preparation would seem our only rational hope of forestalling a potential disaster of unprecedented magnitude; we need to make a beginning.

## The Individual's Contribution

History provides clear examples of individuals whose efforts were instrumental in changing the way we think about mental health problems. Recall that Pinel took off the chains, Dorothea Dix initiated a movement to improve the conditions of asylums, and Clifford Beers inspired the modern mental health movement with his autobiographical account of his own experience with mental illness. Who will lead the next revolution in mental health is anyone's guess. What is clear is that a great deal can be accomplished by individual effort.

When students become aware of the tremendous scope of the mental health problem both nationally and internationally and of the woefully inadequate facilities for coping with it, they often ask, "What can I do?" Thus it seems appropriate to suggest a few of the lines of action that interested students can take.

Many opportunities in mental health work are open to trained personnel, both professional and paraprofessional. Social work, clinical psychology, psychiatry, and other mental health occupations are personally fulfilling. In addition, many occupations, ranging from law enforcement to teaching and the ministry, can and do play key roles in the mental health and well-being of many people. Training in all these fields usually offers individuals opportunities to work in community clinics and related facilities, to gain experience in understanding the needs and problems of people in distress, and to become familiar with community resources.

Citizens can find many ways to be of direct service if they are familiar with national and international resources and programs and if they invest the effort necessary to learn about their community's special needs and problems. Whatever their roles in life—student, teacher, police officer, lawyer, homemaker, business executive, or trade unionist—their interests are directly at stake, for although the mental health of a nation may be manifested in many ways—in its purposes, courage, moral responsibility, scientific and cultural achievements, and quality of daily life—its health and resources derive ultimately from the individuals within it. In a participatory democracy, it is they who plan and implement the nation's goals.

Besides accepting some measure of responsibility for the mental health of others through the quality of one's own interpersonal relationships, there are several other constructive courses of action open to each citizen. These include (1) serving as a volunteer in a mental hospital, community mental health center, or service organization; (2) supporting realistic measures for ensuring comprehensive health services for all age groups; and (3) working toward improved public education, responsible government, the alleviation of prejudice, and the establishment of a more sane and harmonious world.

All of us are concerned with mental health for personal as well as altruistic reasons, for we want to overcome the nagging problems of contemporary living and find our share of happiness in a meaningful and fulfilling life. To do so, we may sometimes need the courage to admit that our problems are too much for us. When existence seems futile or the going becomes too difficult, it may help to remind ourselves of the following basic facts, which have been emphasized throughout this text: From time to time, each of us has serious difficulties in coping with the problems of living. During such crises, we may need psychological and related assistance. Such difficulties are not a disgrace; they can happen to anyone if the stress is severe enough. The early detection and treatment of maladaptive behavior are of great importance in preventing the development of more severe or chronic conditions. Preventive measures—universal, selected, and indicated—are the most effective long-range approach to the solution of both individual and group mental health problems.

## in review

- What are national and international programs aimed at providing solutions to mental health problems?
- Describe several ways in which individuals can contribute to the advancement of mental health.

- After reading the Unresolved Issues feature, discuss the controversy over the effects of managed health care on the treatment and prevention of mental illness.

## UNRESOLVED issues

### The HMOs and Mental Health Care

A **health maintenance organization (HMO)** is a business or management corporation that provides a form of health care coverage in the United States that is fulfilled through contracts with hospitals, doctors, and other health providers. Unlike traditional health insurance, the health care is made available through agreements with health professionals to treat more patients and in return usually to provide services at a discount. This business arrangement allows the HMO to charge a lower monthly premium, which is an advantage over indemnity insurance, provided that its members are willing to abide by the additional restrictions (Frank et al., 2004). The HMO serves as a “gatekeeper” between the patient and the health provider. This arrangement has clearly affected access to mental health care in the United States in that business decisions often take precedence over treatment need. Treatment, when it is allowed by the HMO, tends to be limited in both duration and quality. The disillusionment with HMOs in the 1990s led to the development of alternative health funding or **managed health care** products. Several programs emerged that were less restrictive, giving patients more options in treatment choices. However, this has done little to reduce the anger toward managed care, and there is still a need for an alternative approach to providing more effective health care (Kominski & Melnick, 2007).

Mental health treatment is valuable for preventing as well as easing mental disorders. Yet mental health treatment has been less readily available than physical health treatment, and its cost has been less often reimbursed. HMO programs establish a treatment staff through systems of professionals, referred to as “panels,” who are considered to have efficacy and efficiency in providing a wide range of services. Some HMOs—referred to as “open-panel systems”—have allowed patients some choice of health providers and allow any qualified professional in the community to participate. However, most are closed-panel systems, which limit the selection of available providers. The benefits vary from plan to plan and usually include limits on the problems covered or on the maximum amount of care provided or services available. To keep costs low, some HMOs have operated according to a system of “capitation,” a method of payment in which a health care provider contracts to deliver all the health care services required by a population for a fixed cost or

flat fee per enrolled member or employee (Sanchez & Turner, 2003). The HMO thus assumes some risk, but capitation allows for great profit if the subscriber’s fees can be set higher than the cost of health services.

The need for comprehensive and effective mental health treatment is great. About one in four adults, or about 26.2 percent of Americans ages 18 and older, suffer from a diagnosable mental disorder in a given year (Kessler, Chiu et al., 2005). It has also been estimated that 70 percent of adults and 80 percent of children who require mental health services do not receive treatment, primarily because of discriminatory insurance practices (Sussman, 2009). Many people with mental health problems seek medical treatment for their psychological symptoms, thereby increasing the cost of medical care. In one study, Hunkeler and colleagues (2003) point out a strong association between psychiatric symptoms, impaired functioning, and general medical care costs. About 75 percent of patients with depression seek treatment for physical symptoms (Unutzer et al., 2006). Moreover, patients with other psychiatric conditions such as PTSD also present with physical symptoms (see Chapter 5). Health care costs in general are reportedly rising, and the presence of any psychiatric diagnosis increases the health care cost.

In response to these mental health needs, health care administrators have created a diverse array of programs in an attempt to provide services at a cost that the system can afford.

**Mental Health Treatment—Who Decides What Kind and How Long?** In one common approach to reducing health care costs, the managed care agency negotiates a reduced price directly with the health service provider. The provider then bills the health service organization for the time spent, and the HMO can obtain “low-bid” services from the health professional. This approach poses little financial risk to the provider. As might be apparent even to the casual observer of managed care systems, the procedures for determining the amount of money paid to providers have frequently been a problem for mental health professionals—psychologists and psychiatrists (Resnick et al., 1994). The HMO representative or “gatekeeper” to reimbursement, often a medical generalist untrained in either psychiatric disorders or psychosocial interventions, controls access to

therapy and sometimes the type of treatment to be provided (Resnick et al., 1994). In some systems of managed care, the gatekeeper might be a business professional who, in the view of the health service provider, is determining treatment by requiring that the clinician periodically justify treatment decisions to someone who has little or no background in mental health. Conflicts can develop in such situations, and patients may be deprived of appropriate and necessary care (Resnick et al., 1994). HMOs that are overly cost conscious have come to be viewed by some practitioners as simply tending to business and neglecting patients' needs (Karon, 1995).

### TIME-LIMITED THERAPY

The mental health services typically covered by HMOs have favored less expensive and less labor-intensive approaches. As might be expected, pharmacotherapy is the most frequent mental health treatment provided by HMOs (Frank et al., 2005)—a situation that some research suggests actually reduces health care costs. Other research has shown that cost-containment measures that are intended to reduce drug costs by restricting access to medications can—and often do—wind up increasing total health care costs (Horn, 2003). Further, psychosocial interventions such as individual psychotherapy are discouraged or limited to relatively few sessions. Long-term psychotherapy has been substantially reduced for all but a small number of wealthy private clients (Lazarus, 1996). On the other hand, group psychotherapy is often promoted and encouraged because it is often thought of as cost effective. Many managed care corporations have adopted the model of providing focused, brief, intermittent mental health treatment for most problems. Many forms of behavioral health services such as counseling programs to teach patients how to manage their illness, how to use relaxation response methods, or how to reduce unhealthy behaviors such as smoking or drinking have been implemented to improve health care while reducing costs (Blount et al., 2007).

Patients who require longer treatments or need inpatient hospitalization are typically not well served in managed care organizations. In fact, long-term mental health treatment is usually discouraged by managed health care organizations. For example, most managed care groups approve only short inpatient stays (less than 10 days) and four to six sessions of outpatient mental health treatment at a time. Few if any of the decisions regarding the amount and type of services provided are directly guided by empirical criteria. Decisions whether to cover 8 or 20 sessions of psychotherapy, for example, are arbitrary and often seem capricious to both practitioner and patient (Harwood et al., 1997).

A clear divide has developed between health service providers and managers. Available services are often governed more by financial concerns than by a mental health professional's

judgment. Critics of managed care argue that there is no convincing evidence that current efforts are actually controlling costs (Harwood et al., 1997) and that there is no scientific support for the limited-benefit options being exercised. Some researchers have pointed out that the administrative costs for managed care centers (including high salaries for HMO executives) are exorbitant. Gabbard (1994), for example, estimated that about one-fourth of the health care expenditures in the United States go for managed care administration.

The general lack of mental health care support has clearly created controversy in the field of psychotherapy, and the mental health field is being altered by economic considerations. Sanchez and Turner (2003) provide an overview of the impact of managed care on psychological practice and the provision of mental health services to clients in need. They point out that the economics of the mental health care system have greatly impacted the practice of behavioral health care by limiting treatment to time-limited and symptom-focused services. The most frequently cited problems include the remarkable shift of treatment decision-making power from the behavioral health care provider to policymakers. In addition, practitioners have experienced a reduction in income, which has likely impacted quality of care because less-well-trained (non-doctoral-level) therapists have taken on more responsibility and offer short-term therapeutic approaches instead of needed long-term therapy. The nature of the mental health professions is changing, and there is a growing discontent with health maintenance organizations in society today (Mechanic, 2004). Both clients and mental health professionals have long experienced a breakdown in trust of the managed care system (Shore, 2007).

Although discrimination against mental health care compared with medical or surgical treatment has long affected the provision of mental health treatment in the United States, recent attempts to provide parity for mental health care might bring about some much needed changes. A new law, referred to as the Mental Health Parity Act (MHPA) of 2008, or the Paul Wellstone, Pete Domenici Parity Act Prohibits Discrimination, requires that the annual or lifetime dollar caps on mental health benefits be no lower than the dollar limits for medical and surgical benefits (Sussman, 2009). The parity act prohibits group health insurance plans, typically provided by employers, from restricting access to care by limiting benefits and requiring higher patient costs than those that apply to general medical or surgical benefits.

It is difficult at this point to venture as to what impact the new health care plan and the parity bill will have on improving the quality and availability of mental health care in the United States. Any solutions to the long-standing problems are likely to be complex and require substantial change to the present system.

## summary

### 17.1 What is the importance of prevention in mental health care?

- Many mental health professionals are trying not only to cure mental health problems but also to prevent them, or at least to reduce their effects.
- Prevention can be viewed as focusing on three levels: (1) universal interventions, which attempt to reduce the long-term consequences of having had a disorder; (2) selective interventions, which are aimed at reducing the possibility of disorder and fostering positive mental health efforts in subpopulations that are considered at special risk; and (3) indicated interventions, which attempt to reduce the impact or duration of a problem that has already occurred.

### 17.2 What is the status and contemporary issues of inpatient mental health treatment?

- With the advent of many new psychotropic medications and changing treatment philosophies, there has been a major effort to discharge psychiatric patients into the community
- There has been a great deal of controversy over deinstitutionalization and the failure to provide prompt and adequate follow-up of these patients in the community as soon as possible.

### 17.3 What are the controversial legal issues involving the mentally ill?

- Being mentally ill is not considered sufficient grounds for involuntary commitment. There must be, in addition, evidence that the individual either is dangerous to herself or himself or represents a danger to society.
- It is not an easy matter, even for trained professionals, to determine in advance whether a person is dangerous and likely to harm others. Nevertheless, professionals must sometimes make such judgments.
- Recent court rulings have found professionals liable when patients they were treating caused harm to others. The Tarasoff decision held that a therapist has a duty to protect potential victims if her or his patient has threatened to kill them.

- The insanity plea for capital crimes is an important issue in forensic psychology. Many mental health and legal professionals, journalists, and laypersons have questioned the present use of the not guilty by reason of insanity (NGRI) defense.
- The original legal precedent, the M'Naghten rule, held that at the time of committing the act the accused must have been laboring under such a defect of reason as not to know the nature and quality of the act or not to know that what he or she was doing was wrong.
- More recent broadenings of the insanity plea, as in the American Law Institute standard, leave open the possibility of valid NGRI pleas by persons who are not diagnosed to be psychotic.
- The successful use of the NGRI defense by John Hinckley, attempted assassin of President Reagan, set off a storm of protest. One effective and widely adopted reform was to shift the burden of proof (of insanity) to the defense.

### 17.4 What national and international organizations promote efforts for mental health?

- Federal agencies such as the National Institute of Mental Health (NIMH), the National Institute on Drug Abuse (NIDA), and the National Institute on Alcohol Abuse and Alcoholism (NIAAA) are devoted to promoting research, training, and services to the mental health community.
- Several professional and mental health organizations, many corporations, and a number of volunteer associations are also active in programs to promote mental health.
- International organizations such as the World Health Organization (WHO) and the World Federation for Mental Health (WFMH) have contributed to mental health programs worldwide.

### 17.5 What are the challenges for the future of abnormal psychology?

- More effective planning needs to take place at community, national, and international levels in order to reduce or eliminate mental health problems.
- Many opportunities in mental health work, including social work, clinical psychology, and psychiatry, are open to trained personnel.
- Citizens can become involved in helping the mentally ill in their communities through volunteer work, supporting measures for ensuring comprehensive health services for all, and working toward improved public education, responsible government, and the alleviation of prejudice.

# glossary

Many of the key terms listed in the glossary appear in boldface when first introduced in the text discussion. A number of other terms commonly encountered in this or other psychology texts are also included; you are encouraged to make use of this glossary both as a general reference tool and as a study aid for the course in abnormal psychology.

## A

**1-year prevalence.** The total number of cases of a health-related state or condition in a population for a given year.

**ABAB design.** An experimental design, often involving a single subject, wherein a baseline period (A) is followed by a treatment (B). To confirm that the treatment resulted in a change in behavior, the treatment is then withdrawn (A) and reinstated (B).

**Abnormal behavior.** Maladaptive behavior detrimental to an individual or a group.

**Abnormal psychology.** Field of psychology concerned with the study, assessment, treatment, and prevention of abnormal behavior.

**Abstinence.** Refraining altogether from the use of a particular addictive substance or from a particular behavior.

**Accommodation.** Cognitive process of changing existing cognitive frameworks to make possible the incorporation of discrepant information.

**Acting out.** Ego-defense mechanism of engaging in antisocial or excessive behavior without regard to negative consequences as a way of dealing with emotional stress.

**Activation (arousal).** Energy mobilization required for an organism to pursue its goals and meet its needs.

**Actuarial approach.** Application of probability statistics to human behavior.

**Actuarial procedures.** Methods whereby data about subjects are analyzed by objective procedures or formulas rather than by human judgments.

**Acute.** Term used to describe a disorder of sudden onset, usually with intense symptoms.

**Acute stress disorder.** Disorder that occurs within 4 weeks after a traumatic event and lasts for a minimum of 2 days and a maximum of 4 weeks.

**Adderall.** A habit-forming drug comprised of a combination of dextroamphetamine and amphetamine.

**Addictive behavior.** Behavior based on the pathological need for a substance or activity; it may involve the abuse of substances, such as nicotine, alcohol, or cocaine, or gambling.

**Adjustment.** Outcome of a person's efforts to deal with stress and meet his or her needs.

**Adjustment disorder.** A disorder in which a person's response to a common stressor is maladaptive and occurs within 3 months of the stressor.

**Adjustment disorder with depressed mood.** Moderately severe mood disorder that is similar to dysthymic disorder but has an identifiable, though not severe, psychosocial stressor occurring within 3 months before the onset of depression and does not exceed 6 months in duration.

**Adoption method.** Comparison of biological and adoptive relatives with and without a given disorder to assess genetic versus environmental influences.

**Adrenal cortex.** Outer layer of the adrenal glands; secretes the adrenal steroids and other hormones.

**Adrenal glands.** Endocrine glands located at the upper end of the kidneys; consist of inner adrenal medulla and outer adrenal cortex.

**Adrenaline.** Hormone secreted by the adrenal medulla during strong emotion; causes such bodily changes as an increase in blood sugar and a rise in blood pressure. Also called *epinephrine*.

**Advocacy.** Approach to meeting mental health needs in which advocates, often an interested group of volunteers, attempt to help children or others receive services that they need but often are unable to obtain for themselves.

**Advocacy programs.** Programs aimed at helping people in underserved populations to obtain aid with which to improve their situations.

**Affect.** Emotion or feeling.

**Aftercare.** Follow-up therapy after discharge from a hospital.

**Aggression.** Behavior aimed at hurting or destroying someone or something.

**Agitation.** Marked restlessness and psychomotor excitement.

**Agoraphobia.** Fear of being in places or situations where a panic attack may occur and from which escape would be physically difficult or psychologically embarrassing, or in which immediate help would be unavailable in the event that some mishap occurred.

**AIDS-dementia complex (ADC).** Generalized loss of cognitive functioning that eventually affects a substantial proportion of AIDS patients.

**AIDS-related complex (ARC).** Pre-AIDS manifestation of HIV infection involving minor infections, various nonspecific symptoms (such as unexplained fever), blood cell count abnormalities, and sometimes cognitive difficulties.

**AIDS-related dementia.** See **HIV-associated dementia**.

**Alarm and mobilization.** Selye's first stage of responding to trauma, alerting and mobilizing

a person's resources for coping with the trauma.

**Alcohol withdrawal delirium.** Acute delirium associated with withdrawal from alcohol after prolonged heavy consumption; characterized by intense anxiety, tremors, fever and sweating, and hallucinations.

**Alcoholic.** A term used to characterize a person who is addicted to alcohol.

**Alcoholism.** Dependence on alcohol that seriously interferes with life adjustment.

**Alexithymia.** Term used to denote a personality pattern in which an individual has difficulty identifying and describing feelings.

**Alienation.** Lack or loss of relationships with others.

**Allostatic load.** The biological cost of adapting to stress. Under conditions of high stress our allostatic load is high. When we are calm, our allostatic load is low and our bodies are not experiencing any of the physiological consequences of stress (e.g., racing heart, high levels of cortisol, etc.).

**Alogia.** A term referring to poverty of speech; a symptom that often occurs in schizophrenia.

**Alter identities.** In a person with dissociative identity disorder, personalities other than the host personality.

**Alzheimer's disease.** A progressive and fatal neurodegenerative disorder that is characterized by deterioration in memory, cognition, and basic self-care skills.

**Amnesia.** Total or partial loss of memory.

**Amnestic disorder.** Striking deficit in the ability to recall ongoing events more than a few minutes after they have taken place, or the inability to recall the recent past.

**Amniocentesis.** Technique that involves drawing fluid from the amniotic sac of a pregnant woman so that sloughed-off fetal cells can be examined for chromosomal irregularities, including that of Down syndrome.

**Amphetamine.** Drug that produces a psychologically stimulating and energizing effect.

**Amygdala.** A collection of nuclei that are almond shaped and that lie in front of the hippocampus in the limbic system of the brain. It is involved in the regulation of emotion and is critically involved in the emotion of fear.

**Amyloid plaques.** Found in the brains of people with Alzheimer's disease, these deposits of aluminum silicate and abnormal protein (beta amyloid) are believed to cause loss of neurons.

**Anal stage.** In psychoanalytic theory, stage of psychosexual development in which behavior is presumably focused on anal pleasure and activities.

**Analogue studies.** Studies in which a researcher attempts to emulate the conditions hypothesized as leading to abnormality.

**Androgen.** Hormone associated with the development and maintenance of male characteristics.

**Anesthesia.** Loss or impairment of sensitivity (usually to touch but often applied to sensitivity to pain and other senses as well).

**Anhedonia.** Inability to experience pleasure or joy.

**Anorexia nervosa.** Intense fear of gaining weight or becoming “fat” coupled with refusal to maintain adequate nutrition and with severe loss of body weight.

**Anoxia.** Lack of sufficient oxygen.

**Antabuse.** Drug used in the treatment of alcoholism.

**Anterograde amnesia.** Loss of memory for events that occur *following* trauma or shock.

**Antianxiety drugs.** Drugs that are used primarily for alleviating anxiety.

**Antibody.** Circulating blood substance coded for detection of and binding to a particular antigen.

**Antidepressant drugs.** Drugs that are used primarily to elevate mood and relieve depression. Often also used in the treatment of certain anxiety disorders, bulimia, and certain personality disorders.

**Antigen.** A foreign body (e.g., a virus or bacteria) or an internal threat (e.g., a tumor) that can trigger an immune response.

**Antipsychotics (neuroleptics).** Medications that alleviate or diminish the intensity of psychotic symptoms such as hallucinations or delusions.

**Antisocial personality disorder (ASPD).** Disorder characterized by continual violation of and disregard for the rights of others through deceitful, aggressive, or antisocial behavior, typically without remorse or loyalty to anyone.

**Anxiety.** A general feeling of apprehension about possible danger.

**Anxiety disorder.** An unrealistic, irrational fear or anxiety of disabling intensity. *DSM-IV-TR* recognizes seven types of anxiety disorders: phobic disorders (specific or social), panic disorder (with or without agoraphobia), generalized anxiety disorder, obsessive-compulsive disorder, and posttraumatic stress disorder.

**Anxiety sensitivity.** A personality trait involving a high level of belief that certain bodily symptoms may have harmful consequences.

**Aphasia.** Loss or impairment of ability to communicate and understand language symbols—*involving loss of power of expression by speech, writing, or signs, or loss of ability to comprehend written or spoken language—resulting from brain injury or disease.*

**APOE-4 allele.** Variant of a gene on chromosome 19 that significantly enhances risk for late-onset Alzheimer’s disease.

**Apraxia.** Loss of ability to perform purposeful movements.

**Arousal.** See **Activation**.

**Arteriosclerosis.** Degenerative thickening and hardening of the walls of the arteries, occurring usually in old age.

**Asperger’s disorder.** Severe and sustained childhood impairment in social relationships and peculiar behaviors but without the language delays seen in autism.

**Assertive community treatment (ACT).** Persistent and vigorous follow-up with and aid to patients in managing life problems.

**Assertiveness therapy.** Behavior therapy technique for helping people become more self-assertive in interpersonal relationships.

**Assimilation.** Cognitive process whereby new experiences tend to be worked into existing cognitive frameworks even if the new information has to be reinterpreted or distorted to make it fit.

**Association studies.** Genetic research strategy comparing frequency of certain genetic markers known to be located on particular chromosomes in people with and without a particular disorder.

**Asylums.** Historically, these were institutions meant solely for the care of the mentally ill.

**At risk.** Condition of being considered vulnerable to the development of certain abnormal behaviors.

**Atrophy.** Wasting away or shrinking of a bodily organ, particularly muscle tissue.

**Attachment theory.** Contemporary developmental and psychodynamic theory emphasizing the importance of early experience with attachment relationships in laying the foundation for later functioning throughout life.

**Attention-deficit/hyperactivity disorder (ADHD).** Disorder of childhood characterized by difficulties that interfere with task-oriented behavior, such as impulsivity, excessive motor activity, and difficulties in sustaining attention.

**Attenuated Psychosis Syndrome.** Characterized by psychotic-like symptoms that are less severe and more transient and that lie below the threshold for a full psychotic disorder.

**Attribution.** Process of assigning causes to things that happen.

**Autism.** Pervasive developmental disorder beginning in infancy and involving a wide range of problematic behaviors, including deficits in language, perception, and motor development; defective reality testing; and social withdrawal.

**Autogynephilia.** Paraphilia characterized by sexual arousal in men at the thought or fantasy of being a woman.

**Autonomic nervous system.** Section of the nervous system that regulates the internal organs; consists primarily of ganglia connected with the brain stem and spinal cord; may be subdivided into the sympathetic and parasympathetic systems.

**Autonomic reactivity.** Individual’s characteristic degree of emotional reactivity to stress.

**Autonomy.** Self-reliance; the sense of being an independent person.

**Autosome.** Any chromosome other than those determining sex.

**Aversion therapy.** Form of behavior therapy in which punishment or aversive stimulation is used to eliminate undesired responses.

**Aversive stimulus.** Stimulus that elicits psychic or physical pain.

**Avoidance learning.** Form of conditioning in which a subject learns to behave in a certain way in order to avoid an unpleasant stimulus.

**Avoidant personality disorder.** Extreme social inhibition and introversion, hypersensitivity to criticism and rejection, limited social relationships, and low self-esteem.

**Avolition.** Refers to a psychological state that is characterized by a general lack of drive or motivation to pursue meaningful goals.

**Axes (of DSM).** Evaluation of an individual according to five foci, the first three assessing the person’s present clinical status or condition and the other two assessing broader aspects of the person’s situation.

## B

**Barbiturates.** Synthetic drugs that act as depressants to calm the individual and induce sleep.

**Baseline.** The initial level of responses emitted by an organism.

**B-cell.** A type of white blood cell, produced in the bone marrow, that is (along with T-cells) very important in the immune system. B-cells produce specific antibodies in response to specific antigens.

**Behavior genetics.** Field that studies the heritability of mental disorders and other aspects of psychological functioning such as personality and intelligence.

**Behavior modification.** Change of specific behaviors by learning techniques.

**Behavior therapy.** Use of therapeutic procedures based primarily on principles of classical and operant conditioning.

**Behavioral activation treatment.** Treatment for depression in which the patient and the therapist work together to help the patient find ways to become more active and engaged with life.

**Behavioral contracting.** Positive reinforcement technique using a contract, often between family members, to identify the behaviors to be changed and to specify privileges and responsibilities.

**Behavioral medicine.** Broad interdisciplinary approach to the treatment of physical disorders thought to have psychological factors as major aspects in their causation or maintenance.

- Behavioral perspective.** A theoretical viewpoint organized around the theme that learning is central in determining human behavior.
- Behavioral sciences.** Various interrelated disciplines, including psychology, sociology, and anthropology, that focus on human behavior.
- Behaviorism.** School of psychology that formerly restricted itself primarily to the study of overt behavior.
- Benign.** Of a mild, self-limiting nature; not malignant.
- Bias.** Observer bias occurs when the researcher has preconceived ideas and expectations that influence the observations he or she makes in the research study.
- Binge.** An out-of-control consumption of an amount of food that is far greater than what most people would eat in the same amount of time and under the same circumstances.
- Binge-eating disorder (BED).** Distinct from nonpurging bulimia nervosa, whereby binging is not accompanied by inappropriate compensatory behavior to limit weight gain.
- Biofeedback.** Treatment technique in which a person is taught to influence his or her own physiological processes that were formerly thought to be involuntary.
- Biogenic amines.** Chemicals that serve as neurotransmitters or modulators.
- Biological clocks.** Regular biological cycles of sleep, activity, hormone activity, and metabolism characteristic of each species.
- Biological viewpoint.** Approach to mental disorders emphasizing biological causation.
- Biopsychosocial viewpoint.** A viewpoint that acknowledges the interacting roles of biological, psychosocial, and sociocultural factors in the origins of psychopathology.
- Bipolar disorder with a seasonal pattern.** Bipolar disorder with recurrences in particular seasons of the year.
- Bipolar disorders.** Mood disorders in which a person experiences both manic and depressive episodes.
- Bipolar I disorder.** A form of bipolar disorder in which the person experiences both manic (or mixed) episodes and major depressive episodes.
- Bipolar II disorder.** A form of bipolar disorder in which the person experiences both hypomanic episodes and major depressive episodes.
- Bisexuality.** Sexual attraction to both females and males.
- Blocking.** Involuntary inhibition of recall, ideation, or communication (including sudden stoppage of speech).
- Blood-injection-injury phobia.** Persistent and disproportionate fear of the sight of blood or injury, or the possibility of having an injection. Afflicted persons are likely to experience a drop in blood pressure and sometimes faint.
- Body dysmorphic disorder (BDD).** Obsession with some perceived flaw or flaws in one's appearance.
- Body mass index (BMI).** An estimation of total body fat calculated as body weight in kilograms divided by height (in meters) squared.
- Borderline personality disorder (BPD).** Impulsivity and instability in interpersonal relationships, self-image, and moods.
- Brain pathology.** Diseased or disordered condition of the brain.
- Brain waves.** Minute oscillations of electrical potential given off by neurons in the cerebral cortex and measured by the electroencephalograph (EEG).
- Brief Psychiatric Rating Scale (BPRS).** Objective method of rating clinical symptoms that provides scores on 18 variables (e.g., somatic concern, anxiety, withdrawal, hostility, and bizarre thinking).
- Brief psychotherapy.** Short-term therapy, usually 8 to 10 sessions, focused on restoring an individual's functioning and offering emotional support.
- Brief psychotic disorder.** Brief episodes (lasting a month or less) of otherwise uncomplicated delusional thinking.
- Bulimia nervosa.** Frequent occurrence of binge-eating episodes accompanied by a sense of loss of control of overeating and recurrent inappropriate behavior such as purging or excessive exercise to prevent weight gain.
- C**
- Caffeine.** A drug of dependence found in many commonly available drinks and foods.
- Candidate genes.** Genes that are of specific interest to researchers because they are thought to be involved in processes that are known to be aberrant in that disorder (e.g., serotonin transporter genes in depression, or dopamine receptor genes in schizophrenia).
- Cardiovascular.** Pertaining to the heart and blood vessels.
- Case study method.** An in-depth examination of an individual or family that draws from a number of data sources, including interviews and psychological testing.
- Castrating.** Refers to any source of injury to the genitals, or, more broadly, to a threat to the masculinity of an individual.
- Castration anxiety.** As postulated by Freud, the anxiety a young boy experiences when he desires his mother while at the same time fearing that his father may harm him by cutting off his penis; this anxiety forces the boy to repress his sexual desire for his mother and his hostility toward his father.
- CAT scan.** See **Computerized axial tomography (CAT) scan.**
- Catalepsy.** Condition seen in some schizophrenic psychoses, and some psychotic mood disorders, in which body postures are waxy and semirigid, with the limbs maintaining for prolonged periods any position in which they are placed.
- Catatonic schizophrenia.** See **Schizophrenia, catatonic type.**
- Catecholamines.** Class of monoamine compounds sharing a similar chemical structure. Known to be neurotransmitters—norepinephrine and dopamine.
- Categorical approach.** Approach to classifying abnormal behavior that assumes that (1) all human behavior can be sharply divided into the categories normal and abnormal, and (2) there exist discrete, nonoverlapping classes or types of abnormal behavior, often referred to as mental illnesses or diseases.
- Catharsis.** Discharge of emotional tension associated with something, such as by talking about past traumas.
- Causal pattern.** In a cause-and-effect relationship, a situation in which more than one causal factor is involved.
- Causation.** Relationship in which the preceding variable causes the other(s).
- Central nervous system (CNS).** The brain and spinal cord.
- Cerebral arteriosclerosis.** Hardening of the arteries in the brain.
- Cerebral cortex.** Surface layers of the cerebrum.
- Cerebral hemorrhage.** Bleeding into brain tissue from a ruptured blood vessel.
- Cerebral laceration.** Tearing of brain tissue associated with severe head injury.
- Cerebral syphilis.** Syphilitic infection of the brain.
- Cerebral thrombosis.** Formation of a clot or thrombus in the vascular system of the brain.
- Cerebrovascular accident (CVA).** Blockage or rupture of a large blood vessel in the brain leading to both focal and generalized impairment of brain function. Also called *stroke*.
- Cerebrum.** Main part of the brain; divided into left and right hemispheres.
- Child abuse.** Infliction of physical or psychological damage on a child by parents or other adults.
- Child advocacy.** Movement concerned with protecting rights and ensuring well-being of children.
- Chorea.** Pathological condition characterized by jerky, irregular, involuntary movements. See also **Huntington's disease**.
- Chromosomal anomalies.** Inherited defects or vulnerabilities caused by irregularities in chromosomes.
- Chromosomes.** Chain-like structures within cell nucleus that contain genes.
- Chronic.** Term used to describe a long-standing or frequently recurring disorder, often with progressing seriousness.

**Chronic fatigue syndrome.** A debilitating illness characterized by disabling fatigue that lasts 6 months or more and occurs with other symptoms.

**Chronic major depressive disorder.** A disorder in which a major depressive episode does not remit over a 2-year period.

**Chronic schizophrenic.** A schizophrenic patient whose condition has deteriorated or remained stable over a long period of time (years).

**Circadian rhythms.** The 24-hour rhythmic fluctuations in animals' sleep activity and in the metabolic processes of plants and animals. See also **Biological clocks**.

**Civil commitment.** Procedure whereby a person certified as mentally disordered can be hospitalized, either voluntarily or against his or her will.

**Classical conditioning.** A basic form of learning in which a neutral stimulus is paired repeatedly with an unconditioned stimulus (US) that naturally elicits an unconditioned response (UR). After repeated pairings, the neutral stimulus becomes a conditioned stimulus (CS) that elicits a conditioned response (CR).

**Claustrophobia.** Irrational fear of small enclosed places.

**Client-centered (person-centered) therapy.** Nondirective approach to psychotherapy, developed chiefly by Carl Rogers, that focuses on the natural power of the organism to heal itself; a key goal is to help clients accept and be themselves.

**Clinical diagnosis.** The process through which a clinician arrives at a general "summary classification" of the patient's symptoms by following a clearly defined system such as *DSM-IV-TR* or ICD-10.

**Clinical picture.** Diagnostic picture formed by observation of patient's behavior or by all available assessment data.

**Clinical problem checklist.** Computer-administered psychological assessment procedure for surveying the range of psychological problems a patient is experiencing.

**Clinical psychologist.** Mental health professional with Ph.D. degree or Psy.D. degree in clinical psychology and clinical experience in assessment and psychotherapy.

**Clinical psychology.** Field of psychology concerned with the understanding, assessment, treatment, and prevention of maladaptive behavior.

**Cocaine.** Stimulating and pain-reducing psychoactive drug.

**Cognition.** Act, process, or product of knowing or perceiving.

**Cognitive dissonance.** Condition of tension existing when several of one's beliefs and attitudes are inconsistent with each other.

**Cognitive processes (cognition).** Mental processes, including perception, memory, and

reasoning, by which one acquires knowledge, solves problems, and makes plans.

**Cognitive remediation.** Training efforts designed to help patients improve their neurocognitive (e.g., memory, vigilance) skills. The hope is that this will also help improve patients' overall levels of functioning.

**Cognitive restructuring.** Cognitive-behavioral therapy techniques that aim to change a person's negative or unrealistic thoughts and attributions.

**Cognitive-behavioral perspective.** A theory of abnormal behavior that focuses on how thoughts and information processing can become distorted and lead to maladaptive emotions and behavior.

**Cognitive-behavioral therapy (CBT).** Therapy based on altering dysfunctional thoughts and cognitive distortions.

**Collective unconscious.** Term used by Carl Jung to refer to that portion of the unconscious that he considered common to all humanity, based on wisdom acquired by our predecessors.

**Coma.** Profound stupor with unconsciousness.

**Community mental health.** Application of psychosocial and sociocultural principles to the improvement of given environments.

**Community psychology.** Use of community resources in dealing with maladaptive behavior; tends to be more concerned with community intervention than with personal or individual change.

**Comorbidity.** Occurrence of two or more identified disorders in the same psychologically disordered individual.

**Comparison or control group.** Group of subjects who do not exhibit the disorder being studied but who are comparable in all other respects to the criterion group. Also, a comparison group of subjects who do not receive a condition or treatment the effects of which are being studied.

**Competent to stand trial.** The determination that a person who is charged with a crime has the mental health capability to participate in the proceedings.

**Compulsions.** Overt repetitive behaviors (such as hand washing or checking) or more covert mental acts (such as counting, praying, saying certain words silently, or ordering) that a person feels driven to perform in response to an obsession.

**Compulsive gambling.** See **Pathological gambling**.

**Computer assessment.** Use of computers to obtain or interpret assessment data.

**Computerized axial tomography (CAT) scan.** Radiological technique used to locate and assess the extent of organic damage to the brain without surgery.

**Concordance rate.** The percentage of twins sharing a disorder or trait.

**Conduct disorders.** Childhood and adolescent disorders that can appear by age 9 and are marked by persistent acts of aggressive or anti-social behavior that may or may not be against the law.

**Confabulation.** Filling in of memory gaps with false and often irrelevant details.

**Confidentiality.** Commitment on part of a professional person to keep information he or she obtains from a client confidential.

**Conflict.** Simultaneous arousal of opposing impulses, desires, or motives.

**Congenital.** Existing at birth or before birth, but not necessarily hereditary.

**Congenital defect.** Genetic defect or environmental condition occurring before birth and causing a child to develop a physical or psychological anomaly.

**Conjoint family therapy.** Direct involvement of the family in improving communication, interaction, and relationships among family members and fostering a family system that better meets the needs of each member.

**Consciousness.** Awareness of inner or outer environment.

**Constitution.** Relatively constant biological makeup of an individual, resulting from the interaction of heredity and environment.

**Consultation.** Community intervention approach that aims at helping individuals at risk for disorder by working indirectly through caretaker institutions (e.g., police and teachers).

**Contingency.** Relationship, usually causal, between two events in which one is usually followed by the other.

**Continuous reinforcement.** Reward or reinforcement given regularly after each correct response.

**Contributory cause.** A condition that increases the probability of developing a disorder but that is neither necessary nor sufficient for it to occur.

**Conversion disorder.** Pattern in which symptoms of some physical malfunction or loss of control appear without any underlying organic pathology; originally called *hysteria*.

**Convulsion.** Pathological, involuntary muscle contractions.

**Coping strategies.** Efforts to deal with stress.

**Coprolalia.** Verbal tic in which an individual utters obscenities aloud.

**Coronary heart disease (CHD).** Potentially lethal blockage of the arteries supplying blood to the heart muscle, or myocardium.

**Corpus callosum.** Nerve fibers that connect the two hemispheres of the brain.

**Correlation.** The tendency of two variables to change together. With positive correlation, as one variable goes up, so does the other; with

negative correlation, one variable goes up as the other goes down.

**Correlation coefficient.** A statistic that ranges from +1.0 to -1.0 and reflects the degree of association between two variables. The magnitude of the correlation indicates the strength of the association, and the sign indicates whether the correlation is positive or negative.

**Correlational method/correlational research.** A research strategy that examines whether and how variables go together (covary) without manipulating (changing) any variables.

**Corticovisceral control mechanisms.** Brain mechanisms that regulate autonomic and other bodily functions.

**Cortisol.** Human stress hormone released by the cortex of the adrenal glands.

**Counseling psychology.** Field of psychology that focuses on helping people with problems pertaining to education, marriage, or occupation.

**Countertransference.** Psychodynamic concept that the therapist brings personal issues, based on his or her own vulnerabilities and conflicts, to the therapeutic relationship.

**Couple therapy.** Treatment for disordered interpersonal relationships involving sessions with both members of the relationship present and emphasizing mutual need gratification, social role expectations, communication patterns, and similar interpersonal factors.

**Covert.** Concealed, disguised, not directly observable.

**Covert sensitization.** Behavioral treatment method for extinguishing undesirable behavior by associating noxious mental images with that behavior.

**Criminal responsibility.** Legal question of whether a person should be permitted to use insanity as a defense after having committed a crime.

**Crisis.** Stressful situation that approaches or exceeds the adaptive capacities of an individual or a group.

**Crisis intervention.** Provision of psychological help to an individual or a group in times of severe and special stress.

**Criterion group.** Group of subjects who exhibit the disorder under study.

**Cross-gender identification.** The desire to be, or the insistence that one is, of the opposite sex.

**Cultural competence.** Refers to a psychologist's need to be informed of the issues involved in multicultural assessment.

**Cultural relativism.** Position that one cannot apply universal standards of normality or abnormality to all societies.

**Cultural-familial retardation.** Mental retardation as a result of an inferior quality of interaction with the cultural environment and other people, with no evidence of brain pathology.

**Cyclothymic disorder.** Mild mood disorder characterized by cyclical periods of hypomanic and depressive symptoms.

**Cytokines.** Small protein molecules that enable the brain and the immune system to communicate with each other. Cytokines can augment or enhance an immune system response or cause immunosuppression, depending on the specific cytokine that is released.

## D

**Day hospital.** Community-based mental hospital where patients are treated during the day, returning to their homes at night.

**Debriefing sessions.** Psychological debriefing is a brief, directive treatment method that is used in helping people who have undergone a traumatic situation. Debriefing sessions are usually conducted with small groups of trauma victims shortly after the incident for the purpose of helping them deal with the emotional residuals of the event.

**Defense mechanism.** See **Ego-defense mechanism.**

**Defense-oriented response.** Behavior directed primarily at protecting the self from hurt and disorganization rather than at resolving the situation.

**Deinstitutionalization.** Movement to close mental hospitals and treat people with severe mental disorder in the community.

**Delayed ejaculation disorder.** Retarded ejaculation, or the inability to ejaculate following a normal sexual excitement phase.

**Delinquency.** Antisocial or illegal behavior by a minor.

**Delirium.** State of mental confusion characterized by relatively rapid onset of widespread disorganization of the higher mental processes, caused by a generalized disturbance in brain metabolism. May include impaired perception, memory, and thinking and abnormal psychomotor activity.

**Delirium tremens.** See **Alcohol withdrawal delirium.**

**Delusion.** False belief about reality maintained in spite of strong evidence to the contrary.

**Delusion of grandeur.** False belief that one is a noted or famous person, such as Napoleon or the Virgin Mary.

**Delusion of persecution.** False belief that one is being mistreated or interfered with by one's enemies.

**Delusional disorder.** Nurturing, giving voice to, and sometimes taking action on beliefs that are considered completely false by others; formerly called *paranoia*.

**Delusional system.** Internally coherent, systematized pattern of delusions.

**Dementia.** Progressive deterioration of brain functioning occurring after the completion of brain maturation in adolescence. Characterized

by deficits in memory, abstract thinking, acquisition of new knowledge or skills, visuospatial comprehension, motor control, problem solving, and judgment.

**Dementia of the Alzheimer's type**

(**DAT**). Disorder associated with a progressive dementia syndrome ultimately terminating in death. Onset may be in middle or old age, and symptoms include memory loss, withdrawal, confusion, and impaired judgment.

**Dementia praecox.** Older term for schizophrenia.

**Demonology.** Viewpoint emphasizing supernatural causation of mental disorder, especially "possession" by evil spirits or forces.

**Denial of reality.** Ego-defense mechanism that protects the self from an unpleasant reality by refusing to perceive or face it.

**Dependence.** Tendency to rely overly on others.

**Dependent personality disorder.** Extreme dependence on others, particularly the need to be taken care of, leading to clinging and submissive behavior.

**Dependent variable.** In an experiment, the factor that is observed to change with changes in the manipulated (independent) variables.

**Depersonalization.** Temporary loss of sense of one's own self and one's own reality.

**Depersonalization disorder.** Dissociative disorder in which episodes of depersonalization and derealization become persistent and recurrent.

**Depression.** Emotional state characterized by extraordinary sadness and dejection.

**Depressive personality disorder.** Provisional category of personality disorder in *DSM-IV-TR* that involves a pattern of depressive cognitions and behaviors that begin by early adulthood and is pervasive in nature.

**Depressogenic schemas.** Dysfunctional beliefs that are rigid, extreme, and counterproductive and that are thought to leave one susceptible to depression when experiencing stress.

**Derealization.** Experience in which the external world is perceived as distorted and lacking a stable and palpable existence.

**Desensitization.** Therapeutic process by means of which reactions to traumatic experiences are reduced in intensity by repeatedly exposing a person to them in mild form, either in reality or in fantasy.

**Desire phase.** First phase of the human sexual response, consisting of fantasies about sexual activity or a sense of desire to have sexual activity.

**Deterrence.** Premise that punishment for criminal offenses will deter that criminal and others from future criminal acts.

**Detox center.** Center or facility for receiving and detoxifying alcohol or drug-intoxicated individuals.

**Detoxification.** Treatment directed toward ridding the body of alcohol or other drugs.

**Developmental disorder.** Problem that is rooted in deviations in the development process itself, thus disrupting the acquisition of skills and adaptive behavior and often interfering with the transition to well-functioning adulthood.

**Developmental psychopathology.** Field of psychology that focuses on determining what is abnormal at any point in the developmental process by comparing and contrasting it with normal and expected changes that occur.

#### **Developmental systems**

**approach.** Acknowledgment that genetic activity influences neural activity, which in turn influences behavior, which in turn influences the environment, and that these influences are bidirectional.

**Deviant behavior.** Behavior that deviates markedly from the average or norm.

**Diagnosis.** Determination of the nature and extent of a specific disorder.

**Dialectical behavior therapy.** A unique kind of cognitive and behavioral therapy specifically adapted for treating borderline personality disorder.

**Diathesis.** Predisposition or vulnerability to developing a given disorder.

**Diathesis-stress model.** View of abnormal behavior as the result of stress operating on an individual who has a biological, psychosocial, or sociocultural predisposition to developing a specific disorder.

**Dimensional approach.** Approach to classifying abnormal behavior that assumes that a person's typical behavior is the product of differing strengths or intensities of behavior along several definable dimensions, such as mood, emotional stability, aggressiveness, gender, identity, anxiousness, interpersonal trust, clarity of thinking and communication, social introversion, and so on.

**Direct observation.** Method of collecting research data that involves directly observing behavior in a given situation.

**Direction of effect problem.** Refers to the fact that, in correlational research, it cannot be concluded whether variable A causes variable B or whether variable B causes variable A.

**Directive therapy.** Type of therapeutic approach in which a therapist supplies direct answers to problems and takes much of the responsibility for the progress of therapy.

**Disaster syndrome.** Reactions of many victims of major catastrophes during the traumatic experience and the initial and long-lasting reactions after it.

**Discordant marriage.** Marriage in which one or both of the partners are not gaining satisfaction from the relationship and one spouse may express frustration and disillusionment

in hostile ways, such as nagging, belittling, and purposely doing things to annoy the other.

**Discrimination.** Ability to interpret and respond differently to two or more similar stimuli.

**Disintegration.** Loss of organization or integration in any organized system.

**Disorganization.** Severely impaired integration.

**Disorganized schizophrenia.** See **Schizophrenia, disorganized type.**

**Disorganized symptoms.** Symptoms such as bizarre behavior or incomprehensible speech.

**Disorientation.** Mental confusion with respect to time, place, or person.

**Displacement.** Ego-defense mechanism that discharges pent-up feelings, often of hostility, on objects less dangerous than those arousing the feelings.

**Disrupted family.** Family that is incomplete as a result of death, divorce, separation, or some other circumstance.

**Dissociation.** The human mind's capacity to mediate complex mental activity in channels split off from or independent of conscious awareness.

**Dissociative amnesia.** Psychogenically caused memory failure.

**Dissociative disorders.** Conditions involving a disruption in an individual's normally integrated functions of consciousness, memory, or identity.

**Dissociative fugue.** A dissociative amnesia state in which the person is not only amnesic for some or all aspects of his or her past but also departs from home surroundings.

**Dissociative identity disorder (DID).** Condition in which a person manifests at least two or more distinct identities or personality states that alternate in some way in taking control of behavior. Formerly called *multiple personality disorder*.

**Distress.** Negative stress, associated with pain, anxiety, or sorrow.

**Disturbed family.** Family in which one or both parents behave in grossly eccentric or abnormal ways and may keep the home in constant emotional turmoil.

**Dizygotic (fraternal) twins.** Twins that develop from two separate eggs.

**DNA.** Deoxyribonucleic acid; principal component of genes.

**Dominant gene.** A gene whose hereditary characteristics prevail, in offspring, over any recessive gene that affects the same trait.

**Dopamine.** Neurotransmitter from the catecholamine family that is initially synthesized from tyrosine, an amino acid common in the diet. Dopamine is produced from l-dopa by the enzyme dopamine decarboxylase.

**Dopamine hypothesis.** Hypothesis that schizophrenia is the result of an excess of dopamine activity at certain synaptic sites.

**Double bind.** Situation in which a person will be disapproved for performing a given act and equally disapproved if he or she does not perform it.

**Double depression.** This condition is diagnosed when a person with dysthymia has a superimposed major depressive episode.

**Double-bind communication.** Type of faulty communication in which one person (e.g., a parent) presents to another (e.g., a child) ideas, feelings, and demands that are mutually incompatible.

**Double-blind study.** Often used in studies examining drug treatment effects, a condition where neither the subject nor the experimenter has knowledge about what specific experimental condition (or drug) the subject is receiving.

**Down syndrome.** Form of moderate-to-severe mental retardation associated with a chromosomal abnormality and typically accompanied by characteristic physical features.

**Dream analysis.** Method involving the recording, description, and interpretation of a patient's dreams.

**Drive.** Internal conditions directing an organism toward a specific goal, often involving biological rather than psychological motives.

**Drug abuse.** Use of a drug to the extent that it interferes with health and/or occupational or social adjustment.

**Drug addiction (dependence).** Physiological or psychological dependence on a drug.

**DSM-5.** Current diagnostic manual of the American Psychiatric Association.

**Dwarfism.** Condition of arrested growth and very short stature.

**Dyad.** Two-person group.

**Dynamic formulation.** Integrated evaluation of an individual's personality traits, behavior patterns, environmental demands, and the like to describe the person's current situation and to hypothesize about what is driving the person to behave in maladaptive ways.

**Dysfunction.** Impairment or disturbance in the functioning of an organ or in behavior.

**Dysfunctional beliefs.** Negative beliefs that are rigid, extreme, and counterproductive.

**Dyslexia.** Impairment of the ability to read.

**Dyspareunia.** Painful coitus in a male or a female.

**Dysrhythmia.** Abnormal brain wave pattern.

**Dysthymic disorder.** Moderately severe mood disorder characterized by a persistently depressed mood most of the day for more days than not for at least 2 years. Additional symptoms may include poor appetite, sleep disturbance, lack of energy, low self-esteem, difficulty concentrating, and feelings of hopelessness.

## E

- Early-onset Alzheimer's disease.** Form of Alzheimer's disease that appears in people who are younger than approximately 60 years of age. Thought to be caused by rare genetic mutations.
- Eating disorder not otherwise specified (EDNOS).** A diagnostic category reserved for disorders of eating that do not meet criteria for any other specific eating disorder.
- Eating disorders.** Disorders of food ingestion, regurgitation, or attitude that affect health and well-being, such as anorexia, bulimia, or binge eating.
- Echolalia.** Parrot-like repetition of a few words or phrases.
- Ecstasy.** A human manufactured drug that is taken orally and acts as both a stimulant and a hallucinogen. The drug effects include feelings of mental stimulation, emotional warmth, enhanced sensory perception, and increased physical energy.
- Edema.** Swelling of tissues.
- EEG.** See **Electroencephalogram**.
- Effect size.** A statistical term referring to the strength of the relationship between two variables in a statistical population.
- Efficacy.** In a situation where treatment is tested under ideal conditions (usually in a controlled clinical trial) efficacy is how well a given treatment improves clinical outcome compared to a control or comparison condition.
- Ego.** In psychoanalytic theory, the rational part of the personality that mediates between the demands of the id, the constraints of the superego, and the realities of the external world.
- Ego psychology.** Psychodynamic theory emphasizing the importance of the ego—the “executive branch of the personality”—in organizing normal personality development.
- Egocentric.** Preoccupied with one's own concerns and relatively insensitive to the concerns of others.
- Ego-defense mechanisms.** Psychic mechanisms that discharge or soothe anxiety rather than coping directly with an anxiety-provoking situation; usually unconscious and reality distorting. Also called *defense mechanisms*.
- Electra complex.** Excessive emotional attachment (love) of a daughter for her father; the female counterpart of the Oedipus complex.
- Electroconvulsive therapy (ECT).** Use of electricity to produce convulsions and unconsciousness; a treatment used primarily to alleviate depressive and manic episodes. Also known as *electroshock therapy*.
- Electroencephalogram (EEG).** Graphical record of the brain's electrical activity obtained by placing electrodes on the scalp and measuring the brain wave impulses from various brain areas.
- Embolism.** Lodgment of a blood clot in a blood vessel too small to permit its passage.
- Emotion.** Strong feeling accompanied by physiological changes.
- Emotional disturbance.** Psychological disorder.
- Empathy.** Ability to understand, and to some extent share, the state of mind of another person.
- Encephalitis.** Inflammation of the brain.
- Encopresis.** Disorder in children who have not learned appropriate toileting for bowel movements after age 4.
- Encounter group.** Small group designed to provide an intensive interpersonal experience focusing on feelings and group interactions; used in therapy or to promote personal growth.
- Endocrine glands.** Ductless glands that secrete hormones directly into the lymph or bloodstream.
- Endogenous factors.** Factors originating within an organism that affect behavior.
- Endophenotypes.** Discrete, measurable traits that are thought to be linked to specific genes that might be important in schizophrenia or other mental disorders.
- Endorphins.** Opiates produced in the brain and throughout the body that function like neurotransmitters to dampen pain sensations. They also play a role in the body's building up tolerance to certain drugs.
- Enuresis.** Bed-wetting; involuntary discharge of urine after the age of expected continence (age 5).
- Environmental psychology.** Field of psychology focusing on the effects of an environmental setting on an individual's feelings and behavior.
- Epidemiological studies.** Attempts to establish the pattern of occurrence of certain (mental) disorders in different times, places, and groups of people.
- Epidemiology.** Study of the distribution of diseases, disorders, or health-related behaviors in a given population. Mental health epidemiology is the study of the distribution of mental disorders.
- Epilepsy.** Group of disorders varying from momentary lapses of consciousness to generalized convulsions.
- Epinephrine.** Hormone secreted by the adrenal medulla; also called *adrenaline*.
- Episodic.** Term used to describe a disorder that tends to abate and recur.
- Equilibrium.** Steady state; balance.
- Erotic.** Pertaining to sexual stimulation and gratification.
- Escape learning.** Instrumental response in which a subject learns to terminate or escape an aversive stimulus.
- Essential hypertension.** High blood pressure with no specific known physical cause.
- Estrogens.** Female hormones produced by the ovaries.
- Ethnic group.** Group of people who are treated as distinctive in terms of culture and group patterns.
- Etiology.** Factors that are related to the development (or cause) of a particular disorder.
- Euphoria.** Exaggerated feeling of well-being and contentment.
- Eustress.** Positive stress.
- Evidence-based treatment.** Treatment that has been demonstrated to be superior to a standard comparison treatment or to placebo in a randomized controlled trial.
- Exacerbate.** Intensify.
- Excitement (arousal) phase.** Second phase of the human sexual response, in which there is generally a subjective sense of sexual pleasure and physiological changes, including penile erection in the male and vaginal lubrication and enlargement in the female.
- Exhaustion.** Selye's third and final stage of responding to continued excessive trauma, in which a person's adaptive resources are depleted and the coping patterns developed during the resistance stage fail.
- Exhibitionism.** Intentional exposure of one's genitals to others under inappropriate circumstances and without their consent.
- Existential anxiety.** Anxiety concerning one's ability to find a satisfying and fulfilling way of life.
- Existential neurosis.** Disorder characterized by feelings of alienation, meaninglessness, and apathy.
- Existential psychotherapy.** Type of therapy that is based on existential thought and focuses on individual uniqueness and authenticity on the part of both client and therapist.
- Existentialism.** View of human beings that emphasizes an individual's responsibility for becoming the kind of person he or she should be.
- Exogenous.** Originating from or due to external causes.
- Exorcism.** Religiously inspired treatment procedure designed to drive out evil spirits or forces from a “possessed” person.
- Experimental group.** Group of subjects used to assess the effects of independent variables.
- Experimental method.** Rigorous scientific procedure by which hypotheses are tested.
- Experimental research.** Research that involves the manipulation of a given factor or variable with everything else held constant.
- Exposure and response prevention.** A method of treatment for obsessive-compulsive disorder that combines intense exposure of the patient to feared conditions and then they are asked not to respond by engaging in their usual rituals to the feared stimuli.

**Exposure therapy.** A technique in psychological treatment of anxiety disorders that involves exposing the patient to the feared object or context without any danger in order to overcome the anxiety.

**Expressed emotion (EE).** Type of negative communication involving excessive criticism and emotional overinvolvement directed at a patient by family members.

**External validity.** The extent to which the findings from a single study are relevant to other populations, contexts, or times.

**Exteroceptive conditioning.** Modifying the perception of environmental stimuli acting on the body.

**Extinction.** Gradual disappearance of a conditioned response when it is no longer reinforced.

**Extraversion.** Direction of interest toward the outer world of people and things rather than toward concepts and intellectual concerns.

## F

**Factitious disorder.** Feigning of symptoms to maintain the personal benefits that a sick role may provide, including the attention and concern of medical personnel or family members.

**Factitious disorder by proxy.** A variant of factitious disorder in which a person induces medical or psychological symptoms in another person who is under his or her care (usually a child).

**Factor analysis.** Statistical technique used for reducing a large array of inter-correlated measures to the minimum number of factors necessary to account for the observed overlap or associations among them.

**Fading.** Technique whereby a stimulus causing some reaction is gradually replaced by a previously neutral stimulus such that the latter acquires the property of producing the reaction in question.

**False memories.** “Memories” of events that did not actually happen, often produced by highly leading and suggestive techniques.

**Familial.** Pertaining to characteristics that tend to run in families and have a higher incidence in certain families than in the general population.

**Family aggregation.** The clustering of certain traits, behaviors, or disorders within a given family. Family aggregation may arise because of genetic or environmental similarities.

**Family history method.** Behavior genetic research strategy that examines the incidence of disorder in relatives of an index case to determine whether incidence increases in proportion to the degree of the hereditary relationship.

**Family systems approach.** Form of interpersonal therapy focusing on the within-family behavior of a particular family member and

the assumption that it is largely influenced by the behaviors and communication patterns of other family members.

**Family therapy.** A treatment approach that includes all family members, not just the identified patient.

**Fantasy.** Daydream; also, an ego-defense mechanism by means of which a person escapes from the world of reality and gratifies his or her desires in fantasy achievements.

**Fear.** A basic emotion that involves the activation of the “fight-or-flight” response of the sympathetic nervous system.

**Feedback.** Explicit information pertaining to internal physiological processes or to the social consequences of one’s overt behavior.

**Female orgasmic disorder.** Persistent or recurrent delay in, or absence of, orgasm after a normal sexual excitement phase.

**Female sexual arousal disorder.** Sexual dysfunction involving an absence of sexual arousal and unresponsiveness to most or all forms of erotic stimulation.

**Fetal alcohol syndrome.** Observed pattern in infants born to alcoholic mothers in which there is a characteristic facial or limb irregularity, low body weight, and behavioral abnormality.

**Fetishism.** Sexual variant in which sexual interest centers on some inanimate object or non-sexual part of the body.

**Fetus.** Embryo after the sixth week following conception.

**Fixation.** Ego-defense mechanism involving an unreasonable or exaggerated attachment to some person or arresting of emotional development on a childhood or adolescent level.

**Fixed-interval schedule.** Schedule of reinforcement based on a fixed period of time after the previous reinforced response.

**Fixed-ratio schedule.** Schedule of reinforcement based on reinforcement after a fixed number of nonreinforced responses.

**Flashback.** Involuntary recurrence of perceptual distortions or hallucinations weeks or months after taking a drug; in posttraumatic stress disorder, a dissociative state in which the person briefly relives the traumatic experience.

**Flat affect.** The lack of emotional expression.

**Flooding.** Anxiety-eliciting therapeutic technique involving having a client repeatedly experience the actual internal or external stimuli that had been identified as producing anxiety reactions. *Folie à deux.* See **Shared psychotic disorder.**

**Follow-up study.** Research procedure in which people are studied over a period of time or are recontacted at a later time after an initial study.

**Forensic.** Pertaining or used in the court of law.

**Forensic psychology and psychiatry.** Branches of psychology and psychiatry dealing with

legal problems related to mental disorders and the legal rights and protection of mental patients and members of society at large.

**Fraternal twins.** Dizygotic twins; fertilized by separate germ cells, thus not having the same genetic inheritance. May be of the same or of opposite sexes.

**Free association.** Method for probing the unconscious by having patients talk freely about themselves, their feelings, and their motives.

**Free-floating anxiety.** Anxiety not referable to any specific situation or cause.

**Frontal lobe.** Portion of the brain active in reasoning and other higher thought processes.

**Frotteurism.** A term that refers to interest in rubbing, usually one’s pelvis or erect penis, against a non-consenting person for sexual gratification.

**Frustration.** Thwarting of a need or desire.

**Frustration tolerance.** Ability to withstand frustration without becoming impaired psychologically.

**Fugue.** Dissociative disorder that entails loss of memory for personal information accompanied by actual physical flight from one’s present life situation to a new environment or a less threatening former one.

**Functional mental disorders.** Outdated term used to refer to disorders that were not considered to have an organic basis.

**Functional MRI (fMRI).** Internal scanning technique that measures changes in local oxygenation (blood flow) to specific areas of brain tissue that in turn depend on neuronal activity in those specific regions, allowing the mapping of psychological activity such as sensations, images, and thoughts.

**Functional psychoses.** Severe mental disorders for which a specific organic pathology has not been demonstrated.

## G

**Gambling.** Wagering on games or events in which chance largely determines the outcome.

**Gender dysphoria.** Persistent discomfort about one’s biological sex or the sense that the gender role of that sex is inappropriate.

**Gender identity.** Individual’s identification as being male or female.

**Gender identity disorder.** Identification with members of the opposite sex, persistent discomfort with one’s biological sexual identity, and strong desire to change to the opposite sex.

**General adaptation syndrome.** A model that helps explain the course of a person’s biological deterioration under excessive stress; consists of three stages (alarm reaction, stage of resistance, and exhaustion).

**General paresis.** Mental disorder associated with syphilis of the brain.

- Generalizability.** The extent to which the findings from a single study can be used to draw conclusions about other samples.
- Generalization.** Tendency of a response that has been conditioned to one stimulus to be elicited by other, similar stimuli.
- Generalized anxiety disorder (GAD).** Chronic excessive worry about a number of events or activities, with no specific threat present, accompanied by at least three of the following symptoms: restlessness, fatigue, difficulty concentrating, irritability, muscle tension, sleep disturbance.
- Genes.** Long molecules of DNA that are present at various locations on chromosomes and that are responsible for the transmission of hereditary traits.
- Genetic code.** Means by which DNA controls the sequence and structure of proteins manufactured within each cell and also makes exact duplicates of itself.
- Genetic counseling.** Counseling prospective parents concerning the probability of their having impaired offspring as a result of genetic defects.
- Genetic inheritance.** Potential for development and behavior determined at conception by egg and sperm cells.
- Genetics.** Science of the inheritance of traits and the mechanisms of this inheritance.
- Genital stage.** In psychoanalytic theory, the final stage of psychosexual development, involving a shift from autoeroticism to heterosexual interest.
- Genitalia.** Organs of reproduction, especially the external organs.
- Genito-pelvic pain/penetration disorder.** Recurring difficulties of vaginal penetration or pelvic pain during intercourse.
- Genotype.** A person's total genetic endowment.
- Genotype-environment correlation.** Genotypic vulnerability that can shape a child's environmental experiences.
- Genotype-environment interaction.** Differential sensitivity or susceptibility to their environments by people who have different genotypes.
- Geriatrics.** Science of the diseases and treatment of the aged.
- Germ cells.** Reproductive cells (female ovum and male sperm) that unite to produce a new individual.
- Gerontology.** Science dealing with the study of old age.
- Gestalt psychology.** School of psychology that emphasizes patterns rather than elements or connections, taking the view that the whole is more than the sum of its parts.
- Gestalt therapy.** Therapy designed to increase the integration of thoughts, feelings, and actions and to promote self-awareness and self-acceptance.
- Glucocorticoids.** Adrenocortical hormones involved in sugar metabolism but also having widespread effects on injury-repair mechanisms and resistance to disease; they include cortisol.
- Glutamate.** An excitatory neurotransmitter that is widespread throughout the brain.
- Gonads.** Sex glands.
- Good premorbid schizophrenia.** See **Reactive schizophrenia**.
- Ghrelin.** Ghrelin is a hormone that is produced by the stomach. It stimulates appetite.
- Group therapy.** Psychotherapy administered to several people at the same time.
- Guilt.** Feelings of culpability arising from behavior or desires contrary to one's ethical principles. Involves both self-devaluation and apprehension growing out of fears of punishment.
- Guilty but mentally ill (GBMI).** Plea and possible verdict that would provide an alternative to pleading not guilty by reason of insanity (NGRI) and would allow for placing a defendant in a treatment facility rather than in a prison.
- H**
- Habituation.** Automatic process whereby a person's response to the same stimulus lessens with repeated presentations.
- Half-life.** Time taken for the level of an active drug or medication in the body to be reduced to 50 percent of the original level.
- Halfway house.** Facility that provides aftercare following institutionalization, seeking to ease a person's adjustment to the community.
- Hallucinations.** False perceptions such as things seen or heard that are not real or present.
- Hallucinogens.** Drugs known to induce hallucinations; often referred to as psychedelics.
- Hallucinosis.** Persistent hallucinations in the presence of known or suspected organic brain pathology.
- Hashish.** Strongest drug derived from the hemp plant; a relative of marijuana that is usually smoked.
- Health maintenance organization (HMO).** Health plan that provides services to employers and individuals for a fixed, prepaid fee.
- Health psychology.** Subspecialty within behavioral medicine that deals with psychology's contributions to diagnosis, treatment, and prevention of psychological components of physical dysfunction.
- Hebephrenic schizophrenia.** See **Schizophrenia, disorganized type**.
- Hemiplegia.** Paralysis of one lateral half of the body.
- Heredity.** Genetic transmission of characteristics from parents to their children.
- Hermaphroditism.** Anatomical sexual abnormality in which a person has some sex organs of both sexes.
- Heroin.** Powerful psychoactive drug, chemically derived from morphine, that relieves pain but is even more intense and addictive than morphine.
- Heterosexuality.** Sexual interest in a member of the opposite sex.
- Hierarchy of needs.** Concept, articulated by Maslow, that needs arrange themselves in a hierarchy in terms of importance from the most basic biological needs to those psychological needs concerned with self-actualization.
- High-risk.** Term applied to persons showing great vulnerability to physical or mental disorders.
- Histrionic personality disorder.** Excessive attention seeking, emotional instability, and self-dramatization.
- HIV-associated dementia.** A progressive brain deterioration that is caused by infection from the HIV virus.
- HIV-associated neurocognitive impairment.** Mild or major neurocognitive disorder caused by infection with the human immunodeficiency virus (HIV).
- Hoarding disorder.** A new *DSM-5* diagnosis characterized by long-standing difficulties discarding possessions, even those of little value.
- Homeostasis.** Tendency of organisms to maintain conditions that make possible a constant level of physiological functioning.
- Homosexuality.** Sexual preference for a member of one's own sex.
- Hormones.** Chemical messengers secreted by endocrine glands that regulate development of and activity in various parts of the body.
- Host identity (personality).** The identity in dissociative identity disorder which is most frequently encountered and carries the person's real name. This is not usually the original identity and it may or may not be the best adjusted identity.
- Hostility.** Emotional reaction or drive toward the destruction or damage of an object interpreted as a source of frustration or threat.
- HPA axis.** The hypothalamic-pituitary-adrenal (HPA) axis is a hormonal feedback system that becomes activated by stress and results in the production of cortisol.
- Humanistic perspective.** Approach to understanding abnormal behavior that views basic human nature as good and emphasizes people's inherent capacity for growth and self-actualization.
- Humanistic-experiential therapies.** Psychotherapies emphasizing personal growth and self-direction.
- Huntington's disease.** A rare and fatal degenerative disorder which is manifested in jerking, twitching movements, and mental

deterioration. Caused by a dominant gene on chromosome 4. Formerly called *Huntington's chorea*.

**Hydrocephaly.** Relatively rare condition in which the accumulation of an abnormal amount of cerebrospinal fluid within the cranium causes damage to the brain tissues and enlargement of the skull.

**Hydrotherapy.** Use of hot or cold baths, ice packs, etc., in treatment.

**Hyper-**. Prefix meaning "increased" or "excessive."

**Hyperactivity.** See **Attention-deficit/hyperactivity disorder**.

**Hyperobesity.** Extreme overweight; 100 pounds or more above ideal body weight.

**Hypertension.** High blood pressure, defined as a persisting systolic blood pressure of 140 or more and a diastolic blood pressure of 90 or greater.

**Hyperventilation.** Rapid breathing associated with intense anxiety.

**Hypesthesia.** Partial loss of sensitivity.

**Hypnosis.** Trance-like mental state induced in a cooperative subject by suggestion.

**Hypnotherapy.** Use of hypnosis in psychotherapy.

**Hypo-**. Prefix meaning "decreased" or "insufficient."

**Hypoactive sexual desire disorder.** Sexual dysfunction in which either a man or a woman shows little or no sexual drive or interest.

**Hypochondriacal delusions.** Delusions concerning various horrible disease conditions, such as the belief that one's brain is turning to dust.

**Hypochondriasis.** Preoccupation, based on misinterpretations of bodily symptoms, with the fear that one has a serious disease.

**Hypomania.** Mild form of mania.

**Hypomanic episode.** A condition lasting at least 4 days in which a person experiences abnormally elevated, expansive, or irritable mood. At least three out of seven other designated symptoms similar to those in a manic episode must also be present but to a lesser degree than in mania.

**Hypothalamic-pituitary-adrenal axis (HPA axis).** Brain endocrine system involved in responding to stress in which the hypothalamus and pituitary send messages to the adrenal gland which releases a stress hormone that feeds back on the hypothalamus.

**Hypothalamus.** Key structure at the base of the brain; important in emotion and motivation.

**Hypothesis.** Statement or proposition, usually based on observation, that is tested in an experiment; may be refuted or supported by experimental results but can never be conclusively proved.

**Hypoxia.** Insufficient delivery of oxygen to an organ, especially the brain.

**Hysteria.** Older term used for conversion disorders; involves the appearance of symptoms of organic illness in the absence of any related organic pathology.

## I

**Id.** In psychoanalytic theory, the reservoir of instinctual drives and the first structure to appear in infancy.

**Identical twins.** Monozygotic twins; developed from a single fertilized egg.

**Identification.** Ego-defense mechanism in which a person identifies himself or herself with some person or institution, usually of an illustrious nature.

**Ideology.** System of beliefs.

**Illusion.** Misinterpretation of sensory data; false perception.

**Imaginal exposure.** Form of exposure therapy that does not involve a real stimulus. Instead, the patient is asked to imagine the feared stimulus or situation.

**Immaturity.** Pattern of childhood maladaptive behaviors suggesting lack of adaptive skills.

**Immune reaction.** Complex defensive reaction initiated on detection of an antigen invading the body.

**Immune system.** The body's principal means of defending itself against the intrusion of foreign substances.

**Immunosuppression.** A downregulation or dampening of the immune system. This can be short or long term and can be triggered by injury, stress, illness, and other factors.

**Implicit memory.** Memory that occurs below the conscious level.

**Implicit perception.** Perception that occurs below the conscious level.

**In vivo exposure.** Exposure that takes place in a real-life situation as opposed to the therapeutic or laboratory setting.

**Incentive.** External inducement to behave in a certain way.

**Incest.** Culturally prohibited sexual relations between family members, such as a brother and sister or a parent and child.

**Incidence.** Occurrence (onset) rate of a given disorder in a given population.

**Independent variable.** Factor whose effects are being examined and which is manipulated in some way, while other variables are held constant.

**Index case.** In a genetic study, an individual who evidences the trait in which the investigator is interested. Same as *proband*.

**Indicated intervention.** Early detection and prompt treatment of maladaptive behavior in a person's family and community setting.

**Infantile autism.** See **Autism**.

**Inhibition.** Restraint of impulse or desire.

**Innate.** Inborn.

**Inpatient.** Hospitalized patient.

**Insanity.** Legal term for mental disorder, implying lack of responsibility for one's acts and inability to manage one's affairs.

**Insanity defense (NGRI).** The not guilty by reason of insanity plea used as a legal defense in criminal trials.

**Insight.** Clinically, a person's understanding of his or her illness or of the motivations underlying a behavior pattern; in general psychology, the sudden grasp or understanding of meaningful relationships in a situation.

**Insight therapy.** Type of psychotherapy that focuses on helping a client achieve greater self-understanding with respect to his or her motives, values, coping patterns, and so on.

**Insomnia.** Difficulty in sleeping.

**Instinct.** Inborn tendency to perform particular behavior patterns under certain conditions in the absence of learning.

**Instrumental (operant) conditioning.** Reinforcement of a subject for making a correct response that leads either to receipt of something rewarding or to escape from something unpleasant.

**Insulin coma therapy.** Physiological treatment for schizophrenia that is rarely used today; it involved administration of increasing amounts of insulin until the patient went into shock.

**Integrative behavioral couple therapy.** Modification of traditional behavioral couple therapy that has a focus on acceptance of the partner rather than being solely change oriented.

**Intellectual disability.** A disorder with onset during the developmental period that includes intellectual and adaptive functioning.

**Intellectualization.** Ego-defense mechanism by which a person achieves some measure of insulation from emotional hurt by cutting off or distorting the emotional charge that normally accompanies hurtful situations.

**Intelligence.** The ability to learn, reason, and adapt.

**Intelligence quotient (IQ).** Measurement of "intelligence" expressed as a number or position on a scale.

**Intelligence test.** Test used in establishing a subject's level of intellectual capability.

**Intensive care management (ICM).** Use of multidisciplinary teams with limited caseloads to ensure that discharged patients do not get overlooked and "lost" in the system.

**Interdisciplinary (multidisciplinary)**

**approach.** Integration of various scientific disciplines in understanding, assessing, treating, and preventing mental disorders.

**Intermittent reinforcement.** Reinforcement given intermittently rather than after every response.

**Internal validity.** The extent to which a study is free of confounds, is methodologically sound,

and allows the researcher to have confidence in the findings.

#### **International Classification of Diseases (ICD-10).**

System of classification of disorders published by the World Health Organization.

**Interoceptive conditioning.** This term refers to a learning process that is similar to classic conditioning. There are two conditioned stimuli and one unconditioned response.

**Interoceptive fears.** Fear of various internal bodily sensations.

**Interpersonal accommodation.** Process through which two people develop patterns of communication and interaction that enable them to attain common goals, meet mutual needs, and build a satisfying relationship.

**Interpersonal perspective.** Approach to understanding abnormal behavior that views much of psychopathology as rooted in the unfortunate tendencies we develop while dealing with our interpersonal environments; it thus focuses on our relationships, past and present, with other people.

**Interpersonal therapy (IPT).** A time-limited psychotherapy approach that focuses on the interpersonal context and on building interpersonal skills.

**Intrapsychic conflict.** Inner mental struggles resulting from the interplay of the id, ego, and superego when the three subsystems are striving for different goals.

**Introjection.** Internal process by which a child incorporates symbolically, through images and memories, important people in his or her life.

**Intromission.** Insertion of the penis into the vagina or anus.

**Introspection.** Observing (and often reporting on) one's inner experiences.

**Introversion.** Direction of interest toward one's inner world of experience and toward concepts rather than external events and objects or people.

**Ionizing radiation.** Form of radiation; major cause of gene mutations.

**Isolation.** Ego-defense mechanism by means of which contradictory attitudes or feelings that normally accompany particular attitudes are kept apart, thus preventing conflict or hurt.

#### **J**

**Juvenile delinquency.** Legal term used to refer to illegal acts committed by minors.

**Juvenile paresis.** General paresis in children, usually of congenital origin.

#### **K**

**Klinefelter's syndrome.** Type of mental retardation associated with sex chromosome anomaly.

**Korsakoff's syndrome.** This disorder, also referred to as Korsakoff's dementia, Korsakoff's psychosis, or amnesic-confabulatory syndrome, is a neurological condition

resulting from chronic alcohol abuse and severe malnutrition (vitamin B).

#### **L**

**La belle indifférence.** The unconcern about serious illness or disability that is sometimes characteristic of conversion disorder.

**Labeling.** Assigning a person to a particular diagnostic category, such as schizophrenia.

**Lability.** Instability, particularly with regard to affect.

**Latency stage.** In psychoanalytic theory, a stage of psychosexual development during which sexual motivations recede in importance and a child is preoccupied with developing skills and other activities.

**Latent.** Inactive or dormant.

**Latent content.** In psychoanalytic theory, repressed actual motives of a dream that are seeking expression but are so painful or unacceptable that they are disguised by the manifest content of the dream.

**Late-onset Alzheimer's disease.** The occurrence of Alzheimer's disease in the more elderly. One gene thought to be involved in this form of Alzheimer's disease is the APOE gene.

**Law of effect.** Principle that responses that have rewarding consequences are strengthened and those that have aversive consequences are weakened or eliminated.

**Learned helplessness.** A theory that animals and people exposed to uncontrollable aversive events learn that they have no control over these events and this causes them to behave in a passive and helpless manner when later exposed to potentially controllable events. Later extended to become a theory of depression.

**Learning.** Modification of behavior as a consequence of experience.

**Learning disabled (LD).** Term used to describe children who exhibit deficits in academic skills.

**Learning disorders.** A set of disorders that reflect deficits in academic performance.

**Leptin.** Leptin is a hormone produced by fat cells that acts to reduce food intake.

**Lesbian.** Female homosexual person.

**Lesion.** Anatomically localized area of tissue pathology in an organ or a part of the brain.

**Lethality scale.** Criteria used to assess the likelihood of a person's committing suicide.

**Leukocytes.** See **Lymphocytes**.

**Libido.** In psychoanalytic theory, a term used to describe the instinctual drives of the id; the basic constructive energy of life, primarily sexual in nature.

**Life crisis.** Stress situation that approaches or exceeds a person's capacity to adjust.

**Life history method.** Technique of psychological observation in which the development of particular forms of behavior is traced by

means of records of a subject's past or present behavior.

**Lifestyle.** General pattern of assumptions, motives, cognitive styles, and coping techniques that characterize a person's behavior and give it consistency.

**Lifetime prevalence.** The proportion of living persons in a population who have ever had a disorder up to the time of the epidemiological assessment.

**Linkage analysis.** Genetic research strategy in which occurrence of a disorder in an extended family is compared with that of a genetic marker for a physical characteristic or biological process that is known to be located on a particular chromosome.

**Lithium.** A common salt that consists of a soft, silver-white metal; it has been found to reduce the symptoms of bipolar disorder although it has a number of negative side-effects.

**Lobotomy.** See **Prefrontal lobotomy**.

**Locomotor ataxia.** Muscular incoordination usually resulting from syphilitic damage to the spinal cord pathways.

**Longitudinal design.** A research design in which people are followed over time.

**LSD (lysergic acid diethylamide).** The most potent of the hallucinogens. It is odorless, colorless, and tasteless, and an amount smaller than a grain of salt can produce intoxication.

**Lunacy.** Old term roughly synonymous with insanity.

**Lycanthropy.** Delusion of being a wolf.

**Lymphocyte.** Generalized term for white blood cells involved in immune protection.

#### **M**

**Macrocephaly.** Rare type of mental retardation characterized by an increase in the size and weight of the brain, enlargement of the skull, visual impairment, convulsions, and other neurological symptoms resulting from abnormal growth of glial cells that form the supporting structure for brain tissue.

**Macrophage.** Literally, "big eater." A white blood cell that destroys antigens by engulfment.

**Madness.** Nontechnical term for severe mental disorder.

**Magnetic resonance imaging (MRI).** Internal scanning technique involving measurement of variations in magnetic fields that allows visualization of the anatomical features of internal organs, including the central nervous system and particularly the brain.

**Mainstreaming.** Placement of mentally retarded children in regular school classrooms for all or part of the day.

**Major depressive disorder.** Moderate-to-severe mood disorder in which a person experiences only major depressive episodes but no hypomanic, manic, or mixed episodes. *Single*

*episode* if only one; *recurrent episode* if more than one.

**Major depressive episode.** A mental condition in which a person must be markedly depressed for most of every day for most days for at least 2 weeks. In addition, a total of at least five out of nine designated symptoms must also be present during the same time period.

**Major depressive episode with atypical features.** A type of major depressive episode which includes a pattern of symptoms characterized by marked mood reactivity, as well as at least two out of four other designated symptoms.

**Major depressive episode with catatonic features.** A subset of major depressive disorders that is characterized by severe disturbances in motor function.

**Major depressive episode with melancholic features.** A type of major depressive episode which includes marked symptoms of loss of interest or pleasure in almost all activities, plus at least three of six other designated symptoms.

**Major Neurocognitive Disorder.** A new *DSM-5* diagnosis, this involves severe impairment in cognitive functioning that reflects a significant decline from the person's previous level of performance. The problems in cognitive functioning create problems for the person in terms of their ability to perform routine activities.

**Major tranquilizers.** Antipsychotic drugs, such as the phenothiazines.

**Maladaptive (abnormal) behavior.** Behavior that is detrimental to the well-being of an individual or a group.

**Maladjustment.** More or less enduring failure of adjustment; lack of harmony with self or environment.

**Male erectile disorder.** Sexual dysfunction in which a male is unable to achieve or maintain an erection sufficient for successful sexual gratification; formerly known as impotence.

**Male hypoactive sexual disorder.** Sexual dysfunction in which a man shows little or no sexual drive or interest.

**Malingering.** Consciously faking illness or symptoms of disability to achieve some specific nonmedical objective.

**Managed health care.** System of corporations that secures services from hospitals, physicians, and other providers for treating a designated population, with the goal of holding down health-care cost.

**Mania.** Emotional state characterized by intense and unrealistic feelings of excitement and euphoria.

**Manic episode.** A condition in which a person shows markedly elevated, euphoric, or expansive mood, often interrupted by occasional outbursts of intense irritability or even violence that lasts for at least 1 week. In addition,

at least three out of seven other designated symptoms must also occur.

**Manic-depressive psychoses.** Older term denoting a group of psychotic disorders characterized by prolonged periods of excitement and overactivity (mania) or by periods of depression and underactivity (depression) or by alternation of the two. Now known as *bipolar disorders*.

**Manifest content.** In psychoanalytic theory, the apparent (or obvious) meaning of a dream; masks the latent (or hidden) content.

**Manualized therapy.** Standardization of psycho-social treatments (as in development of a manual) to fit the randomized clinical paradigm.

**Marijuana.** Mild hallucinogenic drug derived from the hemp plant, often smoked in cigarettes called reefers or joints.

**Marital therapy.** See *Couples counseling*.

**Masked disorder.** "Masking" of underlying depression or other emotional disturbance by delinquent behavior or other patterns seemingly unrelated to the basic disturbance.

**Masochism.** Sexual stimulation and gratification from experiencing pain or degradation in relating to a lover.

**Mass madness.** Historically, widespread occurrence of group behavior disorders that were apparently cases of hysteria.

**Masturbation.** Self-stimulation of genitals for sexual gratification.

**Maternal deprivation.** Lack of adequate care and stimulation by the mother or mother surrogate.

**Maturation.** Process of development and body change resulting from heredity rather than learning.

**Medical model.** View of disordered behavior as a symptom of a disease process rather than as a pattern representing faulty learning or cognition.

**Melancholic type.** Subtype of major depression that involves loss of interest or pleasure in nearly all activities and other symptoms, including early morning awakenings, worse depression in the morning, psychomotor agitation or retardation, loss of appetite or weight, excessive guilt, and sadness qualitatively different from that usually experienced after a loss.

**Meninges.** Membranes that envelop the brain and spinal cord.

**Mental age (MA).** Scale unit indicating level of intelligence in relation to chronological age.

**Mental disorder.** Entire range of abnormal behavior patterns.

**Mental hygiene movement.** Movement that advocated a method of treatment focused almost exclusively on the physical well-being of hospitalized mental patients.

**Mental illness.** Serious mental disorder.

**Mental retardation.** Significantly subaverage general intellectual functioning that is

accompanied by significant limitations in adaptive functioning and is obvious during the developmental period.

**Mescaline.** Hallucinogenic drug derived from the peyote cactus.

**Mesmerism.** Theory of "animal magnetism" (hypnosis) formulated by Anton Mesmer.

**Mesocorticolimbic dopamine pathway**

**(MCPL).** Center of psychoactive drug activation in the brain. This area is involved in the release of dopamine and in mediating the rewarding properties of drugs.

**Meta-analysis.** A statistical method used to combine the results of a number of similar research studies. The data from each study are transformed into a common metric called the *effect size*. This allows the data from the various studies to be combined and then analyzed. You can think of a meta-analysis as being like research that you are already familiar with, except that the "participants" are individual research studies, not individual people.

**Methadone.** Synthetic narcotic related to heroin; used in the treatment of heroin addiction because it satisfies the craving for heroin without producing serious psychological impairment.

**Microcephaly.** Type of mental retardation resulting from impaired development of the brain and a consequent failure of the cranium to attain normal size.

**Migraine.** Intensely painful, recurrent headache that typically involves only one side of the head and may be accompanied by nausea and other disturbances.

**Mild (disorder).** Disorder low in severity.

**Mild Neurocognitive Disorder.** A new *DSM-5* diagnosis that is characterized by a modest decline in cognitive functioning that does not interfere with the person's ability to perform the routine tasks.

**Milieu.** Immediate environment, physical or social or both.

**Milieu therapy.** General approach to treatment for hospitalized patients that focuses on making the hospital environment itself a therapeutic community.

**Minnesota Multiphasic Personality Inventory (MMPI/MMPI-2).** Widely used and empirically validated personality scales.

**Minor tranquilizers.** Antianxiety drugs, such as the benzodiazepines.

**Mixed episode.** A condition in which a person is characterized by symptoms of both full-blown manic and major depressive episodes for at least 1 week, whether the symptoms are intermixed or alternate rapidly every few days.

**Model.** Analogy that helps a scientist order findings and see important relationships among them.

- Modeling.** Learning of skills by imitating another person who performs the behavior to be acquired.
- Moderate (disorder).** Disorder intermediate in severity.
- Monoamine-oxidase inhibitors (MAOIs).** Class of antidepressant drugs sometimes used for treating depression.
- Monozygotic twins.** Identical twins, developed from one fertilized egg.
- Mood congruent.** Delusions or hallucinations that are consistent with a person's mood.
- Mood disorders.** Disturbances of mood that are intense and persistent enough to be clearly maladaptive.
- Mood incongruent.** Delusional thinking that is inconsistent with a person's predominant mood.
- Moral management.** Wide-ranging method of treatment that focuses on a patient's social, individual, and occupational needs.
- Moral therapy.** Therapy based on provision of kindness, understanding, and favorable environment; prevalent during early part of the nineteenth century.
- Morbid.** Unhealthful, pathological.
- Morphine.** Addictive drug derived from opium that can serve as a powerful sedative and pain reliever.
- Motivation.** Often used as a synonym for *drive* or *activation*; implies that an organism's actions are partly determined in direction and strength by its own inner nature.
- Motivational interviewing.** A brief form of therapy, often used in areas of substance abuse and addiction, that allows clients to explore their desires, reasons, ability, and need for change.
- Motive.** Internal condition that directs action toward some goal; the term is generally used to include both the drive and the goal to which it is directed.
- Multi-infarct dementia.** See **Vascular dementia**.
- Multiple personality disorder.** See **Dissociative identity disorder**.
- Mutant gene.** Gene that has undergone some change in structure.
- Mutation.** Change in the composition of a gene, usually causing harmful or abnormal characteristics to appear in the offspring.
- Mutism.** Refusal or inability to speak.
- ## N
- Nancy School.** Group of physicians in nineteenth-century Europe who accepted the view that hysteria was a sort of self-hypnosis.
- Narcissism.** Self-love.
- Narcissistic personality disorder.** Exaggerated sense of self-importance, preoccupation with being admired, and lack of empathy for the feelings of others.
- Narcolepsy.** Disorder characterized by transient, compulsive states of sleepiness.
- Narcotic drugs.** Drugs, such as morphine, that lead to physiological dependence and increased tolerance.
- Natural killer cell.** White blood cell that destroys antigens by chemical dissolution.
- Necessary cause.** A condition that must exist for a disorder to occur.
- Need.** Biological or psychological condition whose gratification is necessary for the maintenance of homeostasis or for self-actualization.
- Negative affect.** The experience of an emotional state characterized by negative emotions. Such negative emotions might include anger, anxiety, irritability, and sadness.
- Negative automatic thoughts.** Thoughts that are just below the surface of awareness and that involve unpleasant pessimistic predictions.
- Negative cognitive triad.** Negative thoughts about the self, the world, and the future.
- Negative correlation.** A relationship between two variables such that a high score on one variable is associated with a low score on another variable.
- Negative symptoms.** Symptoms that reflect an absence or deficit in normal functions (e.g., blunted affect, social withdrawal).
- Negative-symptom schizophrenia.** Schizophrenia characterized by an absence or deficit of normal behaviors, such as emotional expressiveness, communicative speech, and reactivity to environmental events.
- Negativism.** Form of aggressive withdrawal that involves refusing to cooperate or obey commands, or doing the exact opposite of what has been requested.
- Neologisms.** New words; a feature of language disturbance in schizophrenia.
- Neonate.** Newborn infant.
- Neoplasm.** Tumor.
- Nervous breakdown.** General term used to refer broadly to lowered integration and inability to deal adequately with one's life situation.
- Neurodevelopmental disorders.** A group of disorders in *DSM-5* that are typically manifested in early childhood.
- Neurofibrillary tangles.** Twisted and web-like nerve filaments that characterize the brains of patients with Alzheimer's disease.
- Neurological examination.** Examination to determine the presence and extent of organic damage to the nervous system.
- Neurology.** Field concerned with the study of the brain and nervous system and disorders thereof.
- Neuron.** Individual nerve cell.
- Neurophysiology.** Branch of biology concerned with the functioning of nervous tissue and the nervous system.
- Neuropsychological assessment.** Use of psychological tests that measure a person's cognitive, perceptual, and motor performance to obtain clues to the extent and locus of brain damage.
- Neuropsychological disorders.** Disorders that occur when there has been significant organic impairment or damage to a normal adolescent or adult brain.
- Neuropsychological mood syndromes.** Serious mood disturbances apparently caused by disruptions in the normal physiology of cerebral function.
- Neuropsychological personality syndromes.** Changes in an individual's general personality style or traits following brain injury of one or another type.
- Neurosis.** Term historically used to characterize maladaptive behavior resulting from intrapsychic conflict and marked by prominent use of defense mechanisms.
- Neurosurgery.** Surgery on the nervous system, especially the brain.
- Neurosyphilis.** Syphilis affecting the central nervous system.
- Neurotic behavior.** Anxiety-driven, exaggerated use of avoidance behaviors and defense mechanisms.
- Neurotic disorders.** Psychodynamic term for anxiety-driven mental health conditions that are manifest through avoidance patterns and defensive reactions.
- Neuroticism.** Personality pattern including the tendency to experience anxiety, anger, hostility, depression, self-consciousness, impulsiveness, and vulnerability.
- Neurotransmitters.** Chemical substances that are released into a synapse by the presynaptic neuron and that transmit nerve impulses from one neuron to another.
- NGRI plea.** The not guilty by reason of insanity plea, or NGRI, is a legal defense a defendant might use to claim that he or she was not guilty of a crime because of insanity.
- Nicotine.** Addictive alkaloid that is the chief active ingredient in tobacco and a drug of dependence.
- Night hospital.** Mental hospital in which an individual may receive treatment during all or part of the night while carrying on his or her usual occupation in the daytime.
- Nihilistic delusion.** Fixed belief that everything is unreal.
- Nomenclature.** A formalized naming system.
- Nondirective therapy.** Approach to psychotherapy in which a therapist refrains from giving advice or directing the therapy. See also **Client-centered psychotherapy**.
- Norepinephrine.** Catecholamine neurotransmitter substance.
- Norm.** Standard based on the measurement of a large group of people; used for comparing the scores of an individual with those of others in a defined group.
- Normal.** Conforming to the usual or norm; healthy.

**Normal distribution.** Tendency for most members of a population to cluster around a central point or average with respect to a given trait, with the rest spreading out to the two extremes in decreasing frequency.

**NREM sleep.** Stages of sleep not characterized by the rapid eye movements that accompany dreaming.

## O

**Obesity.** The condition of having elevated fat masses in the body. Obesity is defined as having a body mass index (BMI) of 30 or higher.

**Objective personality tests.** Structured tests, such as questionnaires, self-inventories, or rating scales, used in psychological assessment.

**Object-relations theory.** In psychoanalytic theory, this viewpoint focuses on an infant or young child's interactions with "objects" (i.e., real or imagined people), as well as how they make symbolic representations of important people in their lives.

**Observational learning.** Learning through observation alone without directly experiencing an unconditioned stimulus (for classical conditioning) or a reinforcement (for instrumental conditioning).

**Observational method.** Systematic technique by which observers are trained to watch and record behavior without bias.

**Observational research.** In contrast to experimental research (which involves manipulating variables in some way and seeing what happens), in observational research the researcher simply observes or assesses the characteristics of different groups, learning about them without manipulating the conditions to which they are exposed. Sometimes called *correlational research*, although the former is the preferred term.

**Obsessions.** Persistent and recurrent intrusive thoughts, images, or impulses that a person experiences as disturbing and inappropriate but has difficulty suppressing.

**Obsessive-compulsive disorder (OCD).** Anxiety disorder characterized by the persistent intrusion of unwanted and intrusive thoughts or distressing images; these are usually accompanied by compulsive behaviors designed to neutralize the obsessive thoughts or images or to prevent some dreaded event or situation.

**Obsessive-compulsive personality disorder (OCPD).**

Perfectionism and excessive concern with maintaining order, control, and adherence to rules.

**Occipital lobe.** Portion of cerebrum concerned chiefly with visual function.

**Oedipus complex.** Desire for sexual relations with a parent of opposite sex; specifically, the desire of a boy for his mother, with his father a hated rival.

**Olfactory hallucinations.** Hallucinations involving the sense of smell.

**Operant (or instrumental) conditioning.** Form of learning in which if a particular response is reinforced, it becomes more likely to be repeated on similar occasions.

**Operational definition.** Definition of a concept on the basis of a set of operations that can be observed and measured.

**Opium.** Narcotic drug that leads to physiological dependence and the development of tolerance; derivatives are morphine, heroin, and codeine.

**Oppositional defiant disorder (ODD).**

Childhood disorder that appears by age 6 and is characterized by persistent acts of aggressive or antisocial behavior that may or may not be against the law.

**Oral stage.** First stage of psychosexual development in Freudian theory, in which mouth or oral activities are the primary source of pleasure.

**Organic mental disorders.** Outdated term used to refer to disorders that resulted from some identifiable brain pathology.

**Organic viewpoint.** Concept that all mental disorders have an organic basis. See also **Biological viewpoint**.

**Orgasm.** Third phase of the human sexual response, during which there is a release of sexual tension and a peaking of sexual pleasure.

**Outcome research.** Studies of effectiveness of treatment.

**Outpatient.** Ambulatory client who visits a hospital or clinic for examination and treatment, as distinct from a hospitalized client.

**Ovaries.** Female gonads.

**Overanxious disorder.** Disorder of childhood characterized by excessive worry and persistent fears unrelated to any specific event; often includes somatic and sleeping problems.

**Overcompensation.** Type of ego-defense mechanism in which an undesirable trait is covered up by exaggerating a desirable trait.

**Overloading.** Subjecting an organism to excessive stress, for example, forcing the organism to handle or "process" an excessive amount of information.

**Overprotection.** Shielding a child to the extent that he or she becomes too dependent on the parent.

**Overt behavior.** Activities that can be observed by an outsider.

**Ovum.** Female gamete or germ cell.

## P

**Pain disorder.** Experience of pain of sufficient duration and severity to cause significant life disruption in the absence of medical pathology that would explain it.

**Panic.** A basic emotion that involves activation of the "fight-or-flight" response of the sympathetic nervous system and that is often characterized by an overwhelming sense of fear or terror.

**Panic attack.** A severe, intense fear response that appears to come out of the blue; it has many physical and cognitive symptoms such as fear of dying or losing control.

**Panic disorder.** Occurrence of repeated unexpected panic attacks, often accompanied by intense anxiety about having another one.

**Panic provocation procedures.** A variety of biological challenge procedures that provoke panic attacks at higher rates in people with panic disorder than in people without panic disorder.

**Paradigm.** Model or pattern; in research, a basic design specifying concepts considered legitimate and procedures to be used in the collection and interpretation of data.

**Paranoia.** Symptoms of delusions and impaired contact with reality without the bizarre, fragmentation, and severe personality disorganization characteristic of schizophrenia.

**Paranoid personality disorder.** Pervasive suspiciousness and distrust of others.

**Paranoid schizophrenia.** See **Schizophrenia, paranoid type**.

**Paraphilics.** Persistent sexual behavior patterns in which unusual objects, rituals, or situations are required for full sexual satisfaction.

**Paraprofessional.** Person who has been trained in mental health services but not at the professional level.

**Parasympathetic nervous system.** Division of the autonomic nervous system that controls most of the basic metabolic functions essential for life.

**Paresis.** See **General paresis**.

**Paresthesia.** Exceptional sensations, such as tingling.

**Parkinson's disease.** A neurodegenerative disease characterized by motor problems (rigidity, tremors) and caused by destruction of dopamine neurons in the brain.

**Passive-aggressive personality disorder.**

Provisional category of personality disorder in *DSM-IV-TR* characterized by a pattern of passive resistance to demands in social or work situations, which may take such forms as simple resistance to performing routine tasks, being sullen or argumentative, or alternating between defiance and submission.

**Pathogenic.** Pertaining to conditions that lead to pathology.

**Pathological gambling.** Progressive disorder characterized by loss of control over gambling, preoccupation with gambling and obtaining money for gambling, and irrational gambling behavior in spite of adverse consequences.

- Pathology.** Abnormal physical or mental condition.
- PCP.** Phencyclidine; developed as a tranquilizer but not marketed because of its unpredictability. Known on the street as “angel dust,” this drug produces stupor and, at times, prolonged coma or psychosis.
- Pedigree (family history) method.** Observation of samples of relatives of each subject or each carrier of the trait or disorder in question.
- Pedophilic disorder.** A paraphilia in which an adult’s preferred or exclusive sexual partner is a prepubertal child.
- Pemoline.** Drug, similar to Ritalin, used to treat ADHD
- Perception.** Interpretation of sensory input.
- Perceptual filtering.** Processes involved in selective attention to aspects of the great mass of incoming stimuli that continually impinge on an organism.
- Perfectionism.** The need to get things exactly right. A personality trait that may increase risk for the development of eating disorders, perhaps because perfectionistic people may be more likely to idealize thinness.
- Performance test.** Test in which perceptual-motor rather than verbal content is emphasized.
- Peripheral nervous system.** Nerve fibers passing between the central nervous system and the sense organs, muscles, and glands.
- Perseveration.** Persistent continuation of a line of thought or activity once it is under way. Clinically inappropriate repetition.
- Persistent depressive disorder.** A new *DSM-5* disorder that involves long-standing depressed mood (2 years or more). The disorder incorporates dysthymic disorder and chronic major depression from *DSM-IV*.
- Personality.** Unique pattern of traits that characterize an individual.
- Personality disorder.** Gradual development of inflexible and distorted personality and behavioral patterns that result in persistently maladaptive ways of perceiving, thinking about, and relating to the world.
- Personality or psychological decompensation.** Inability to adapt to sustained or severe stressors.
- Personality profile.** Graphical summary that is derived from several tests or subtests of the same test battery or scale and that shows the personality configuration of an individual or group of individuals.
- Personality test.** See **Objective personality tests** and **Projective personality tests**.
- Person-centered therapy.** See **Client-centered therapy**.
- Pervasive developmental disorders (PDDs).** Severely disabling conditions marked by deficits in language, perceptual, and motor development; defective reality testing; and inability to function in social situations.
- Pessimistic attributional style.** Cognitive style involving a tendency to make internal, stable, and global attributions for negative life events.
- PET scan.** See **Positron emission tomography**.
- Phagocyte.** Circulating white blood cell that binds to antigens and partially destroys them by engulfment.
- Phallic stage.** In psychoanalytic theory, the stage of psychosexual development during which genital exploration and manipulation occur.
- Pharmacology.** The science of drugs.
- Pharmacotherapy.** Treatment by means of drugs.
- Phenomenological.** Pertaining to the immediate perceiving and experiencing of an individual.
- Phenotype.** The observed structural and functional characteristics of a person that result from interaction between the genotype and the environment.
- Phenylketonuria (PKU).** Type of mental retardation resulting from a baby’s lack of a liver enzyme needed to break down phenylalanine, an amino acid found in many foods.
- Phobia.** Persistent and disproportionate fear of some specific object or situation that presents little or no actual danger.
- Physiological dependence.** Type of drug dependence involving withdrawal symptoms when drug is discontinued.
- Pick’s disease.** Form of presenile dementia.
- Pineal gland.** Small gland at the base of the brain that helps regulate the body’s biological clock and may also establish pace of sexual development.
- Pituitary gland.** Endocrine gland associated with many regulatory functions.
- Placebo effect.** Positive effect experienced after an inactive treatment is administered in such a way that a person thinks he or she is receiving an active treatment.
- Placebo treatment.** An inert pill or otherwise neutral intervention that produces desirable therapeutic effects because of the subject’s expectations that it will be beneficial.
- Plaques.** Abnormal accumulations of protein found in the brains of patients with Alzheimer’s disease.
- Play therapy.** Use of play activities in psychotherapy with children.
- Pleasure principle.** Demand that an instinctual need be immediately gratified regardless of reality or moral considerations.
- Point prevalence.** The number of cases of a specific condition or disorder that can be found in a population at one given point in time.
- Polygenic.** Caused by the action of many genes together in an additive or interactive fashion.
- Poor premorbid schizophrenia.** See **Process schizophrenia**.
- Positive correlation.** A relationship between two variables such that a high score on one variable is associated with a high score on another variable.
- Positive psychology.** A new field that focuses on human traits (e.g., optimism) and resources that are potentially important for health and well-being.
- Positive reinforcer.** Reinforcer that increases the probability of recurrence of a given response.
- Positive symptoms.** Symptoms that are characterized by something being added to normal behavior or experience. Includes delusions, hallucinations, motor agitation, and marked emotional turmoil.
- Positive-symptom schizophrenia.** Schizophrenia characterized by something added to normal behavior and experience, such as marked emotional turmoil, motor agitation, delusions, and hallucinations.
- Positron emission tomography (PET) scan.** Scanning technique that measures metabolic processes to appraise how well an organ is functioning.
- Posthypnotic amnesia.** Subject’s lack of memory for the period during which he or she was hypnotized.
- Posthypnotic suggestion.** Suggestion given during hypnosis to be carried out by a subject after he or she is brought out of hypnosis.
- Postpartum depression.** Depression occurring after childbirth. Most commonly it is mild and transient (postpartum blues) but can become a major depressive episode.
- Posttraumatic stress disorder (PTSD).** Disorder that occurs following an extreme traumatic event, in which a person reexperiences the event, avoids reminders of the trauma, and exhibits persistent increased arousal.
- Posttraumatic theory (of DID).** The view that DID starts from the child’s attempt to cope with an overwhelming sense of hopelessness and powerlessness in the face of repeated traumatic abuse.
- Predisposition.** Tendency to develop certain symptoms under given stress conditions.
- Prefrontal lobotomy.** Surgical procedure used before the advent of antipsychotic drugs, in which the frontal lobes of the brain were severed from the deeper centers underlying them, resulting in permanent structural changes in the brain.
- Prejudice.** Emotionally toned conception favorable or unfavorable to some person, group, or idea—typically in the absence of sound evidence.
- Premature ejaculation.** Persistent and recurrent onset of orgasm and ejaculation with minimal sexual stimulation.
- Prematurity.** Birth of an infant before the end of a normal period of pregnancy.

**Premorbid.** Existing before the onset of mental disorder.

**Prenatal.** Before birth.

**Prepared learning.** The view that people are biologically prepared through evolution to more readily acquire fears of certain objects or situations that may once have posed a threat to our early ancestors. For example, people more readily develop fears of snakes and spiders if they are paired with aversive events, than they develop fears of knives or guns.

**Presenile dementia.** Mental disorders resulting from brain degeneration before old age.

**Presenting problem.** Major symptoms and behavior the client is experiencing.

**Prevalence.** In a population, the proportion of active cases of a disorder that can be identified at a given point in time or during a given period.

**Primary gain.** In psychodynamic theory it is the goal achieved by symptoms of conversion disorder by keeping internal intrapsychic conflicts out of awareness. In contemporary terms it is the goal achieved by symptoms of conversion disorder by allowing the person to escape or avoid stressful situations.

**Primary prevention.** Older term for preventive efforts aimed at reducing the incidence of a disease or disorder and fostering positive health. See **Universal prevention**.

**Primary process thinking.** Gratification of id demands by means of imagery or fantasy without the ability to undertake the realistic actions needed to meet those instinctual demands.

**Proband.** In a genetic study, the original individual who evidences the trait in which the investigator is interested. Same as *index case*.

**Problem checklist.** Inventory used in behavioral assessment to determine an individual's fears, moods, and other problems.

**Problem drinker.** Behavioral term referring to one who has serious problems associated with drinking.

**Process schizophrenia.** Schizophrenic pattern—marked by seclusiveness, gradual waning of interest in the surrounding world, diminished emotional responsiveness, and mildly inappropriate responses—that develops gradually and tends to be long lasting; alternatively known as *poor premorbid schizophrenia* and *chronic schizophrenia*.

**Prodromal.** Considered to be an early (sub-clinical) stage of schizophrenia, characterized by very low-level symptoms or behavioral idiosyncrasies.

**Prognosis.** Prediction of the probable course and outcome of a disorder.

**Projection.** Ego-defense mechanism of attributing one's own unacceptable motives or characteristics to others.

**Projective personality tests.** Techniques that use various ambiguous stimuli that a subject is encouraged to interpret and from which the subject's personality characteristics can be analyzed.

**Prolonged exposure.** A behaviorally oriented treatment strategy in which the patient is asked to vividly recount the traumatic event over and over until there is a decrease in their emotional responses.

**Prospective research.** Method that often focuses on individuals who have a higher-than-average likelihood of becoming psychologically disordered before abnormal behavior is observed.

**Protective factors.** Influences that modify a person's response to an environmental stressor, making it less likely that the person will experience the adverse effects of the stressor.

**Prototypal approach.** Approach to classifying abnormal behavior that assumes the existence of prototypes of behavior disorders that, rather than being mutually exclusive, may blend into others with which they share many characteristics.

**Psilocybin.** Hallucinogenic drug derived from a variety of mushrooms.

**Psychedelic drugs.** Drugs such as LSD that often produce hallucinations.

**Psychiatric nursing.** Field of nursing primarily concerned with mental disorders.

**Psychiatric social worker.** Professional who has had graduate training in social work with psychiatric specialization, typically leading to a master's degree.

**Psychiatrist.** Medical doctor who specializes in the diagnosis and treatment of mental disorders.

**Psychiatry.** Field of medicine concerned with understanding, assessing, treating, and preventing mental disorders.

**Psychic trauma.** Any aversive experience that inflicts serious psychological damage on a person.

**Psychoactive substance.** Drug that affects mental functioning.

**Psychoactive substance abuse.** Pathological use of a substance resulting in potentially hazardous behavior or in continued use despite a persistent social, psychological, occupational, or health problem.

**Psychoactive substance dependence.** Use of a psychoactive substance to the point where one has a marked physiological need for increasing amounts of the substance to achieve the desired effects.

**Psychoanalysis.** Methods Freud used to study and treat patients.

**Psychoanalytic perspective.** Theory of psychopathology, initially developed by Freud, that emphasizes the inner dynamics of unconscious motives.

**Psychodrama.** Psychotherapeutic technique in which the acting of various roles is an essential part.

**Psychodynamic perspectives.** Theories of psychopathology based on modification and revision of Freud's theories.

**Psychodynamic therapy.** Psychological treatment that focuses on individual personality dynamics, usually from a psychodynamic or psychodynamically derived perspective.

**Psychogenic.** Of psychological origin: originating in the psychological functioning of an individual.

**Psychogenic amnesia.** Amnesia of psychological origin, common in initial reactions to traumatic experiences.

**Psychogenic illness.** Psychologically induced or maintained disease.

**Psychohistory.** A field of study analyzing history according to psychoanalytic principles.

**Psychological assessment.** The use of psychological procedures such as behavioral observations, interview, and psychological tests to obtain a picture of a client's mental health symptoms and personality.

**Psychological autopsy.** Analytical procedure used to determine whether or not death was self-inflicted and, if so, why.

**Psychological need.** Need emerging out of environmental interactions, for example, the need for social approval.

**Psychological screening.** Use of psychological procedures or tests to detect psychological problems among applicants in preemployment evaluations.

**Psychological test.** Standardized procedure designed to measure a subject's performance on a specified task.

**Psychomotor.** Involving both psychological and physical activity.

**Psychomotor retardation.** Slowing down of psychological and motor functions.

**Psychoneuroimmunology.** Study of the interactions between the immune system and the nervous system and the influence of these factors on behavior.

**Psychopathology.** Abnormal behavior.

**Psychopathy.** A condition involving the features of antisocial personality disorder and such traits as lack of empathy, inflated and arrogant self-appraisal, and glib and superficial charm.

**Psychopharmacology.** Science of determining which drugs alleviate which disorders and why they do so.

**Psychophysiological (psychosomatic) disorders.** Physical disorders in which psychological factors are believed to play a major causal role.

**Psychophysiological variables.** Measures of biological functioning including heart rate, blood pressure, EEG, and so on.

**Psychosexual development.** Freudian view of development as involving a succession of stages, each characterized by a dominant mode of achieving libidinal pleasure.

**Psychosexual stages of development.**

According to Freudian theory, there are five stages of psychosexual development, each characterized by a dominant mode of achieving sexual pleasure: the oral stage, the anal stage, the phallic stage, the latency stage, and the genital stage.

**Psychosis.** Severe impairment in the ability to tell what is real and what is not real.

**Psychosocial deprivation.** Lack of needed stimulation and interaction during early life.

**Psychosocial viewpoints.** Approaches to understanding mental disorders that emphasize the importance of early experience and an awareness of social influences and psychological processes within an individual.

**Psychosurgery.** Brain surgery used in the past with excessive frequency in the treatment of functional mental disorders.

**Psychotherapy.** Treatment of mental disorders by psychological methods.

**Psychotropic drugs.** Drugs whose main effects are mental or behavioral in nature.

**Purge.** Purging refers to the removal of food from the body by such means as self-induced vomiting or misuse of laxatives, diuretics, and enemas.

## Q

**Q-sort.** Personality measure in which a subject, or a clinician, sorts a number of statements into piles according to their applicability to the subject.

## R

**Racism.** Prejudice and discrimination directed toward individuals or groups because of their racial background.

**Random assignment.** A procedure used to create equivalent groups in which every research participant has an equal chance of being assigned to any group in the study.

**Random sample.** Sample drawn in such a way that each member of a population has an equal chance of being selected; it is hoped that such a sample will be fully representative of the population from which it is drawn.

**Randomized clinical trials (RCTs).** A clinical trial in which participants are randomly assigned to different treatments.

**Randomized controlled trials.** A randomized controlled trial involves a specific treatment group (the group the researchers are most interested in) as well as a control treatment group (against which the treatment group will be compared). Participants have an equal chance of being placed in either group because placement is determined randomly.

**Rape.** Sexual activity that occurs under actual or threatened forcible coercion of one person by another.

**Rapid cycling.** A pattern of bipolar disorder involving at least four manic or depressive episodes per year.

**Rapport.** Interpersonal relationship characterized by a spirit of cooperation, confidence, and harmony.

**Rating scales.** Formal structure for organizing information obtained from clinical observation and self-reports to encourage reliability and objectivity.

**Rational emotive behavior therapy (REBT).**

Form of psychotherapy focusing on changing a client's maladaptive thought processes, on which maladaptive emotional responses and thus behavior are presumed to depend.

**Rationalization.** Ego-defense mechanism that involves the use of contrived "explanations" to conceal or disguise unworthy motives for a person's behavior.

**Reaction formation.** Ego-defense mechanism that prevents the awareness or expression of unacceptable desires via the exaggerated adoption of seemingly opposite behavior.

**Reactive schizophrenia.** Schizophrenia pattern—marked by confusion and intense emotional turmoil—that normally develops suddenly and has identifiable precipitating stressors; alternatively known as *good premorbid schizophrenia*, *Type I schizophrenia*, and *acute schizophrenia*.

**Reality principle.** Awareness of the demands of the environment and adjustment of behavior to meet these demands.

**Reality testing.** Behavior aimed at testing or exploring the nature of a person's social and physical environment; often used more specifically to refer to testing the limits of the permissiveness of the social environment.

**Recessive gene.** Gene that is effective only when paired with an identical gene.

**Recidivism.** Shift back to one's original behavior (often delinquent or criminal) after a period of treatment or rehabilitation.

**Recompensation.** Increase in integration or inner organization. Opposite of *decompensation*.

**Recurrence.** A new occurrence of a disorder after a remission of symptom.

**Recurrent.** Term used to describe a disorder pattern that tends to come and go.

**Recurrent major depressive episode with a seasonal pattern.**

A form of major depression where the episodes of depression recur on a regular seasonal basis (fall/winter), but not at other times of the year.

**Referral.** Sending or recommending an individual or family for psychological assessment or treatment.

**Regression.** Ego-defense mechanism of retreat to an earlier developmental level involving less mature behavior and responsibility.

**Rehabilitation.** Use of reeducation rather than punishment to overcome behavioral deficits.

**Reinforcement.** The process of rewarding desired responses.

**Relapse.** Return of the symptoms of a disorder after a fairly short period of time.

**Reliability.** Degree to which a measuring device produces the same result each time it is used to measure the same thing or when two or more different raters use it.

**REM sleep.** Stage of sleep involving rapid eye movements (REM); associated with dreaming.

**Remission.** Marked improvement or recovery appearing in the course of a mental illness; may or may not be permanent.

**Representative sample.** Small group selected in such a way as to be representative of the larger group from which it is drawn.

**Repression.** Ego-defense mechanism that prevents painful or dangerous thoughts from entering consciousness.

**Residential treatment.** Out-of-home placements for children and adolescents with mental health problems.

**Residual schizophrenia.** See **Schizophrenia, residual type**.

**Resilience.** The ability to adapt successfully to even very difficult circumstances.

**Resistance.** Selye's second stage of responding to continuing trauma, involving finding some means to deal with the trauma and adjust to it. In psychodynamic treatment, the person's unwillingness or inability to talk about certain thoughts, motives, or experiences.

**Resistance to extinction.** Tendency of a conditioned response to persist despite lack of reinforcement.

**Resolution.** Final phase of the human sexual response, during which a person has a sense of relaxation and well-being.

**Response shaping.** Positive reinforcement technique used in therapy to establish, by gradual approximation, a response not initially in a person's behavioral repertoire.

**Reticular activating system (RAS).** Fibers going from the reticular formation to higher brain centers and presumably functioning as a general arousal system.

**Reticular formation.** Neural nuclei and fibers in the brain stem that apparently play an important role in arousing and alerting an organism and in controlling attention.

**Retrograde amnesia.** Loss of memory for events that occurred during a circumscribed period prior to brain injury or damage.

**Retrospective research.** Research approach that attempts to retrace earlier events in the life of a subject.

**Retrospective strategy.** Method of trying to uncover the probable causes of abnormal behavior by looking backward from the present.

**Rigidity.** Tendency to follow established coping patterns, with failure to see alternatives or extreme difficulty in changing one's established patterns.

**Ritalin.** Central nervous system stimulant often used to treat ADHD.

**Role-playing.** Form of assessment in which a person is instructed to play a part, enabling a clinician to observe a client's behavior directly.

**Rorschach Inkblot Test.** Use of 10 inkblot pictures to which a subject responds with associations that come to mind. Analysis of these responses enables a clinician to infer personality characteristics.

**Rumination.** Refers to the process of going over and over in one's mind or going over a thought repeatedly time and again.

## S

**Sadism.** Achievement of sexual gratification by inflicting physical or psychic pain or humiliation on a sexual partner.

**Saint Vitus's dance.** Name given to the dancing mania (and mass hysteria) that spread from Italy to Germany and the rest of Europe in the Middle Ages.

**Sample.** Group on which measurements are taken; should normally be representative of the population about which an inference is to be made.

**Sampling.** The process of selecting a representative subgroup from a defined population of interest.

**Scapegoating.** Displacement of aggression onto some object, person, or group other than the source of frustration.

**Schedule of reinforcement.** Program of rewards for requisite behavior.

**Schema.** An underlying representation of knowledge that guides current processing of information and often leads to distortions in attention, memory, and comprehension.

**Schizoaffective disorder.** Form of psychotic disorder in which the symptoms of schizophrenia co-occur with symptoms of a mood disorder.

**Schizoid personality disorder.** Inability to form social relationships or express feelings and lack of interest in doing so.

**Schizophrenia.** Disorder characterized by hallucinations, delusions, disorganized speech and behavior, as well as problems in self-care and general functioning.

**Schizophrenia, catatonic type.** Type of schizophrenia in which the central feature is pronounced motor symptoms, of either an excited or a stuporous type, which sometimes make for difficulty in differentiating this condition from a psychotic mood disorder.

**Schizophrenia, disorganized type.** Type of schizophrenia that usually begins at an earlier age and represents a more severe disintegration of the personality than in the other types of schizophrenia.

**Schizophrenia, paranoid type.** Type of schizophrenia in which a person is increasingly suspicious, has severe difficulties in interpersonal relationships, and experiences absurd, illogical, and often changing delusions.

**Schizophrenia, residual type.** Diagnostic category used for people who have experienced a schizophrenic episode from which they have recovered enough to not show prominent symptoms but are still manifesting some mild signs of their past disorder.

**Schizophrenia, undifferentiated type.** Type of schizophrenia in which a person meets the usual criteria for being schizophrenic—including (in varying combinations) delusions, hallucinations, thought disorder, and bizarre behavior—but does not clearly fit into one of the other types because of a mixed symptom picture.

**Schizophreniform disorder.** Category of schizophrenic-like psychosis less than 6 months in duration.

**Schizophrenogenic.** Schizophrenia-causing.

**Schizotypal personality disorder.** Excessive introversion, pervasive social interpersonal deficits, cognitive and perceptual distortions, and eccentricities in communication and behavior.

**Seasonal affective disorder.** Mood disorder involving at least two episodes of depression in the past 2 years occurring at the same time of year (most commonly fall or winter), with remission also occurring at the same time of year (most commonly spring).

**Secondary gain.** External circumstances that tend to reinforce the maintenance of disability.

**Secondary prevention.** Older term for prevention techniques that typically involve emergency or crisis intervention, with efforts focused on reducing the impact, duration, or spread of a problem. See **Selective intervention**.

**Secondary process thinking.** Reality-oriented rational processes of the ego for dealing with the external world and the exercise of control over id demands.

**Secondary reinforcer.** Reinforcement provided by a stimulus that has gained reward value by being associated with a primary reinforcing stimulus.

**Sedative.** Drug used to reduce tension and induce relaxation and sleep.

**Selective intervention.** Mobilization of prevention resources to eliminate or reduce a particular type of problem (such as teenage pregnancy or alcohol or drug abuse).

**Selective mutism.** Condition that involves the persistent failure to speak in specific social

situations and interferes with educational or social adjustment.

### Selective serotonin reuptake inhibitors (SSRIs).

A medication that inhibits serotonin that is used in the treatment of depression.

**Self (ego).** Integrating core of a personality that mediates between needs and reality.

**Self-acceptance.** Being satisfied with one's attributes and qualities while remaining aware of one's limitations.

**Self-actualizing.** Achieving one's full potentialities as a human being.

**Self-concept.** A person's sense of his or her own identity, worth, capabilities, and limitations.

**Self-esteem.** Feeling of personal worth.

**Self-evaluation.** Way in which an individual views the self, in terms of worth, adequacy, etc.

**Self-ideal (ego-ideal).** Person or "self" a person thinks he or she could and should be.

**Self-identity.** Individual's delineation and awareness of his or her continuing identity as a person.

**Self-instructional training.** Cognitive-behavioral method aimed at teaching a person to alter his or her covert behavior.

**Self-monitoring.** Observing and recording one's own behavior, thoughts, and feelings as they occur in various natural settings.

**Self-reinforcement.** Reward of self for desired or appropriate behavior.

**Self-report data.** Data collected directly from participants, typically by means of interviews or questionnaires.

**Self-report inventory.** Procedure in which a subject is asked to respond to statements in terms of their applicability to him or her.

**Self-schema.** Our view of what we are, what we might become, and what is important to us.

**Self-statements.** A person's implicit verbalizations of what he or she is experiencing.

**Senile.** Pertaining to old age.

**Senile dementia.** Mental disorders that sometimes accompany brain degeneration in old age.

**Sensate focus learning.** Learning to derive pleasure from touching one's partner and being touched by him or her; this training is used in sexual therapy to enhance sexual feelings and help overcome sexual dysfunction.

**Sensory deprivation.** Restriction of sensory stimulation below the level required for normal functioning of the central nervous system.

**Sentence completion test.** Projective technique utilizing incomplete sentences that a person is to complete, analysis of which enables a clinician to infer personality dynamics.

**Separation anxiety disorder.** Childhood disorder characterized by unrealistic fears, oversensitivity, self-consciousness, nightmares, and chronic anxiety.

- Separation-individuation.** According to Mahler, a developmental phase in which a child gains an internal representation of the self as distinct from representations of other objects.
- Sequelae.** Symptoms remaining as the aftermath of a disorder.
- Serotonin.** A neurotransmitter from the indoleamine class that is synthesized from the amino acid tryptophan. Also referred to as 5-HT(5-hydroxytryptamine), this neurotransmitter is thought to be involved in a wide range of psychopathological conditions.
- Set point.** The tendency of our bodies to resist efforts to bring about a marked change (increase or decrease) in weight.
- Severe (disorder).** Disorder of a high degree of seriousness.
- Severe major depressive episode with psychotic features.** Major depression involving loss of contact with reality, often in the form of delusions or hallucinations.
- Sex chromosomes.** Pair of chromosomes inherited by an individual that determine sex and certain other characteristics.
- Sexual abuse.** Sexual contact that involves physical or psychological coercion or occurs when at least one individual cannot reasonably consent to the contact.
- Sexual aversion disorder.** Sexual dysfunction in which a person shows extreme aversion to, and avoidance of, all genital sexual contact with a partner.
- Sexual dysfunction.** Impairment either in the desire for sexual gratification or in the ability to achieve it.
- Shaping.** Form of instrumental conditioning; at first, all responses resembling the desired one are reinforced, then only the closest approximations, until finally the desired response is attained.
- Shared psychotic disorder.** Psychosis in which two or more people develop persistent, interlocking delusional ideas. Also known as *folie à deux*.
- Sheltered workshops.** Workshops where mentally retarded or otherwise handicapped persons can engage in constructive work in the community.
- Short-term crisis therapy.** Brief treatment that focuses on the immediate problem an individual or family is experiencing.
- Siblings.** Offspring of the same parents.
- Sick role.** Protected role provided by society via the medical model for a person suffering from severe physical or mental disorder.
- Significant others.** In interpersonal theory of psychological development, parents or others on whom an infant is dependent for meeting all physical and psychological needs.
- Signs.** Objective observations that suggest to a diagnostician a patient's physical or mental disorder.
- Simple phobia.** See **Specific phobia**.
- Simple tension headaches.** Common headaches in which stress leads to contraction of the muscles surrounding the skull; these contractions result in vascular constrictions that cause headache.
- Single-case research design.** An experimental research design (e.g., an ABAB design) that involves only one subject.
- Situational test.** Test that measures performance in a simulated life situation.
- Sleepwalking disorder.** Disorder of childhood that involves repeated episodes of leaving the bed and walking around without being conscious of the experience or remembering it later. Also known as *somnambulism*.
- Social exchange view.** Model of interpersonal relationships based on the premise that such relationships are formed for mutual gratification of needs.
- Social introversion.** Trait characterized by shy, withdrawn, and inhibited behavior.
- Social norms.** Group standards concerning which behaviors are viewed as acceptable and which as unacceptable.
- Social pathology.** Abnormal patterns of social organization, attitudes, or behavior; undesirable social conditions that tend to produce individual pathology.
- Social phobia.** Fear of situations in which a person might be exposed to the scrutiny of others and fear of acting in a humiliating or embarrassing way.
- Social recovery.** Ability to manage independently as an economically effective and interpersonally connected member of society.
- Social role.** Behavior expected of a person occupying a given position in a group.
- "Social" self.** Façade a person displays to others, as contrasted with the private self.
- Social work.** Applied offshoot of sociology concerned with analyzing social environments and providing services that enhance the adjustment of a client in both family and community settings.
- Social worker.** Person in a mental health field with a master's degree in social work (MSW) plus supervised training in clinical or social service agencies.
- Socialization.** Process by which a child acquires the values and impulse controls deemed appropriate by his or her culture.
- Social-learning programs.** Behavioral programs using learning techniques, especially token economies, to help patients assume more responsibility for their own behavior.
- Sociocognitive theory (of DID).** View that DID develops when a highly suggestible person learns to adopt and enact the roles of multiple identities, mostly because clinicians have inadvertently suggested, legitimized, and reinforced them and because these different identities are geared to the individual's own personal goals.
- Sociocultural viewpoint.** Perspective that focuses on broad social conditions that influence the development or behavior of individuals and groups.
- Socioeconomic status.** Position on social and economic scale in community; determined largely by income and occupational level.
- Sociogenic.** Having its roots in sociocultural conditions.
- Sociopathic personality.** See **Antisocial personality disorder**.
- Sodium pentothal.** Barbiturate drug sometimes used in psychotherapy to produce a state of relaxation and suggestibility.
- Soma.** Greek word for body.
- Somatic.** Pertaining to the body.
- Somatic weakness.** Special vulnerability of given organ systems to stress.
- Somatization disorder.** Multiple complaints, over a long period beginning before age 30, of physical ailments that are inadequately explained by independent findings of physical illness or injury and that lead to medical treatment or to significant life impairment.
- Somatoform disorders.** Conditions involving physical complaints or disabilities that occur without any evidence of physical pathology to account for them.
- Somnambulism.** See **Sleepwalking disorder**.
- Spasm.** Intense, involuntary, usually painful contraction of a muscle or group of muscles.
- Spasticity.** Marked hypertonicity or continual overcontraction of muscles, causing stiffness, awkwardness, and motor incoordination.
- Specific learning disorders.** Developmental disorders involving deficits in language, speech, mathematical, or motor skills.
- Specific phobia.** Persistent or disproportionate fears of various objects, places, or situations, such as fears of situations (airplanes or elevators), other species (snakes, spiders), or aspects of the environment (high places, water).
- Specifiers (in mood disorders).** Different patterns of symptoms that sometimes characterize major depressive episodes which may help predict the course and preferred treatments for the condition.
- Sperm.** Male gamete or germ cell.
- Split-brain research.** Research associated with split-brain surgery, which cuts off the transmission of information from one cerebral hemisphere to the other by severing the corpus callosum.
- Spontaneous recovery.** The return of a learned response at some time after extinction has occurred.
- Stage of exhaustion.** Selye's third and final stage in the general adaptation syndrome, in which an organism is no longer able to resist continuing stress; may result in death.
- Stage of resistance.** Second stage of the general adaptation syndrome.
- Standardization.** Procedure for establishing the expected performance range on a test.

**Stanford-Binet.** Standardized intelligence test for children.

**Startle reaction.** Sudden involuntary motor reaction to intense unexpected stimuli; may result from mild stimuli if a person is hypersensitive.

**Statistical significance.** A measure of the probability that a research finding could have occurred by chance alone.

**Statutory rape.** Sexual intercourse with a minor.

**Steady states (homeostasis).** Tendency of an organism to maintain conditions that make possible a constant level of physiological functioning.

**Stereotyping.** The tendency to jump to conclusions (often negative) about what a person is like based on the beliefs about that group that exist (often incorrectly) in the culture (e.g., French people are rude, homosexuals have good taste in clothes, mental patients are dangerous, etc.).

**Stereotypy.** Persistent and inappropriate repetition of phrases, gestures, or acts.

**Stigma.** Negative labeling.

**Stimulants.** Drugs that tend to increase feelings of alertness, reduce feelings of fatigue, and enable a person to stay awake over sustained periods of time.

**Stimulus generalization.** Spread of a conditioned response to some stimulus similar to, but not identical with, the conditioned stimulus.

**Strattera.** A medication used in the treatment of ADHD.

**Stress.** Effects created within an organism by the application of a stressor.

**Stress tolerance.** A person's ability to withstand stress without becoming seriously impaired.

**Stress-inoculation therapy.** Type of self-instructional training focused on altering self-statements that a person routinely makes in stress-producing situations.

**Stress-inoculation training.** Preventive strategy that prepares people to tolerate an anticipated threat by changing the things they say to themselves before the crisis.

**Stressors.** Adjustive demands that require coping behavior on the part of an individual or group.

**Stroke.** See **Cerebrovascular accident**.

**Structural family therapy.** Treatment of an entire family by analysis of interaction among family members.

**Structured assessment interview.** Interview with set introduction and that follows a predetermined set of procedures and questions throughout.

**Stupor.** Condition of lethargy and unresponsiveness, with partial or complete unconsciousness.

**Sublimation.** Ego-defense mechanism that channels frustrated expression of sexual energy into substitutive activities.

**Substance abuse.** Maladaptive pattern of substance use manifested by recurrent and significant adverse consequences related to the use of the substance.

**Substance dependence.** Severe form of substance use disorder involving physiological dependence on the substance, tolerance, withdrawal, and compulsive drug taking.

**Substance-related disorders.** Patterns of maladaptive behavior centered on the regular use of a substance, such as a drug or alcohol.

**Substitution.** Acceptance of substitute goals or satisfactions in place of those originally sought or desired.

**Successive approximation.** See **Shaping**.

**Sufficient cause.** A condition that guarantees the occurrence of a disorder.

**Suicide.** Taking one's own life.

**Suicidology.** Study of the causes and prevention of suicide.

**Superego.** Conscience; ethical or moral dimensions (attitudes) of personality.

**Suppression.** Conscious forcing of desires or thoughts out of consciousness; conscious inhibition of desires or impulses.

**Surrogate.** Substitute for another person, such as a parent or mate.

**Symbol.** Image, word, object, or activity that is used to represent something else.

**Symbolism.** Representation of one idea or object by another.

**Sympathetic division.** Division of the autonomic nervous system that is active in emergency conditions of extreme cold, violent effort, and emotions.

**Sympathetic-adrenomedullary (SAM) system.** System designed to mobilize resources and prepare for a fight-or-flight response.

**Symptoms.** Patient's subjective description of a physical or mental disorder.

**Synapse.** Site of communication from the axon of one neuron to the dendrites or cell body of another neuron—a tiny filled space between neurons.

**Syndrome.** Group or pattern of symptoms that occur together in a disorder and represent the typical picture of the disorder.

**System.** Assemblage of interdependent parts, living or nonliving.

**Systematic desensitization.** Behavior therapy technique for extinguishing maladaptive anxiety responses by teaching a person to relax or behave, while in the presence of the anxiety-producing stimulus, in some other way that is inconsistent with anxiety.

## T

**Tachycardia.** Rapid heartbeat.

**Tactile hallucinations.** Hallucinations involving the sense of touch.

**Tarantism.** Dancing mania that occurred in Italy in the thirteenth century.

**Tarasoff decision.** Ruling by a California court (1974) that a therapist has a duty to warn a prospective victim of an explicit threat expressed by a client in therapy.

**Tardive dyskinesia.** Neurological disorder resulting from excessive use of antipsychotic drugs. Side effects can occur months to years after treatment has been initiated or has stopped. The symptoms involve involuntary movements of the tongue, lips, jaw, and extremities.

**Task-oriented response.** Making changes in one's self, one's surroundings, or both, depending on the situation.

**Tay-Sachs disease.** Genetic disorder of lipid metabolism usually resulting in death by age 3.

**T-cell.** A type of white blood cell that, when activated, can recognize specific antigens. T-cells play an important role in the immune system.

**Telepathy.** Communication from one person to another without use of any known sense organs.

**Temperament.** Pattern of emotional and arousal responses and characteristic ways of self-regulation that are considered to be primarily hereditary or constitutional.

**Temporal lobe.** Portion of the cerebrum located in front of the occipital lobe and separated from the frontal and parietal lobes by the fissure of Sylvius.

**Tension.** Condition arising from the mobilization of psychobiological resources to meet a threat; physically, involves an increase in muscle tone and other emergency changes; psychologically, is characterized by feelings of strain, uneasiness, and anxiety.

**Tertiary prevention.** Older term for preventive techniques focused on reducing long-term consequences of disorders or serious problems. See **Indicated prevention**.

**Test validity.** Degree to which a test actually measures what it was designed to measure.

**Testes.** Male reproductive glands or gonads.

**Testosterone.** Male sex hormone.

**Test-retest reliability.** Consistency with which a test measures a given trait on repeated administrations of the test to given subjects.

**Thematic Apperception Test (TAT).** Use of a series of simple pictures about which a subject is instructed to make up stories. Analysis of the stories gives a clinician clues about the person's conflicts, traits, personality dynamics, and the like.

**Therapeutic.** Pertaining to treatment or healing.

**Therapeutic community.** Hospital environment used for therapeutic purposes.

**Therapy.** Treatment; application of various treatment techniques.

**Third variable problem.** Refers to the problem of making causal inferences in correlational research, where the correlation between two variables could be due to their shared correlation with an unmeasured third variable.

**Thyroid.** Endocrine gland located in the neck that influences body metabolism, rate of physical growth, and development of intelligence.

**Thyroxin.** Hormone secreted by the thyroid glands.

**Tic.** Persistent, intermittent muscle twitch or spasm, usually limited to a localized muscle group, often of the facial muscles.

**Token economies.** Reinforcement techniques often used in hospital or institutional settings in which patients are rewarded for socially constructive behaviors with tokens that can then be exchanged for desired objects or activities.

**Tolerance.** Need for increased amounts of a substance to achieve the desired effects.

**Tourette's syndrome.** Extreme tic disorder involving uncontrollable multiple motor and vocal patterns.

**Toxic.** Poisonous.

**Toxicity.** Poisonous nature of a substance.

**Traditional behavioral couple therapy.** Widely used form of therapy that uses behavioral approaches to bring about changes in the marital relationship.

**Trait.** Characteristic of a person that can be observed or measured.

**Trance.** Sleep-like state in which the range of consciousness is limited and voluntary activities are suspended; a deep hypnotic state.

**Tranquilizers.** Drugs used for reduction of psychotic symptoms (major tranquilizers) or reduction of anxiety and tension (minor tranquilizers).

**Transference.** In psychodynamic therapy, a process whereby clients project onto the therapist attitudes and feelings that they have had for a parent or others close to them.

**Transsexualism.** Individuals who identify with members of the opposite sex (as opposed to acceptance of their own biological sex) and who strongly desire to (and often do) change their sex. In most cases this is gender identity disorder in adults.

**Transvestic disorder.** Achievement of sexual arousal and satisfaction by dressing as a member of the opposite sex.

**Trauma.** Severe psychological or physiological stressor.

**Traumatic.** Pertaining to a wound or injury or to psychic shock.

**Traumatic brain injury (TBI).** Brain damage resulting from motor vehicle crashes, bullets, or other objects entering the brain, and other severe impacts to the head.

**Traumatic childhood abuse.** Mistreatment in childhood severe enough to cause psychological damage.

**Treatment contract.** Explicit arrangement between a therapist and a client designed to bring about specific behavioral changes.

**Tremor.** Repeated fine spastic movement.

**Trichotillomania.** Chronic pulling out of one's own hair.

**Tricyclic antidepressants.** Medications used to treat depression, and sometimes anxiety disorders, that are thought to block the reuptake of norepinephrine and serotonin at the synapse.

**T-score distribution.** A standard distribution of scores that allows for a comparison of scores on a test by comparing scores with a group of known values.

**Twin method.** The use of identical and non-identical twins to study genetic influences on abnormal behavior.

**Type A behavior pattern.** Excessive competitive drive even when it is unnecessary, impatience or time urgency, and hostility.

**Type D personality.** Type D (for distressed) personality is characterized by high levels of negative emotions and social anxiety. Research suggests that Type D personality is linked to heart attacks.

**Type I schizophrenia.** Psychotic behavior of the positive syndrome variety thought to involve chiefly temporolimbic brain structures.

**Type II schizophrenia.** Psychotic behavior of the negative syndrome variety thought to involve chiefly frontal brain structures.

## U

**Unconscious.** In psychoanalytic theory, a major portion of the mind, which consists of a hidden mass of instincts, impulses, and memories and is not easily available to conscious awareness, yet plays an important role in behavior.

**Underarousal.** Inadequate physiological response to a given stimulus.

**Undifferentiated schizophrenia.** See **Schizophrenia, undifferentiated type.**

**Undoing.** Ego-defense mechanism of atoning for or magically trying to dispel unacceptable desires or acts.

**Unipolar depressive disorder.** Mood disorder in which a person experiences only depressive episodes, as opposed to bipolar disorder, in which both manic and depressive episodes occur.

**Universal intervention.** The tasks of altering conditions that cause or contribute to mental disorders (risk factors) and establishing conditions that foster positive mental health (protective factors).

**Unstructured assessment interviews.** Typically subjective interviews that do not follow a predetermined set of questions. The beginning statements in the interview are usually general, and follow-up questions are tailored for each client. The content of the interview questions is influenced by the habits or theoretical views of the interviewer.

## V

**Vaginismus.** Involuntary spasm of the muscles at the entrance to the vagina that prevents penetration and sexual intercourse.

**Validity.** Extent to which a measuring instrument actually measures what it purports to measure.

**Variable.** Characteristic or property that may assume any one of a set of different qualities or quantities.

**Vascular dementia.** A brain disorder in which a series of small strokes destroy neurons, leading to brain atrophy and behavioral impairments that are similar to Alzheimer's disease.

**Vasomotor.** Pertaining to the walls of the blood vessels.

**Vegetative.** Withdrawn or deteriorated to the point of leading a passive, vegetable-like existence.

**Verbal test.** Test in which a subject's ability to understand and use words and concepts is important in making the required responses.

**Vertigo.** Dizziness.

**Virilism.** Accentuation of masculine secondary sex characteristics, especially in a woman or young boy, caused by hormonal imbalance.

**Viscera.** Internal organs.

**Voyeurism.** Achievement of sexual pleasure through clandestine "peeping," usually watching other people disrobe and/or engage in sexual activities.

**Vulnerabilities.** Factors that render a person susceptible to behaving abnormally.

## W

**Wechsler Intelligence Scale for Children (WISC).** Standardized intelligence test for children.

**Withdrawal.** Intellectual, emotional, or physical retreat.

**Withdrawal symptoms.** Physical symptoms such as sweating, tremors, and tension that accompany abstinence from some drugs.

**Word salad.** Jumbled or incoherent use of words by psychotic or disoriented individuals.

## X

**X chromosome.** Sex-determining chromosome; all female gametes contain X chromosomes, and if the fertilized ovum has also received an X chromosome from its father, it will be female.

**YYY syndrome.** Chromosomal anomaly in males (presence of an extra Y chromosome) possibly related to impulsive behavior.

## Y

**Y chromosome.** Sex-determining chromosome found in half of the total number of male gametes; its uniting with an X chromosome provided by a female produces a male offspring.

## Z

**Zygote.** Fertilized egg cell formed by the union of male and female gametes.
